Displaying a Critical Section
Debugging a Deadlock
Debugging a Failed Driver Unload
Reading Bug Check Callback Data
Debugging a User-Mode Failure with KD
Crashing and Rebooting the Target Computer
Mapping Driver Files
Messages from the Target

Specialized Debugging Techniques

Windows Runtime Debugging
Kernel-Mode Driver Framework Debugging
User-Mode Driver Framework Debugging
Debugging Device Nodes and Device Stacks
Debugging Plug and Play and Power Issues
Debugging a User-Mode Failure with KD
Debugging a Device Installation Co-Installer
Debugging a Dual-Boot Machine
Debugging Windows Setup and the OS Loader
Debugging CSRSS
Debugging WinLogon
Debugging BIOS Code
Specifying Module and Function Owners
RPC Debugging
ACPI Debugging
NDIS Debugging
Kernel Streaming Debugging
SCSI Miniport Debugging
Plug and Play Debugging
Debugging a Service Application
Attaching to a Target Computer Running Hyper-V

Symbols for Windows Debugging (WinDbg, KD, CDB, NTSD)

Debugging Tools for Windows (WinDbg, KD, CDB, NTSD)

5/26/2017 • 3 min to read • [Edit Online](#)

April 2017

Start here for an overview of Debugging Tools for Windows. This tool set includes WinDbg and other debuggers.

3 ways to get Debugging Tools for Windows

- **As part of the WDK**

Install Microsoft Visual Studio and then install the Windows Driver Kit (WDK). Debugging Tools for Windows is included in the WDK. You can [get the integrated environment here](#).

- **As part of the Windows SDK**

Install the Windows Software Development Kit (SDK). Debugging Tools for Windows is included in the Windows SDK. You can [get the Windows SDK here](#).

- **As a standalone tool set**

If you want to download only Debugging Tools for Windows, [install the Windows SDK](#), and, during the installation, select the **Debugging Tools for Windows** box and clear all the other boxes.

Getting Started with Windows Debugging

To get started with Windows debugging, see [Getting Started with Windows Debugging](#).

To get started with debugging kernel mode drivers, see [Debug Universal Drivers - Step by Step Lab \(Echo Kernel-Mode\)](#). This is a step by step lab that shows how to use WinDbg to debug the sample KMDF echo driver.

Debugging environments

After you install Visual Studio and the WDK, you'll have six available [debugging environments](#). All of these debugging environments provide user interfaces for the same underlying debugging engine, which is implemented in dbgeng.dll. This debugging engine is called the *Windows debugger*, and the six debugging environments are collectively called the *Windows debuggers*.

Note Visual Studio includes its own debugging environment and debugging engine, which together are called the *Visual Studio debugger*. For information on debugging in Visual Studio, see [Visual Studio debugger](#). If you are looking to debug managed code such as C#, using the Visual Studio is often easiest way to get started.

Windows debuggers

The Windows debuggers can run on x86-based, x64-based, or ARM-based processors, and they can debug code that's running on x86-based, x64-based, or ARM-based processors. Sometimes the debugger and the code being debugged run on the same computer, but other times the debugger and the code being debugged run on separate computers. In either case, the computer that's running the debugger is called the *host computer*, and the computer that is being debugged is called the *target computer*. The Windows debuggers support the following versions of Windows for both the host and target computers.

- Windows 10 and Windows Server 2016
- Windows 8.1 and Windows Server 2012 R2
- Windows 8 and Windows Server 2012
- Windows 7 and Windows Server 2008 R2

Symbols and Symbol Files

Symbol files hold a variety of data which are not actually needed when running the binaries, but are very useful when debugging code. For more information about creating and using symbol files, see [Symbols for Windows debugging \(WinDbg, KD, CDB, NTSD\)](#).

Blue Screens and crash dump files

If Windows stops working and displays a blue screen, the computer has shut down abruptly to protect itself from data loss and displays a bug check code. For more information, see [Bug Checks \(Blue Screens\)](#). You analyze crash dump files that are created when Windows shuts down by using WinDbg and other Windows debuggers. For more information, see [Crash dump analysis using the Windows debuggers \(WinDbg\)](#).

Tools and utilities

In addition to the debuggers, Debugging Tools for Windows includes a set of tools that are useful for debugging. For a full list of the tools, see [Tools Included in Debugging Tools for Windows](#).

Additional documentation

For additional information related to Debugging Tools for Windows, see [Debugging Resources](#). For information on what's new in Windows 10, see [Debugging Tools for Windows: New for Windows 10](#).

Getting Started with Windows Debugging

5/26/2017 • 5 min to read • [Edit Online](#)

This section covers how to get started with Windows Debugging. If your goal is to use the debugger to analyze a crash dump, see [Crash dump analysis using the Windows debuggers \(WinDbg\)](#).

To get started with Windows Debugging, complete the following tasks.

1. Determine which devices will serve as the host system and the target system. The debugger runs on the host system and the code that you want to debug runs on the target system.

Host <-----> **Target**

Because it is common to stop instruction execution on the processor during debugging, typically, two systems are used. In some situations, it is possible that the second system is a virtual system, for example, a virtual PC that is running on the same PC. However, if your code is communicating to low level hardware, using a virtual PC may not be the best approach. For more information, see [Setting Up Network Debugging of a Virtual Machine Host](#).

1. Determine if you will be doing kernel or user mode debugging. *Kernel mode* - Kernel mode is the processor access mode in which the operating system and privileged programs run. Kernel mode code has permission to access any part of the system, and is not restricted like user mode code. It can gain access to any part of any other process running in either user mode or kernel mode. Much of the core OS functionality and many hardware device drivers run in kernel mode.

User mode - Applications and subsystems run on the computer in user mode. Processes that run in user mode do so within their own virtual address spaces. They are restricted from gaining direct access to many parts of the system, including system hardware, memory that was not allocated for their use, and other portions of the system that might compromise system integrity. Because processes that run in user mode are effectively isolated from the system and other user mode processes, they cannot interfere with these resources.

If your goal is to debug a driver, determine if the driver is a kernel mode driver (typically described as a WDM or KMDF driver) or a user mode driver (UMDF).

For some issues, it can be difficult to determine which mode the code is executing in. In that case, you may need to pick one mode and look to see what information is available in that mode. Some issues require using the debugger in both user and kernel mode.

Depending on what mode you decide to debug in, you will need to configure and use the debuggers in different ways. Some debug commands operate the same, and some commands operate differently in different modes.

For information about using the debugger in kernel mode, see [Getting Started with WinDbg \(Kernel-Mode\)](#) and [Debug Universal Drivers - Step by Step Lab \(Echo Kernel-Mode\)](#) and [Debug Drivers - Step by Step Lab \(Sysvad Kernel-Mode\)](#). For information about using the debugger in user mode, see [Getting Started with WinDbg \(User-Mode\)](#).

1. Choose your debugger environment. WinDbg works well in most situations, but there are times when you may want to use another debugger such as console debuggers for automation or even Visual Studio. For more information, see [Debugging Environments](#).

2. Determine how you will connect the target and host system. Typically, an Ethernet network connection is used to connect the target and host system. If you are doing early bring up work, or don't have an Ethernet connection on the device, other network connection options are available. For more information, see these topics:

- [Setting Up Kernel-Mode Debugging Manually](#)
- [Setting Up Kernel-Mode Debugging over a Network Cable Manually](#)
- [Setting Up Kernel-Mode Debugging using Serial over USB Manually](#)
- [Setting Up Network Debugging of a Virtual Machine Host](#)

If you wish to debug using Visual Studio, then refer to these topics.

- [Setting Up Kernel-Mode Debugging in Visual Studio](#)
- [Setting Up Kernel-Mode Debugging over a Network Cable in Visual Studio](#)
- [Setting Up Kernel-Mode Debugging using Serial over USB in Visual Studio](#)
- [Setting Up Kernel-Mode Debugging of a Virtual Machine in Visual Studio](#)
- [Setting Up User-Mode Debugging in Visual Studio](#)

1. Choose either the 32-bit or 64-bit debugging tools. This choice is dependent on the version of Windows that is running on the target and host systems and whether you are debugging 32-bit or 64-bit code. For more information, see [Choosing the 32-Bit or 64-Bit Debugging Tools](#).
2. Configure symbols. You must load the proper symbols to use all of the advanced functionality that WinDbg provides. If you do not have symbols properly configured, you will receive messages indicating that symbols are not available when you attempt to use functionality that is dependent on symbols. For more information, see [Symbols for Windows debugging \(WinDbg, KD, CDB, NTSD\)](#).
3. Configure source code. If your goal is to debug your own source code, you will need to configure a path to your source code. For more information, see [Source Path](#).
4. Become familiar with debugger operation. The [Debugger Operation](#) section of the documentation describes debugger operation for various tasks. For example, the [Loading Debugger Extension DLLs](#) topic explains how to load debugger extensions. To learn more about working with WinDbg, see [Debugging Using WinDbg](#).
5. Become familiar with debugging techniques. [Standard Debugging Techniques](#) apply to most debugging scenarios, and examples include setting breakpoints, inspecting the call stack, and finding a memory leak. [Specialized Debugging Techniques](#) apply to particular technologies or types of code. Examples are Plug and Play debugging, Kernel Mode Driver Framework debugging, and RPC debugging.
6. Use the debugger reference commands. Over time, you will use different debug commands as you work in the debugger. Use the [.hh \(Open HTML Help File\)](#) command in the debugger to display help information about any debug command. For more information about the available commands, see [Debugger Reference](#).
7. Use debugging extensions for specific technologies. There are a number of debugging extensions that provide parsing of domain specific data structures. For more information, see [Specialized Extensions](#).

This section contains the following topics.

Getting Started with WinDbg (User-Mode)

5/31/2017 • 6 min to read • [Edit Online](#)

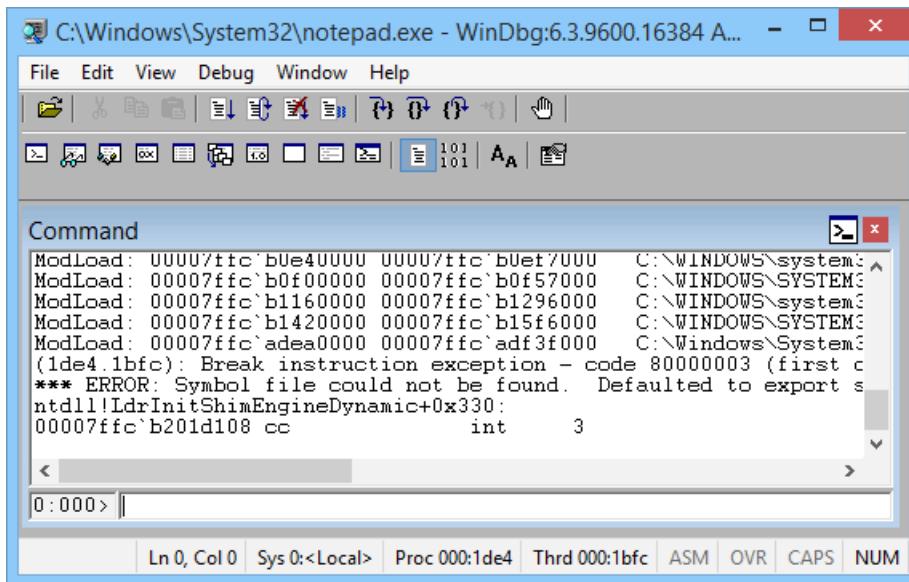

WinDbg is a kernel-mode and user-mode debugger that is included in Debugging Tools for Windows. Here we provide hands-on exercises that will help you get started using WinDbg as a user-mode debugger.

For information about how to get Debugging Tools for Windows, see [Debugging Tools for Windows \(WinDbg, KD, CDB, NTSD\)](#). After you have installed the debugging tools, locate the installation directories for 64-bit (x64) and 32-bit (x86) versions of the tools. For example:

- C:\Program Files (x86)\Windows Kits\8.1\Debuggers\x64
- C:\Program Files (x86)\Windows Kits\8.1\Debuggers\x86

Launch Notepad and attach WinDbg

1. Navigate to your installation directory, and open WinDbg.exe.
2. On the **Help** menu, choose **Contents**. This opens the debugger documentation CHM file. The debugger documentation is also available online [here](#).
3. On the **File** menu, choose **Open Executable**. In the Open Executable dialog box, navigate to the folder that contains notepad.exe (for example, C:\Windows\System32). For **File name**, enter notepad.exe. Click **Open**.

4. Near the bottom of the WinDbg window, in the command line, enter this command:

```
.sympath srv*.
```

The output is similar to this:

```
Symbol search path is: srv*
Expanded Symbol search path is: cache*;SRV*https://msdl.microsoft.com/download/symbols
```

The symbol search path tells WinDbg where to look for symbol (PDB) files. The debugger needs symbol files to obtain information about code modules (function names, variable names, and the like).

Enter this command, which tells WinDbg to do its initial finding and loading of symbol files:

.reload

5. To see the symbols for the Notepad.exe module, enter this command:

```
x notepad!\*
```

Note If you don't see any output, enter **.reload** again.

```
To see symbols in the Notepad.exe module that contain main, enter this command:
```

```
**x notepad!\*main\***
```

The output is similar to this:

```
...
000000d0`428ff7e8 00007ff6`3282122f notepad!WinMain
...
...
```

1. To put a breakpoint at notepad!WinMain, enter this command:

```
bu notepad!WinMain
```

To verify that your breakpoint was set, enter this command:

```
bl
```

The output is similar to this:

```
0 e 00007ff6`32825f64      0001 (0001)  0:**** notepad!WinMain
```

2. To start Notepad running, enter this command:

```
g
```

Notepad runs until it comes to the **WinMain** function, and then breaks in to the debugger.

To see a list of code modules that are loaded in the Notepad process, enter this command:

```
lm
```

The output is similar to this:

```
0:000> lm
start          end            module name
00007ffc`32820000 00007ffc`3285a000  notepad    (pdb symbols)      C:\...\notepad.pdb
00007ffc`ab7e0000 00007ffc`ab85b000  WINSPOOL   (deferred)
00007ffc`aba10000 00007ffc`abc6a000  COMCTL32   (deferred)

00007ffc`b1010000 00007ffc`b1155000  GDI32     (deferred)
00007ffc`b1160000 00007ffc`b1296000  RPCRT4    (deferred)
00007ffc`b12a0000 00007ffc`b1411000  USER32    (deferred)
00007ffc`b1420000 00007ffc`b15f6000  combase    (deferred)
00007ffc`b16c0000 00007ffc`b17f9000  MSCTF     (deferred)
00007ffc`b1800000 00007ffc`b189a000  COMDLG32  (deferred)
00007ffc`b18a0000 00007ffc`b18f1000  SHLWAPI   (deferred)
00007ffc`b1b60000 00007ffc`b1cd8000  ole32     (deferred)
00007ffc`b1cf0000 00007ffc`b1e2a000  KERNEL32   (pdb symbols)      C:\...\kernel32.pdb
00007ffc`b1eb0000 00007ffc`b1ee4000  IMM32     (deferred)
00007ffc`b1f50000 00007ffc`b20fa000  ntdll    (private pdb symbols) C:\...\ntdll.pdb
```

To see a stack trace, enter this command:

k

The output is similar to this:

```
Breakpoint 0 hit
notepad!WinMain:
00007ffc`32825f64 488bc4      mov     rax,rs
0:000> k
Child-SP      RetAddr      Call Site
00000048`4e0cf6a8 00007ffc`3282122f notepad!WinMain
00000048`4e0cf6b0 00007ffc`b1cf16ad notepad!WinMainCRTStartup+0x1a7
00000048`4e0cf770 00007ffc`b1fc4629 KERNEL32!BaseThreadInitThunk+0xd
00000048`4e0cf7a0 00000000`00000000 ntdll!RtlUserThreadStart+0x1d ...
```

3. To start Notepad running again, enter this command:

g

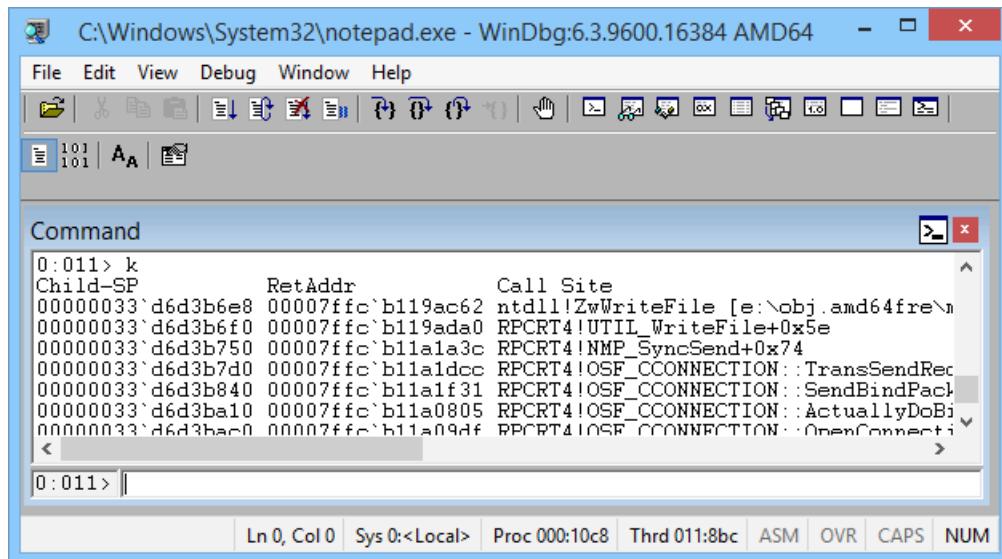

4. To break in to Notepad, choose **Break** from the **Debug** menu.

5. To set and verify a breakpoint at **ZwWriteFile**, enter these commands:

bu ntdll!ZwWriteFile

bl

6. Enter **g** to start Notepad running again. In the Notepad window, enter some text and choose **Save** from the **File** menu. The running code breaks in when it comes to **ZwCreateFile**. Enter **k** to see the stack trace.

In the WinDbg window, just to the left of the command line, notice the processor and thread numbers. In this example the current processor number is 0, and the current thread number is 11. So we are looking at the stack trace for thread 11 (which happens to be running on processor 0).

7. To see a list of all threads in the Notepad process, enter this command (the tilde):

~

The output is similar to this:

```
0:011> ~
 0  Id: 10c8.128c Suspend: 1 Teb: 00007ff6`31cdd000 Unfrozen
 1  Id: 10c8.1a10 Suspend: 1 Teb: 00007ff6`31cdb000 Unfrozen
 2  Id: 10c8.1850 Suspend: 1 Teb: 00007ff6`31cd9000 Unfrozen
 3  Id: 10c8.1774 Suspend: 1 Teb: 00007ff6`31cd7000 Unfrozen
 4  Id: 10c8.1e80 Suspend: 1 Teb: 00007ff6`31cd5000 Unfrozen
 5  Id: 10c8.10ac Suspend: 1 Teb: 00007ff6`31cd3000 Unfrozen
 6  Id: 10c8.13a4 Suspend: 1 Teb: 00007ff6`31bae000 Unfrozen
 7  Id: 10c8.2b4 Suspend: 1 Teb: 00007ff6`31bac000 Unfrozen
 8  Id: 10c8.1df0 Suspend: 1 Teb: 00007ff6`31baa000 Unfrozen
 9  Id: 10c8.1664 Suspend: 1 Teb: 00007ff6`31ba8000 Unfrozen
10  Id: 10c8.15e4 Suspend: 1 Teb: 00007ff6`31ba6000 Unfrozen
. 11  Id: 10c8.8bc Suspend: 1 Teb: 00007ff6`31ba4000 Unfrozen
```

In this example, there are 12 threads with indexes 0 through 11.

8. To look at the stack trace for thread 0, enter these commands:

~0s

k

The output is similar to this:

```
0:011> ~0s
USER32!SystemParametersInfoW:
00007ffc`b12a4d20 48895c2408      mov     qword ptr [rsp+8], ...
0:000> k
Child-SP      RetAddr      Call Site
00000033`d1e9da48 00007ffc`adfb227d USER32!SystemParametersInfoW
(Inline Function) -----`----- uxtheme!IsHighContrastMode+0x1d
00000033`d1e9da50 00007ffc`adfb2f12 uxtheme!IsThemeActive+0x4d
...
00000033`d1e9f810 00007ffc`b1cf16ad notepad!WinMainCRTStartup+0x1a7
00000033`d1e9f8d0 00007ffc`b1fc4629 KERNEL32!BaseThreadInitThunk+0xd
00000033`d1e9f900 00000000`00000000 ntdll!RtlUserThreadStart+0x1d
```

9. To quit debugging and detach from the Notepad process, enter this command:

```
qd
```

Launch your own application and attach WinDbg

Suppose you have written and built this small console application.

```
...
void MyFunction(long p1, long p2, long p3)
{
    long x = p1 + p2 + p3;
    long y = 0;
    y = x / p2;
}

void main ()
{
    long a = 2;
    long b = 0;
    MyFunction(a, b, 5);
}
```

For this exercise, we will assume that the built application (MyApp.exe) and the symbol file (MyApp.pdb) are in C:\MyApp\x64\Debug. We will also assume that the application source code is in C:\MyApp\MyApp.

1. Open WinDbg.
2. On the **File** menu, choose **Open Executable**. In the Open Executable dialog box, navigate to C:\MyApp\x64\Debug. For **File name**, enter MyApp.exe. Click **Open**.
3. Enter these commands:

```
.sympath srv\*
.sympath+ C:\MyApp\x64\Debug
.srcpath C:\MyApp\MyApp
```

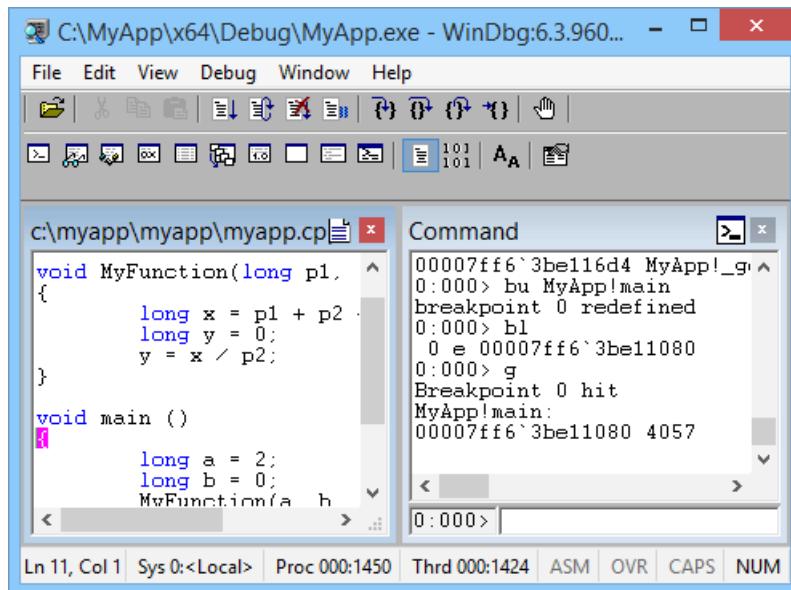

Now WinDbg knows where to find symbols and source code for your application.

4. Enter these commands:

```
.reload
bu MyApp!main
g
```

Your application breaks in to the debugger when it comes to its **main** function.

WinDbg displays your source code and the Command window.

5. On the **Debug** menu, choose **Step Into** (or press **F11**). Continue stepping until you have stepped into **MyFunction**. When you step into the line `y = x / p2`, your application will crash and break in to the debugger. The output is similar to this:

```
(1450.1424): Integer divide-by-zero - code c0000094 (first chance)
First chance exceptions are reported before any exception handling.
This exception may be expected and handled.
MyApp!MyFunction+0x44:
00007ff6`3be11064 f77c2428    idiv    eax,dword ptr [rsp+28h] ss:00000063`2036f808=00000000
```

6. Enter this command:

```
!analyze -v
```

WinDbg displays an analysis of the problem (division by 0 in this case).

```

FAULTING_IP:
MyApp!MyFunction+44 [c:\myapp\myapp\myapp.cpp @ 7]
00007ff6`3be11064 f77c2428      idiv     eax,dword ptr [rsp+28h]

Getting Started with WinDbg (Kernel-Mode)

5/31/2017 • 8 min to read • [Edit Online](#)

WinDbg is a kernel-mode and user-mode debugger that is included in Debugging Tools for Windows. Here we provide hands-on exercises that will help you get started using WinDbg as a kernel-mode debugger.

For information about how to get Debugging Tools for Windows, see [Debugging Tools for Windows \(WinDbg, KD, CDB, NTSD\)](#). After you have installed the debugging tools, locate the installation directories for 64-bit (x64) and 32-bit (x86) versions of the tools. For example:

- C:\Program Files (x86)\Windows Kits\8.1\Debuggers\x64
- C:\Program Files (x86)\Windows Kits\8.1\Debuggers\x86

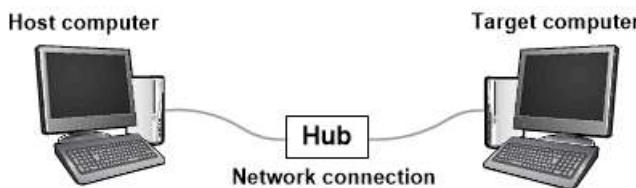

Set up a kernel-mode debugging

A kernel-mode debugging environment typically has two computers: the *host computer* and the *target computer*. The debugger runs on the host computer, and the code being debugged runs on the target computer. The host and target are connected by a debug cable.

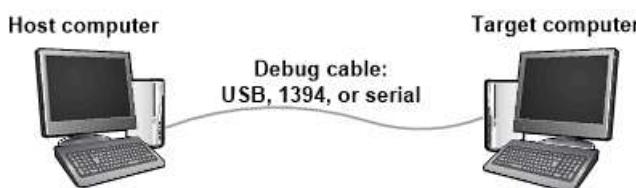

The Windows debuggers support these types of cables for debugging:

- Ethernet
- USB 2.0
- USB 3.0
- 1394
- Serial (also called null modem)

If your target computer is running Windows 8 or later, you can use any type of debug cable, including Ethernet. This diagram illustrates a host and target computer connected for debugging over Ethernet cable.

If your target computer is running a version of Windows earlier than Window 8, then you cannot use Ethernet for debugging; you must use USB, 1394, or serial. This diagram illustrates a host and target computer connected by a USB, 1394, or serial debug cable.

For details about how to set up the host and target computers, see [Setting Up Kernel-Mode Debugging Manually](#).

Establish a kernel-mode debugging session

After you have set up your host and target computer and connected them with a debug cable, you can establish a kernel-mode debugging session by following the instructions in the same topic that you used for getting set up.

For example, if you decided to set up your host and target computers for debugging over Ethernet, you can find instructions for establishing a kernel-mode debugging session in this topic:

- [Setting Up Kernel-Mode Debugging over a Network Cable Manually](#)

Likewise, if you decided to set up your host and target computers for debugging over USB 2.0, you can find instructions for establishing a kernel-mode debugging session in this topic:

- [Setting Up Kernel-Mode Debugging over a USB 2.0 Cable Manually](#)

Get started using WinDbg

1. On the host computer, open WinDbg and establish a kernel-mode debugging session with the target computer.
2. In WinDbg, choose **Contents** from the **Help** menu. This opens the debugger documentation CHM file. The debugger documentation is also available online [here](#).
3. When you establish a kernel-mode debugging session, WinDbg might break in to the target computer automatically. If WinDbg has not already broken in, choose **Break** from the **Debug** menu.
4. Near the bottom of the WinDbg window, in the command line, enter this command:

```
.sympath srv\*
```

The output is similar to this:

```
Symbol search path is: srv*  
Expanded Symbol search path is: cache*;SRV*https://msdl.microsoft.com/download/symbols
```

The symbol search path tells WinDbg where to look for symbol (PDB) files. The debugger needs symbol files to obtain information about code modules (function names, variable names, and the like).

Enter this command, which tells WinDbg to do its initial finding and loading of symbol files:

```
.reload
```

5. To see a list of loaded modules, enter this command:

```
!m
```

The output is similar to this:

```
0:000>3: kd> !m  
start end module name  
fffff800`00000000 fffff800`00088000 CI (deferred)  
...  
fffff800`01143000 fffff800`01151000 BasicRender (deferred)  
fffff800`01151000 fffff800`01163000 BasicDisplay (deferred)  
...  
fffff800`02a0e000 fffff800`03191000 nt (pdb symbols) C:\...\ntkrnlmp.pdb  
fffff800`03191000 fffff800`03200000 hal (deferred)  
...
```

6. To start target computer running, enter this command:

```
g
```

7. To break in again, choose **Break** from the **Debug** menu.

8. Enter this command to examine the _FILE_OBJECT data type in the nt module:

dt nt!_FILE_OBJECT

The output is similar to this:

```
0:000>0: kd> dt nt!_FILE_OBJECT
+0x000 Type          : Int2B
+0x002 Size          : Int2B
+0x008 DeviceObject  : Ptr64 _DEVICE_OBJECT
+0x010 Vpb           : Ptr64 _VPB
...
+0x0c0 IrpList        : _LIST_ENTRY
+0x0d0 FileObjectExtension : Ptr64 Void
```

9. Enter this command to examine some of the symbols in the nt module:

x nt!*CreateProcess*

The output is similar to this:

```
0:000>0: kd> x nt!*CreateProcess*
fffff800`030821cc nt!ViCreateProcessCallbackInternal (<no parameter info>
...
fffff800`02e03904 nt!MmCreateProcessAddressSpace (<no parameter info>
fffff800`02cece00 nt!PspCreateProcessNotifyRoutine = <no type information>
...
```

10. Enter this command to put a breakpoint at **MmCreateProcessAddressSpace**:

bu nt!MmCreateProcessAddressSpace

To verify that the breakpoint is set, enter this command:

bl

The output is similar to this:

```
0:000>0: kd> bu nt!MmCreateProcessAddressSpace
0: kd> bl
0 e fffff800`02e03904      0001 (0001) nt!MmCreateProcessAddressSpace
```

Enter **g** to let the target computer run.

11. If the target computer doesn't break in to the debugger immediately, perform a few actions on the target computer (for example, open Notepad). The target computer will break in to the debugger when **MmCreateProcessAddressSpace** is called. To see the stack trace, enter these commands:

.reload

k

The output is similar to this:

```
0:000>2: kd> k
Child-SP      RetAddr      Call Site
fffffd000`224b4c88 fffff800`02d96834 nt!MmCreateProcessAddressSpace
fffffd000`224b4c90 fffff800`02dfef17 nt!PspAllocateProcess+0x5d4
fffffd000`224b5060 fffff800`02b698b3 nt!NtCreateUserProcess+0x55b
...
000000d7`4167fbb0 00007ffd`14b064ad KERNEL32!BaseThreadInitThunk+0xd
000000d7`4167fbe0 00000000`00000000 ntdll!RtlUserThreadStart+0x1d
```

12. On the **View** menu, choose **Disassembly**.

On the **Debug** menu, choose **Step Over** (or press **F10**). Enter step commands a few more times as you watch the Disassembly window.

13. Clear your breakpoint by entering this command:

bc *

Enter **g** to let the target computer run. Break in again by choosing **Break** from the **Debug** menu or pressing **CTRL-Break**.

14. To see a list of all processes, enter this command:

!process 0 0

The output is similar to this:

```
0:000>0: kd> !process 0 0
**** NT ACTIVE PROCESS DUMP ****
PROCESS fffffe000002287c0
    SessionId: none Cid: 0004 Peb: 00000000 ParentCid: 0000

```

15. Copy the address of one process, and enter this command:

!process Address 2

For example: **!process fffffe00000d5290 2**

The output shows the threads in the process.

```
0:000>0:000>0: kd> !process fffffe00000d52900 2
PROCESS fffffe00000d52900

...

```

20. The output of **!devnode 0 1** displays the address of the physical device object (PDO) for the node. Copy the address of a physical device object (PDO), and enter this command:

!devstack PdoAddress

For example: *PdoAddress***!devstack 0xfffffe00001159610**

```

0:000>0: kd> !devstack 0xfffffe00001159610
!DevObj          !DrvObj          !DevExt          ObjectName
fffffe00001d50040  \Driver\partmgr  fffffe00001d50190
fffffe00001d51450  \Driver\disk    fffffe00001d515a0  DR0
fffffe00001156e50  \Driver\ACPI    fffffe000010d8bf0

```

21. To get information about the driver disk.sys, enter this command:

!drvobj disk 2

```

0:000>0: kd> !drvobj disk 2
Driver object (fffffe00001d52680) is for:
  \Driver\disk
DriverEntry:  ffffff800006b1270 disk!GsDriverEntry
DriverStartIo: 00000000
DriverUnload:  ffffff800010b0b5c CLASSPNP!ClassUnload
AddDevice:    ffffff800010aa110 CLASSPNP!ClassAddDevice

Dispatch routines:
[00] IRP_MJ_CREATE          ffffff8000106d160  CLASSPNP!ClassGlobalDispatch
[01] IRP_MJ_CREATE_NAMED_PIPE ffffff80002b0ab24  nt!IoPInvalidDeviceRequest
[02] IRP_MJ_CLOSE            ffffff8000106d160  CLASSPNP!ClassGlobalDispatch
[03] IRP_MJ_READ              ffffff8000106d160  CLASSPNP!ClassGlobalDispatch
...
[1b] IRP_MJ_PNP              ffffff8000106d160  CLASSPNP!ClassGlobalDispatch

```

22. The output of !drvobj displays addresses of dispatch routines: for example, CLASSPNP!ClassGlobalDispatch. To set and verify a breakpoint at ClassGlobalDispatch, enter these commands:

bu CLASSPNP!ClassGlobalDispatch

bl

Enter g to let the target computer run.

If the target computer doesn't break in to the debugger immediately, perform a few actions on the target computer (for example, open Notepad and save a file). The target computer will break in to the debugger when **ClassGlobalDispatch** is called. To see the stack trace, enter these commands:

.reload

k

The output is similar to this:

```

2: kd> k
Child-SP      RetAddr      Call Site

Choosing the 32-Bit or 64-Bit Debugging Tools

5/26/2017 • 1 min to read • [Edit Online](#)

When you install Debugging Tools for Windows, you get both a 32-bit set of tools and a 64-bit set of tools. If you use the Microsoft Visual Studio [debugging environment](#), you don't have to be concerned about whether to use the 32- or 64-bit set because Visual Studio automatically chooses the correct debugging tools.

If you are using one of the other debugging environments (WinDbg, KD, CDB, or NTSD), you have to make the choice yourself. To determine which set of debugging tools to use, you need to know the type of processor that is running on your host computer and whether the host computer is running a 32- or 64-bit version of Windows.

The computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*.

Host computer running a 32-bit version of Windows

If your host computer is running a 32-bit version of Windows, use the 32-bit debugging tools. (This situation applies to both x86-based and x64-based targets.)

x64-based host computer running a 64-bit version of Windows

If your host computer uses an x64-based processor and is running a 64-bit version of Windows, the following rules apply:

- If you are analyzing a dump file, you can use either the 32-bit debugging tools or the 64-bit debugging tools. (It is not important whether the dump file is a user-mode dump file or a kernel-mode dump file, and it is not important whether the dump file was made on an x86-based or an x64-based platform.)
- If you are performing live kernel-mode debugging, you can use either the 32-bit debugging tools or the x64 debugging tools. (This situation applies to both x86-based and x64-based targets.)
- If you are debugging live user-mode code that is running on the same computer as the debugger, use the 64-bit tools for debugging 64-bit code and 32-bit code running on WOW64. To set the debugger for 32-bit or 64-bit mode, use the **.effmach** command.
- If you are debugging live 32-bit user-mode code that is running on a separate target computer, use the 32-bit debugging tools.

Debugging Environments

5/26/2017 • 5 min to read • [Edit Online](#)

Starting with Windows Driver Kit (WDK) 8.0, the driver development environment and the Windows debugger are integrated into Microsoft Visual Studio.

After you install Visual Studio and the WDK, you have six available debugging environments:

- Visual Studio with integrated Windows debugger
- Microsoft Windows Debugger (WinDbg)
- Microsoft Kernel Debugger (KD)
- NTKD
- Microsoft Console Debugger (CDB)
- Microsoft NT Symbolic Debugger (NTSD)

The following sections describe the debugging environments.

Visual Studio with integrated Windows debugger

Starting with WDK 8.0, the driver development environment and the Windows debugger are integrated into Visual Studio. In this integrated environment, most of the tools you need for coding, building, packaging, testing, debugging, and deploying a driver are available in the Visual Studio user interface.

Typically kernel-mode debugging requires two computers. The debugger runs on the *host computer* and the code being debugged runs on the *target computer*. With the Windows debugger integrated into Visual Studio, you can perform a wide variety of debugging tasks, including those shown in the following list, from the host computer.

- Configure a set of target computers for debugging.
- Configure the debugging connections to a set of target computers.
- Launch a kernel-mode debugging session between the host computer and a target computer.
- Debug a user-mode process on the host computer.
- Debug a user-mode process on a target computer.
- Connect to remote debugging sessions.
- View assembly code and source code.
- View and manipulate local variables, parameters, and other symbols.
- View and manipulate memory.
- Navigate call stacks.
- Set breakpoints.
- Execute debugger commands.

You can also build drivers, deploy drivers, and run driver tests from within the Visual Studio user interface. If you make use of the Visual Studio integration provided by both the WDK and Debugging Tools for Windows, you can perform almost all of the driver development, packaging, deployment, testing, and debugging tasks from within Visual Studio on the host computer. Here are some of the WDK capabilities that have been integrated into Visual Studio.

- Configure a set of target computers for driver testing.
- Create and sign a driver package.
- Deploy a driver package to a target computer.

- Install and load a driver on a target computer.
- Test a driver on a target computer.

WinDbg

Microsoft Windows Debugger (WinDbg) is a powerful Windows-based debugger that is capable of both user-mode and kernel-mode debugging. WinDbg provides debugging for the Windows kernel, kernel-mode drivers, and system services, as well as user-mode applications and drivers.

WinDbg uses the Visual Studio debug symbol formats for source-level debugging. It can access any symbol or variable from a module that has PDB symbol files, and can access any public function's name that is exposed by modules that were compiled with COFF symbol files (such as Windows .dbg files).

WinDbg can view source code, set breakpoints, view variables (including C++ objects), stack traces, and memory. Its Debugger Command window allows the user to issue a wide variety of commands.

For kernel-mode debugging, WinDbg typically requires two computers (the host computer and the target computer). WinDbg also supports various remote debugging options for both user-mode and kernel-mode targets.

WinDbg is a graphical-interface counterpart to CDB/NTSD and to KD/NTKD.

KD

Microsoft Kernel Debugger (KD) is a character-based console program that enables in-depth analysis of kernel-mode activity on all NT-based operating systems. You can use KD to debug kernel-mode components and drivers, or to monitor the behavior of the operating system itself. KD also supports multiprocessor debugging.

Typically, KD does not run on the computer being debugged. You need two computers (the *host computer* and the *target computer*) for kernel-mode debugging.

NTKD

There is a variation of the KD debugger named NTKD. It is identical to KD in every way, except that it spawns a new text window when it is started, whereas KD inherits the Command Prompt window from which it was invoked.

CDB

Microsoft Console Debugger (CDB) is a character-based console program that enables low-level analysis of Windows user-mode memory and constructs. CDB is extremely powerful for debugging a program that is currently running or has recently crashed (live analysis), yet simple to set up. It can be used to investigate the behavior of a working application. In the case of a failing application, CDB can be used to obtain a stack trace or to look at the guilty parameters. It works well across a network (using a remote access server), as it is character-based.

With CDB, you can display and execute program code, set breakpoints, and examine and change values in memory. CDB can analyze binary code by disassembling it and displaying assembly instructions. It can also analyze source code directly.

Because CDB can access memory locations through addresses or global symbols, you can refer to data and instructions by name rather than by address, making it easy to locate and debug specific sections of code. CDB supports debugging multiple threads and processes. It is extensible, and can read and write both paged and non-paged memory.

If the target application is itself a console application, the target will share the console window with CDB. To spawn a separate console window for a target console application, use the -2 command-line option.

NTSD

There is a variation of the CDB debugger named Microsoft NT Symbolic Debugger (NTSD). It is identical to CDB in every way, except that it spawns a new text window when it is started, whereas CDB inherits the Command Prompt window from which it was invoked.

Like CDB, NTSD is fully capable of debugging both console applications and graphical Windows programs. (The name *Console Debugger* is used to indicate the fact that CDB is classified as a console application; it does not imply that the target application must be a console application.)

Since the **start** command can also be used to spawn a new console window, the following two constructions will give the same results:

```
start cdb parameters
ntsd parameters
```

It is possible to redirect the input and output from NTSD (or CDB) so that it can be controlled from a kernel debugger (either Visual Studio, WinDbg, or KD). If this technique is used with NTSD, no console window will appear at all. Controlling NTSD from the kernel debugger is therefore especially useful, since it results in an extremely light-weight debugger that places almost no burden on the computer containing the target application. This combination can be used to debug system processes, shutdown, and the later stages of boot up. See [Controlling the User-Mode Debugger from the Kernel Debugger](#) for details.

Setting Up Debugging (Kernel-Mode and User-Mode)

5/26/2017 • 1 min to read • [Edit Online](#)

There are two ways you can set up debugging with the Windows debuggers. You can use Microsoft Visual Studio (integrated with the Windows Driver Kit (WDK)), or you can do the setup manually. After you set up kernel-mode debugging, you can use Visual Studio, WinDbg, or KD to establish a debugging session. After you set up user-mode debugging, you can use Visual Studio, WinDbg, CDB, or NTSD to establish a debugging session.

Note The Windows debuggers are included in Debugging Tools for Windows. These debuggers are different from the Visual Studio debugger, which is included with Visual Studio. For more information, see [Windows Debugging](#).

Setting Up Kernel-Mode Debugging over a Network Cable Manually

5/31/2017 • 9 min to read • [Edit Online](#)

Debugging Tools for Windows supports kernel debugging over an Ethernet network. This topic describes how to set up Ethernet debugging manually.

As an alternative to setting up Ethernet debugging manually, you can do the setup using Microsoft Visual Studio. For more information, see [Setting Up Kernel-Mode Debugging over a Network Cable in Visual Studio](#).

The computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*. The host computer must be running Windows XP or later, and the target computer must be running Windows 8 or later.

Debugging over a network has the following advantages compared to debugging over other types of cable.

- The host and target computers can be anywhere on the local network.
- It is easy to debug many target computers from one host computer.
- Network cable is inexpensive and readily available.
- Given any two computers, it is likely that they will both have Ethernet adapters. It is less likely that they will both have serial ports or both have 1394 ports.

Supported Network Adapters

The host computer can use any network adapter, but the target computer must use a network adapter that is supported by Debugging Tools for Windows. For a list of supported network adapters, see [Supported Ethernet NICs for Network Kernel Debugging in Windows 8.1](#).

Determining the IP Address of the Host Computer

Use one of the following procedures to determine the IP address of the host computer.

- On the host computer, open a Command Prompt window and enter the following command:

ipconfig

Make a note of the IPv4 address of the network adapter that you intend to use for debugging.

- On the target computer, open a Command Prompt window and enter the following command, where *HostName* is the name of the host computer:

ping -4 HostName

Choosing a Port for Network Debugging

Choose a port number that will be used for debugging on both the host and target computers. You can choose any number from 49152 through 65535. The port that you choose will be opened for exclusive access by the debugger running on the host computer. Take care to choose a port number that is not used by any other applications that run on the host computer.

Note The range of port numbers that can be used for network debugging might be limited by your company's network policy. There is no way to tell from the host computer what the limitations are. To determine whether

your company's policy limits the range of ports that can be used for network debugging, check with your network administrators.

If you connect several target computers to a single host computer, each connection must have a unique port number. For example, if you connect 100 target computers to a single host computer, you can assign port 50000 to the first connection, port 50001 to the second connection, port 50002 to the third connection, and so on.

Note A different host computer could use the same range of ports (50000 through 50099) to connect to another 100 target computers.

Setting Up the Target Computer

1. Verify that the target computer has a supported network adapter.
2. Connect the supported adapter to a network hub or switch using standard CAT5 or better network cable. Do not use a crossover cable, and do not use a crossover port in your hub or switch.
3. In an elevated Command Prompt window, enter the following commands, where *w.x.y.z* is the IP address of the host computer, and *n* is a port number of your choice:

bcddedit /debug on

bcddedit /dbgsettings net hostip:*w.x.y.z* port:*n*

4. **bcddedit** will display an automatically generated key. Copy the key and store it on a removable storage device like a USB flash drive. You will need the key when you start a debugging session on the host computer.

Note We strongly recommend that you use an automatically generated key. However, you can create your own key as described later in the Creating Your Own Key section.

5. If there is more than one network adapter in the target computer, use Device Manager to determine the PCI bus, device, and function numbers for the adapter you want to use for debugging. Then in an elevated Command Prompt window, enter the following command, where *b*, *d*, and *f* are the bus number, device number, and function number of the adapter:

bcddedit /set "{dbgsettings}" busparams *b.d.f*

6. Reboot the target computer.

Caution If your target computer is in a docking station, and you have network debugging enabled for a network adapter that is part of the docking station, do not remove the computer from the docking station. If you need to remove the target computer from the docking station, disable kernel debugging first. To disable kernel debugging on the target computer, open a Command Prompt window as Administrator and enter the command **bcddedit /debug off**. Reboot the target computer.

Note If you intend to install the Hyper-V role on the target computer, see [Setting Up Network Debugging of a Virtual Machine Host](#).

Setting Up the Host Computer

Connect the network adapter of the host computer to a network hub or switch using standard CAT5 (or higher-level) network cable. Do not use a crossover cable, and do not use a crossover port in your hub or switch.

Starting the Debugging Session

Using WinDbg

On the host computer, open WinDbg. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog

box, open the **Net** tab. Enter your port number and key. Click **OK**.

You can also start a session with WinDbg by opening a Command Prompt window and entering the following command, where *n* is your port number and *Key* is the key that was automatically generated by **bcdedit** when you set up the target computer:

```
windbg -k net:port=n,key=Key
```

If you are prompted about allowing WinDbg to access the port through the firewall, allow WinDbg to access the port for all the different network types.

Using KD

On the host computer, open a Command Prompt window. Enter the following command, where *n* is your port number and *Key* is the key that was automatically generated by **bcdedit** when you set up the target computer:

```
kd -k net:port=n,key=Key
```

If you are prompted about allowing KD to access the port through the firewall, allow KD to access the port for all the different network types.

Allowing the debugger through the firewall

When you first attempt to establish a network debugging connection, you might be prompted to allow the debugging application (WinDbg or KD) access through the firewall. Client versions of Windows display the prompt, but Server versions of Windows do not display the prompt. You should respond to the prompt by checking the boxes for all three network types: domain, private, and public. If you do not get the prompt, or if you did not check the boxes when the prompt was available, you must use Control Panel to allow access through the firewall. Open **Control Panel > System and Security**, and click **Allow an app through Windows Firewall**. In the list of applications, locate Windows GUI Symbolic Debugger and Windows Kernel Debugger. Use the check boxes to allow those two applications through the firewall. Restart your debugging application (WinDbg or KD).

How the Debugger Obtains an IP Address for the Target Computer

The kernel debugging driver on the target computer attempts to use Dynamic Host Configuration Protocol (DHCP) to get a routable IP address for the network adapter that is being used for debugging. If the driver obtains a DHCP-assigned address, then the target computer can be debugged by host computers located anywhere on the network. If the driver fails to obtain a DHCP-assigned address, it uses Automatic Private IP Addressing (APIPA) to obtain a local link IP address. Local link IP addresses are not routable, so a host and target cannot use a local link IP address to communicate through a router. In that case, network debugging will work if you plug the host and target computers into the same network hub or switch.

Creating Your Own Key

To keep the target computer secure, packets that travel between the host and target computers must be encrypted. We strongly recommend that you use an automatically generated encryption key (provided by **bcdedit** when you configure the target computer). However, you can choose to create your own key. Network debugging uses a 256-bit key that is specified as four 64-bit values, in base 36, separated by periods. Each 64-bit value is specified by using up to 13 characters. Valid characters are the letters a through z and the digits 0 through 9. Special characters are not allowed. The following list gives examples of valid (although not strong) keys:

- 1.2.3.4
- abc.123.def.456
- dont.use.previous.keys

To specify your own key, open an elevated Command Prompt window on the target computer. Enter the

following command, where *w.x.y.z* is the IP address of the host computer, and *n* is your port number, and *Key* is your key:

```
bcdedit /dbgsettings net hostip:w.x.y.z port:n key:Key
```

Reboot the target computer.

Troubleshooting Tips for Debugging over a Network Cable

Debugging application must be allowed through firewall

Your debugger (WinDbg or KD) must have access through the firewall. You can use Control Panel to allow access through the firewall. Open **Control Panel > System and Security**, and click **Allow an app through Windows Firewall**. In the list of applications, locate Windows GUI Symbolic Debugger and Windows Kernel Debugger. Use the check boxes to allow those two applications through the firewall. Restart your debugging application (WinDbg or KD).

Port number must be in range allowed by network policy

The range of port numbers that can be used for network debugging might be limited by your company's network policy. To determine whether your company's policy limits the range of ports that can be used for network debugging, check with your network administrator. On the target computer, open a Command Prompt window as Administrator and enter the command **bcdedit /dbgsettings**. The output will be similar to this.

key	xxxxxx.xxxxx.xxxxx.xxxxx
debugtype	NET
debugport	1
baudrate	115200
hostip	10.125.4.86
port	50085

Notice the value of **port**. For example, in the preceding output, the value of **port** is 50085. If the value of **port** lies outside the range allowed by your network administrator, enter the following command, where *w.x.y.z* is the IP address of the host computer, and *n* is a port number in the allowed range

```
bcdedit /dbgsettings net hostip:w.x.y.z port:n
```

Reboot the target computer.

Note In the preceding output from **bcdedit**, the debugport and baudrate entries do not apply to debugging over a network cable. Those entries apply to debugging over a serial cable, but they sometimes appear even though the target is configured for debugging over a network cable.

Specify busparams if target computer has multiple network adapters

If your target computer has more than one network adapter, you must specify the bus, device, and function numbers of the network adapter that you intend to use for debugging. To specify the bus parameters, Open Device Manager, and locate the network adapter that you want to use for debugging. Open the property page for the network adapter, and make a note of the bus number, device number, and function number. In an elevated Command Prompt Window, enter the following command, where *b*, *d*, and *f* are the bus, device and function numbers in decimal format:

```
bcdedit /set "{dbgsettings}" busparams b.d.f
```

Reboot the target computer.

Setting Up Kernel-Mode Debugging over a 1394 Cable Manually

5/31/2017 • 4 min to read • [Edit Online](#)

Debugging Tools for Windows supports kernel debugging over a 1394 (Firewire) cable. This topic describes how to set up 1394 debugging manually.

As an alternative to setting up 1394 debugging manually, you can do the setup using Microsoft Visual Studio. For more information, see [Setting Up Kernel-Mode Debugging over a 1394 Cable in Visual Studio](#).

The computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*. The host and target computers must each have a 1394 adapter and must be running Windows XP or later. The host and target computers do not have to be running the same version of Windows.

Setting Up the Target Computer

1. Connect a 1394 cable to the 1394 controllers that you have chosen for debugging on the host and target computers.
2. In an elevated Command Prompt window, enter the following commands, where *n* is a channel number of your choice, from 0 through 62:

bcdeedit /debug on

bcdeedit /dbgsettings 1394 channel:*n*

3. If there is more than one 1394 controller on the target computer, you must specify the bus, device, and function numbers of the 1394 controller that you intend to use for debugging. For more information, see [Troubleshooting Tips for 1394 Debugging](#).
4. Do not reboot the target computer yet.

Starting a Debugging Session for the First Time

1. Determine the bitness (32-bit or 64-bit) of Windows running on the host computer.
2. On the host computer, open a version of WinDbg (as Administrator) that matches the bitness of Windows running on the host computer. For example, if the host computer is running a 64-bit version of Windows, open the 64-bit version of WinDbg as Administrator.
3. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **1394** tab. Enter your channel number, and click **OK**.

At this point, the 1394 debug driver gets installed on the host computer. This is why it is important to match the bitness of WinDbg to the bitness of Windows. After the 1394 debug driver is installed, you can use either the 32-bit or 64-bit version of WinDbg for subsequent debugging sessions.

4. Reboot the target computer.

Starting a Debugging Session

Using WinDbg

- On the host computer, open WinDbg. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **1394** tab. Enter your channel number, and click **OK**.

You can also start a session with WinDbg by entering the following command in a Command Prompt window, where *n* is your channel number:

windbg /k 1394:channel=n

Using KD

- On the host computer, open a Command Prompt window and enter the following command, where *n* is your channel number:

kd /k 1394:channel=n

Using Environment Variables

On the host computer, you can use environment variables to specify the 1394 channel. Then you do not have to specify the channel each time you start a debugging session. To use environment variables to specify the 1394 channel, open a Command Prompt window and enter the following commands, where *n* is your channel number:

- **set _NT_DEBUG_BUS=1394**
- **set _NT_DEBUG_1394_CHANNEL=n**

To start a debugging session, open a Command Prompt window and enter one of the following commands:

- **kd**
- **windbg**

Additional Information

For complete documentation of the **bcdeedit** command and the boot.ini file, see Boot Options for Driver Testing and Debugging in the Windows Driver Kit (WDK) documentation.

Troubleshooting Tips for Debugging over a 1394 Cable

Most 1394 debugging problems are caused by using multiple 1394 controllers in either the host or target computer. Using multiple 1394 controllers in the host computer is not supported. The 1394 debug driver, which runs on the host, can communicate only with the first 1394 controller enumerated in the registry. If you have a 1394 controller built into the motherboard and a separate 1394 card, either remove the card or disable the built-in controller in the BIOS settings of the computer.

The target computer can have multiple 1394 controllers, although this is not recommended. If your target computer has a 1394 controller on the motherboard, use that controller for debugging, if possible. If there is an additional 1394 card, you should remove the card and use the onboard controller. Another solution is to disable the onboard 1394 controller in the BIOS settings of the computer.

If you decide to have multiple 1394 controllers enabled on the target computer, you must specify bus parameters so that the debugger knows which controller to claim for debugging. To specify the bus parameters, Open Device Manager on the target computer, and locate the 1394 controller that you want to use for debugging. Open the property page for the controller, and make a note of the bus number, device number, and function number. In an elevated Command Prompt Window, enter the following command, where *b*, *d*, and *f* are the bus, device and function numbers in decimal format:

bcdeedit -set "{dbgsettings}" busparams b.d.f.

Reboot the target computer.

Setting Up Kernel-Mode Debugging over a USB 3.0 Cable Manually

5/31/2017 • 4 min to read • [Edit Online](#)

Debugging Tools for Windows supports kernel debugging over a USB 3.0 cable. This topic describes how to set up USB 3.0 debugging manually.

As an alternative to setting up USB 3.0 debugging manually, you can do the setup using Microsoft Visual Studio. For more information, see [Setting Up Kernel-Mode Debugging over a USB 3.0 Cable in Visual Studio](#).

The computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*.

Debugging over a USB 3.0 cable requires the following hardware:

- A USB 3.0 debug cable. This is an A-A crossover cable that has only the USB 3.0 lines and no Vbus.
- On the host computer, an xHCI (USB 3.0) host controller
- On the target computer, an xHCI (USB 3.0) host controller that supports debugging

Setting Up the Target Computer

On the target computer, launch the UsbView tool. The UsbView tool is included in Debugging Tools for Windows. In UsbView, locate all of the xHCI host controllers. In UsbView, expand the nodes of the xHCI host controllers. Look for an indication that a port on the host controller supports debugging.

```
[Port1]
Is Port User Connectable: yes
Is Port Debug Capable: yes
Companion Port Number: 3
Companion Hub Symbolic Link Name: USB#ROOT_HUB30#5&32bab638&0&0#\...
Protocols Supported:
USB 1.1: no
USB 2.0: no
USB 3.0: yes
```

Make a note of the bus, device, and function numbers for the xHCI controller that you intend to use for debugging. UsbView displays these numbers. In the following example, the bus number is 48, the device number is 0, and the function number is 0.

```
USB xHCI Compliant Host Controller
...
DriverKey: {36fc9e60-c465-11cf-8056-444553540000}\0020
...
Bus.Device.Function (in decimal): 48.0.0
```

After you have identified an xHCI controller that supports debugging, the next step is to locate the physical USB connector that is associated with a port on the xHCI controller. To find the physical connector, plug any USB 3.0 device into any USB connector on the target computer. Refresh UsbView to see where your device is located. If UsbView shows your device connected to your chosen xHCI host controller, then you have found a physical USB connector that you can use for USB 3.0 debugging. On the target computer, open a Command Prompt window as

Administrator, and enter these commands:

bcddedit /debug on **bcddedit /dbgsettings usb targetname:TargetName** where *TargetName* is a name that you create for the target computer. Note that *TargetName* does not have to be the official name of the target computer; it can be any string that you create as long as it meets these restrictions:

- The maximum length of the string is 24 characters.
- The only characters in the string are the hyphen (-), the underscore(_), the digits 0 through 9, and the letters A through Z (upper or lower case).

If you have more than one USB host controller on the target computer, enter this command:

bcddedit /set "{dbgsettings}" busparams b.d.f where *b*, *d*, and *f* are the bus, device, and function numbers for the USB host controller that you intend to use for debugging. The bus, device, and function numbers must be in decimal format.

Example:

bcddedit /set "{dbgsettings}" busparams 48.0.0 Reboot the target computer.

Starting a Debugging Session for the First Time

1. Connect a Universal Serial Bus (USB) 3.0 debug cable to the USB 3.0 ports that you have chosen for debugging on the host and target computers.
2. Determine the bitness (32-bit or 64-bit) of Windows running on the host computer.
3. On the host computer, open a version of WinDbg (as Administrator) that matches the bitness of Windows running on the host computer. For example, if the host computer is running a 64-bit version of Windows, open the 64-bit version of WinDbg as Administrator.
4. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **USB** tab. Enter the target name that you created when you set up the target computer. Click **OK**.

At this point, the USB debug driver gets installed on the host computer. This is why it is important to match the bitness of WinDbg to the bitness of Windows. After the USB debug driver is installed, you can use either the 32-bit or 64-bit version of WinDbg for subsequent debugging sessions.

Starting a Debugging Session

Using WinDbg

On the host computer, open WinDbg. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **USB** tab. Enter the target name that you created when you set up the target computer. Click **OK**.

You can also start a session with WinDbg by entering the following command in a Command Prompt window, where *TargetName* is the target name you created when you set up the target computer:

windbg /k usb:targetname=TargetName

Using KD

On the host computer, open a Command Prompt window and enter the following command, where *TargetName* is the target name you created when you set up the target computer:

kd /k usb:targetname=TargetName

Troubleshooting tips for debugging over USB 3.0

In some cases, power transitions can interfere with debugging over USB 3.0. If you have this problem, disable selective suspend for the xHCI host controller (and its root hub) that you are using for debugging.

1. In Device Manager, navigate to the node for the xHCI host controller. Right click the node, and choose **Properties**. If there is a **Power Management** tab, open the tab, and clear the **Allow the computer to turn off this device to save power** check box.
2. In Device Manager, navigate to the node for the root hub of the xHCI host controller. Right click the node, and choose **Properties**. If there is a **Power Management** tab, open the tab, and clear the **Allow the computer to turn off this device to save power** check box.

When you have finished using the xHCI host controller for debugging, enable selective suspend for the xHCI host controller.

Setting Up Kernel-Mode Debugging over a USB 2.0 Cable Manually

5/31/2017 • 7 min to read • [Edit Online](#)

Debugging Tools for Windows supports kernel debugging over a USB 2.0 cable. This topic describes how to set up USB 2.0 debugging manually.

As an alternative to setting up USB 2.0 debugging manually, you can do the setup using Microsoft Visual Studio. For more information, see [Setting Up Kernel-Mode Debugging over a USB 2.0 Cable in Visual Studio](#).

The computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*.

Debugging over a USB 2.0 cable requires the following hardware:

- A USB 2.0 debug cable. This cable is not a standard USB 2.0 cable because it has an extra hardware component that makes it compatible with the USB2 Debug Device Functional Specification. You can find these cables with an Internet search for the term *USB 2.0 debug cable*.
- On the host computer, an EHCI (USB 2.0) host controller
- On the target computer, an EHCI (USB 2.0) host controller that supports debugging

Setting Up the Target Computer

1. On the target computer, launch the UsbView tool. The UsbView tool is included in Debugging Tools for Windows.
2. In UsbView, locate all of the host controllers that are compatible with the EHCI specification. For example, you could look for controllers that are listed as Enhanced.
3. In UsbView, expand the nodes of the EHCI host controllers. Look for an indication that a host controller supports debugging, and look for the number of the debug port. For example, UsbView displays this output for an EHCI host controller that supports debugging on port 1.

```
Xxx xxx xxx USB2 Enhanced Host Controller - 293A
...
Debug Port Number: 1
Bus.Device.Function (in decimal): 0.29.7
```

Note Many EHCI host controllers support debugging on port 1, but some EHCI host controllers support debugging on port 2.

4. Make a note of the bus, device, and function numbers for the EHCI controller that you intend to use for debugging. UsbView displays these number. In the preceding example, the bus number is 0, the device number is 29, and the function number is 7.
5. After you have identified the EHCI controller and the port number that supports debugging, the next step is to locate the physical USB connector that is associated with the correct port number. To find the physical connector, plug any USB 2.0 device into any USB connector on the target computer. Refresh UsbView to see where your device is located. If UsbView shows your device connected to the EHCI host controller and port that you identified as the debug port, then you have found a physical USB connector that you can use for debugging. It could be that there is no external physical USB connector that is associated with a debug port

on an EHCI controller. In that case, you can look for a physical USB connector inside the computer. Perform the same steps to determine whether the internal USB connector is suitable for kernel debugging. If you cannot find a physical USB connector (either external or internal) that is associated with a debug port, then you cannot use the computer as a target for debugging over a USB 2.0 cable.

Note See [this remark](#) for an exception.

6. On the target computer, open a Command Prompt window as Administrator, and enter these commands:

- **bcDEDIT /debug on**
- **bcDEDIT /dbgsettings usb targetname:TargetName**

where *TargetName* is a name that you create for the target computer. Note that *TargetName* does not have to be the official name of the target computer; it can be any string that you create as long as it meets these restrictions:

- The maximum length of the string is 24 characters.
- The only characters in the string are the hyphen (-), the underscore(_), the digits 0 through 9, and the letters A through Z (upper or lower case).

7. If there is more than one USB host controller on the target computer, enter this command:

Windows 7 or later

bcDEDIT /set "{dbgsettings}" busparams b.d.f

where *b*, *d*, and *f* are the bus, device, and function numbers for the host controller. The bus, device, and function numbers must be in decimal format (for example, **busparams 0.29.7**).

Windows Vista

bcDEDIT /set "{current}" loadoptions busparams=f.d.f

where *b*, *d*, and *f* are the bus, device, and function numbers for the host controller. The bus, device, and function numbers must be in hexadecimal format (for example, **busparams=0.1D.7**).

8. Reboot the target computer.

Setting Up the Host Computer

1. Verify that the host computer is not configured to be the target of USB debugging. (If necessary, open a Command Prompt window as Administrator, enter **bcDEDIT /debug off**, and reboot.)
2. On the host computer, use UsbView to find the EHCI host controllers and ports that support debugging. If possible, plug one end of the USB 2.0 debug cable into an EHCI port (on the host computer) that does not support debugging. Otherwise, plug the cable into any EHCI port on the host computer.
3. Plug the other end of the USB 2.0 debug cable into the connector that you identified previously on the target computer.

Starting a Debugging Session for the First Time

1. Determine the bitness (32-bit or 64-bit) of Windows running on the host computer.
2. On the host computer, open a version of WinDbg (as Administrator) that matches the bitness of Windows running on the host computer. For example, if the host computer is running a 64-bit version of Windows, open the 64-bit version of WinDbg as Administrator.
3. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **USB** tab. Enter the target name that you created when you set up the target computer. Click **OK**.

At this point, the USB debug driver gets installed on the host computer. This is why it is important to match the bitness of WinDbg to the bitness of Windows. After the USB debug driver is installed, you can use either the 32-bit or 64-bit version of WinDbg for subsequent debugging sessions.

Note The USB 2.0 debug cable is actually two cables with a dongle in the middle. The direction of the dongle is important; one side powers the device, and the other side does not. If USB debugging doesn't work, try swapping the direction of the dongle. That is, unplug both cables from the dongle, and swap the sides that the cables are connected to.

Starting a Debugging Session

Using WinDbg

On the host computer, open WinDbg. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **USB** tab. Enter the target name that you created when you set up the target computer. Click **OK**.

You can also start a session with WinDbg by entering the following command in a Command Prompt window, where *TargetName* is the target name you created when you set up the target computer:

```
windbg /k usb:targetname=TargetName
```

Using KD

On the host computer, open a Command Prompt window and enter the following command, where *TargetName* is the target name you created when you set up the target computer:

```
kd /k usb:targetname=TargetName
```

What if USBView shows a debug-capable port, but does not show the port mapped to any physical connector?

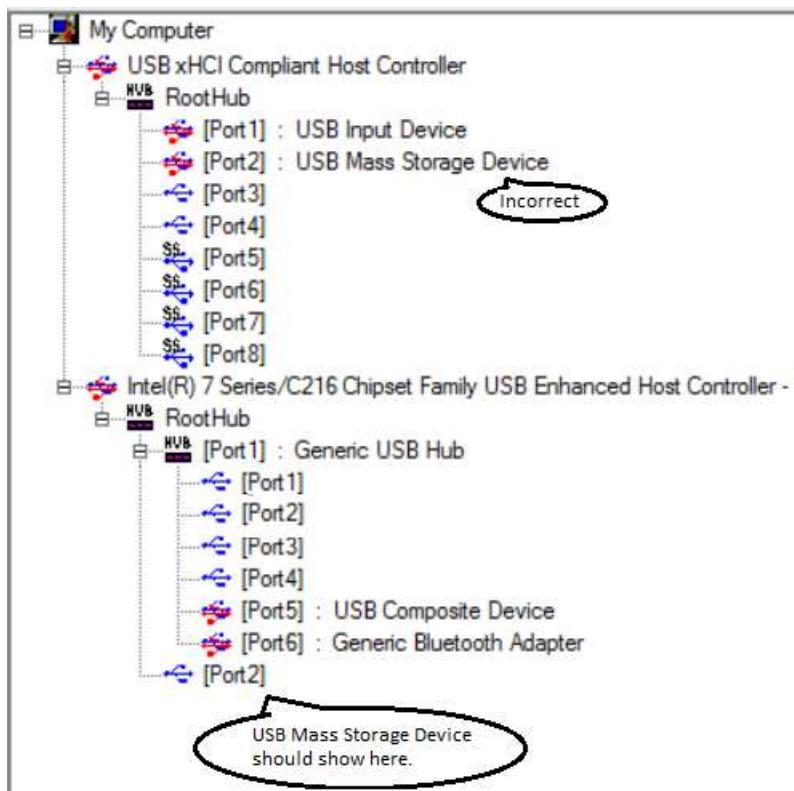

On some computers, USBView shows a debug-capable port, but does not show the port mapped to any physical USB connector. For example, USBView might show port 2 as the debug port number for an eHCl controller.

```
... USB Enhanced Host Controller ...
...
Debug Port Number: 2
Bus.Device.Function (in decimal): 0.29.0
```

Also, when you use USBView to look at the individual port, it is listed as debug-capable.

```
[Port 2]
Is Port User Connectable: Yes
Is Port Debug Capable: Yes
...
Protocols Supported
USB 1.1      yes
USB 2.0      yes
USB 3.0      no
```

But when you plug in a USB 2.0 device (like a flash drive) to all the USB connectors on the computer, USBView never show your device connected to the debug-capable port (port 2 in this example). USBView might show the external connector mapped to a port of an xHCl controller when in fact the external connector is mapped to the debug-capable port of the eHCl controller.

In a case like this, you might still be able to establish kernel-mode debugging over a USB 2.0 cable. In the example given here, you would plug your USB 2.0 debug cable into the connector that shows as being mapped to Port 2 of the xHCI controller. Then you would set your bus parameters to the bus, device, and function numbers of the eHCI controller (in this example, 0.29.0).

bcdeedit /set "{dbgsettings}" busparams 0.29.0

Additional Support

For troubleshooting tips and detailed instructions on setting up kernel debugging over USB, see [Setting Up Kernel Debugging with USB 2.0](#) in MSDN Blogs.

Setting Up Kernel-Mode Debugging over a Serial Cable Manually

5/26/2017 • 4 min to read • [Edit Online](#)

Debugging Tools for Windows supports kernel debugging over a null-modem cable. Null-modem cables are serial cables that have been configured to send data between two serial ports. They are available at most computer stores. Do not confuse null-modem cables with standard serial cables. Standard serial cables do not connect serial ports to each other. For information about how null-modem cables are wired, see [Null-Modem Cable Wiring](#).

This topic describes how to set up serial debugging manually. As an alternative to setting up serial debugging manually, you can do the setup using Microsoft Visual Studio. For more information, see [Setting Up Kernel-Mode Debugging over a Serial Cable in Visual Studio](#).

The computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*.

Setting Up the Target Computer

1. On the target computer, open a Command Prompt window as Administrator, and enter the following commands, where *n* is the number of the COM port used for debugging on the target computer, and *rate* is the baud rate used for debugging:

```
bcdedit /debug on
```

```
bcdedit /dbgsettings serial debugport:n baudrate:rate
```

Note The baud rate must be the same on the host computer and target computer. The recommended rate is 115200.

2. Reboot the target computer.

Starting the Debugging Session

Connect the null-modem cable to the COM ports that you have chosen for debugging on the host and target computers.

Using WinDbg

On the host computer, open WinDbg. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **COM** tab. In the **Baud rate** box, enter the rate you have chosen for debugging. In the **Port** box, enter **COM*n*** where *n* is the COM port number you have chosen for debugging on the host computer. Click **OK**.

You can also start a session with WinDbg by entering the following command in a Command Prompt window; *n* is the number of the COM port used for debugging on the host computer, and *rate* is the baud rate used for debugging:

```
windbg -k com:port=COMn,baud=rate
```

Using KD

On the host computer, open a Command Prompt window, and enter the following command, where *n* is the number of the COM port used for debugging on the host computer, and *rate* is the baud rate used for debugging:

```
kd -k com:port=COMn,baud=rate
```

Using Environment Variables

On the host computer, you can use environment variables to specify the COM port and the baud rate. Then you do not have to specify the port and baud rate each time you start a debugging session. To use environment variables to specify the COM port and baud rate, open a Command Prompt window and enter the following commands, where *n* is the number of the COM port used for debugging on the host computer, and *rate* is the baud rate used for debugging:

- `set _NT_DEBUG_PORT=COMn`
- `set _NT_DEBUG_BAUD_RATE=rate`

To start a debugging session, open a Command Prompt window, and enter one of the following commands:

- `kd`
- `windbg`

Troubleshooting Tips for Debugging over a Serial Cable

Specify correct COM port on both host and target

Determine the numbers of the COM ports you are using for debugging on the host and target computers. For example, suppose you have your null-modem cable connected to COM1 on the host computer and COM2 on the target computer.

On the target computer, open a Command Prompt window as Administrator, and enter `bcdedit /dbgsettings`. If you are using COM2 on the target computer, the output of `bcdedit` should show `debugport 2`.

On the host computer, specify the correct COM port when you start the debugger or when you set environment variables. If you are using COM1 on the host computer, use one of the following methods to specify the COM port.

- In WinDbg, in the Kernel Debugging dialog box, enter COM1 in the **Port** box.
- `windbg -k com:port=COM1, ...`
- `kd -k com:port=COM1, ...`
- `set _NT_DEBUG_PORT=COM1`

Baud rate must be the same on host and target

The baud rate used for debugging over a serial cable must be set to the same value on the host and target computers. For example, suppose you have chosen a baud rate of 115200.

On the target computer, open a Command Prompt window as Administrator, and enter `bcdedit /dbgsettings`. The output of `bcdedit` should show `baudrate 115200`.

On the host computer, specify the correct baud rate when you start the debugger or when you set environment variables. Use one of the following methods to specify a baud rate of 115200.

- In WinDbg, in the Kernel Debugging dialog box, enter 115200 in the **Baud rate** box.
- `windbg -k ..., baud=115200`
- `kd -k ..., baud=115200`
- `set _NT_DEBUG_BAUD_RATE=115200`

Null Modem Cable Wiring

The following tables show how null-modem cables are wired.

9-pin connector

CONNECTOR 1	CONNECTOR 2	SIGNALS
2	3	Tx - Rx
3	2	Rx - Tx
7	8	RTS - CTS
8	7	CTS - RTS
4	1+6	DTR - (CD+DSR)
1+6	4	(CD+DSR) - DTR
5	5	Signal ground

25-pin connector

CONNECTOR 1	CONNECTOR 2	SIGNALS
2	3	Tx - Rx
3	2	Rx - Tx
4	5	RTS - CTS
5	4	CTS - RTS
6	20	DSR - DTR
20	6	DTR - DSR
7	7	Signal ground

Signal Abbreviations

ABBREVIATION	SIGNAL
Tx	Transmit data
Rx	Receive data
RTS	Request to send
CTS	Clear to send
DTR	Data terminal ready
DSR	Data set ready
CD	Carrier detect

Additional Information

For complete documentation of the **bcdedit** command, see Boot Options for Driver Testing and Debugging in the Windows Driver Kit (WDK) documentation.

Setting Up Kernel-Mode Debugging using Serial over USB Manually

5/26/2017 • 4 min to read • [Edit Online](#)

The [Sharks Cove development board](#) supports serial debugging over a USB cable.

This topic describes how to set up serial debugging over a USB cable manually. As an alternative to setting up manually, you can do the setup using Microsoft Visual Studio. For more information, see [Setting Up Kernel-Mode Debugging using Serial over USB in Visual Studio](#).

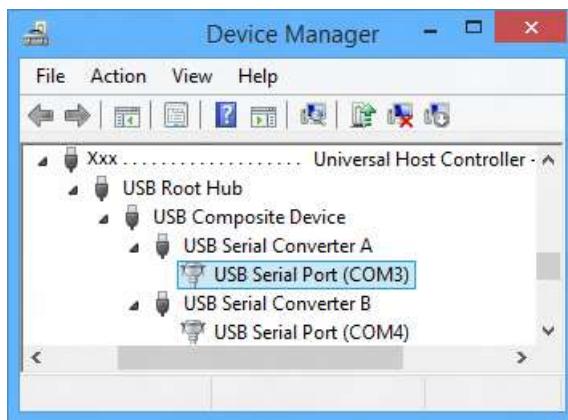

The computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*. In this topic, the Sharks Cove board is the target computer.

Setting up a Host Computer for debugging the Sharks Cove board

1. On the host computer, open Device Manager. On the **View** menu, choose **Devices by Type**.
2. On the Sharks Cove board, locate the debug connector. This is the micro USB connector shown in the following picture.

3. Use a USB 2.0 cable to connect the host computer to the debug connector on the Sharks Cove board.
4. On the host computer, in Device Manager, two COM ports will get enumerated. Select the lowest numbered COM port. On the **View** menu, choose **Devices by Connection**. Verify that the COM port is listed under one of the USB host controllers.

Make a note of the COM port number. This is the lowest COM port number that shows under the USB host controller node. For example, in the preceding screen shot, the lowest COM port number under the USB host controller is COM3. You will need this COM port number later when you start a debugging session. If the driver is not already installed for the COM port, right click the COM port node, and choose **Update**

Driver. Then select **Search automatically for updated driver software**. You will need an internet connection for this.

Setting Up the Sharks Cove Board as the Target Computer

1. On the target computer (Sharks Cove board), open a Command Prompt window as Administrator, and enter these commands:

```
bcddedit /debug on
```

```
bcddedit /dbgsettings serial debugport:1 baudrate:115200
```

2. Reboot the target computer.

Starting the Debugging Session

Using WinDbg

On the host computer, open WinDbg. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **COM** tab. In the **Baud rate** box, enter 115200. In the **Port** box, enter COM n where n is the COM port number you noted previously. Click **OK**.

You can also start a session with WinDbg by entering the following command in a Command Prompt window; n is the number of the COM port that you noted on the host computer:

```
windbg -k com:port=COMn,baud=115200
```

Using KD

On the host computer, open a Command Prompt window, and enter the following command, where n is the COM port number you noted previously:

```
kd -k com:port=COMn,baud=115200
```

Using Environment Variables

On the host computer, you can use environment variables to specify the COM port and the baud rate. Then you do not have to specify the port and baud rate each time you start a debugging session. To use environment variables to specify the COM port and baud rate, open a Command Prompt window and enter the following commands, where n is the number COM port number you noted previously:

- **set _NT_DEBUG_PORT=COM n**
- **set _NT_DEBUG_BAUD_RATE=115200**

To start a debugging session, open a Command Prompt window, and enter one of the following commands:

- **kd**
- **windbg**

Troubleshooting Tips for Serial Debugging over a USB Cable

Specify correct COM port on both host and target

On the target computer (Sharks Cove board), verify that you are using COM1 for debugging. Open a Command Prompt window as Administrator, and enter **bcddedit /dbgsettings**. The output of **bcddedit** should show

```
debugport 1 .
```

On the host computer, specify the correct COM port when you start the debugger or when you set environment variables. This is the lowest numbered COM port that was enumerated under the USB host controller in Device Manager. For example, if COM3 is the desired port, use one of the following methods to specify the COM port.

- In WinDbg, in the Kernel Debugging dialog box, enter COM3 in the **Port** box.
- **windbg -k com:port=COM3, ...**
- **kd -k com:port=COM3, ...**
- **set _NT_DEBUG_PORT=COM3**

Baud rate must be the same on host and target

The baud rate must be 115200 on both the host and target computers.

On the target computer (Sharks Cove board), open a Command Prompt window as Administrator, and enter **bcdedit /dbgsettings**. The output of **bcdedit** should show `baudrate 115200`.

On the host computer, specify the correct baud rate when you start the debugger or when you set environment variables. Use one of the following methods to specify a baud rate of 115200.

- In WinDbg, in the Kernel Debugging dialog box, enter 115200 in the **Baud rate** box.
- **windbg -k ..., baud=115200**
- **kd -k ..., baud=115200**
- **set _NT_DEBUG_BAUD_RATE=115200**

Additional Information

For complete documentation of the **bcdedit** command, see Boot Options for Driver Testing and Debugging in the Windows Driver Kit (WDK) documentation.

Setting Up Kernel-Mode Debugging of a Virtual Machine Manually

5/26/2017 • 4 min to read • [Edit Online](#)

Debugging Tools for Windows supports kernel debugging of a virtual machine. The virtual machine can be located on the same physical computer as the debugger or on a different computer that is connected to the same network. This topic describes how to set up debugging of a virtual machine manually.

As an alternative to setting up debugging of a virtual machine manually, you can do the setup using Microsoft Visual Studio. For more information, see [Setting Up Kernel-Mode Debugging of a Virtual Machine in Visual Studio](#).

The computer that runs the debugger is called the *host computer*, and the virtual machine being debugged is called the *target virtual machine*.

Setting Up the Target Virtual Machine

1. In the virtual machine, in an elevated Command Prompt window, enter the following commands.

```
bcdedit /debug on
```

```
bcdedit /dbgsettings serial debugport:n baudrate:115200
```

where *n* is the number of a COM port on the virtual machine.

2. Reboot the virtual machine.
3. In the virtual machine, configure the COM port to map to a named pipe. The debugger will connect through this pipe. For more information about how to create this pipe, see your virtual machine's documentation.

Starting the Debugging Session Using WinDbg

On the host computer, open WinDbg. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **COM** tab. Check the **Pipe** box, and check the **Reconnect** box. For **Baud Rate**, enter 115200. For **Resets**, enter 0.

If the debugger is running on the same computer as the virtual machine, enter the following for **Port**.

`\.\pipe\PipeName.`

If the debugger is running on a different computer from the virtual machine, enter the following for **Port**.

`\VMHost\pipe\PipeName`

Click **OK**.

You can also start WinDbg at the command line. If the debugger is running on the same physical computer as the virtual machine, enter the following command in a Command Prompt window.

```
windbg -k com:pipe,port=\.\pipe\PipeName,resets=0,reconnect
```

If the debugger is running on a different physical computer from the virtual machine, enter the following command in a Command Prompt window.

```
windbg -k com:pipe,port=\VMHost\pipe\PipeName,resets=0,reconnect
```

Starting the Debugging Session Using KD

To debug a virtual machine that is running on the same physical computer as the debugger, enter the following command in a Command Prompt window.

kd -k com:pipe,port=\\.\\pipe*PipeName*,resets=0,reconnect

To debug a virtual machine that is running on a different physical computer from the debugger, enter the following command in a Command Prompt window.

kd -k com:pipe,port=\\\\VMHost\\pipe*PipeName*,resets=0,reconnect

Parameters

VMHost

Specifies the name of the computer that the virtual machine is running on.

PipeName

Specifies the name of the pipe that you created on the virtual machine.

resets=0

Specifies that an unlimited number of reset packets can be sent to the target when the host and target are synchronizing. Use the **resets=0** parameter for Microsoft Virtual PC and other virtual machines whose pipes drop excess bytes. Do not use this parameter for VMware or other virtual machines whose pipes do not drop all excess bytes.

reconnect

Causes the debugger to automatically disconnect and reconnect the pipe if a read/write failure occurs. Additionally, if the debugger does not find the named pipe when the debugger is started, the *reconnect* parameter causes the debugger to wait for a pipe that is named *PipeName* to appear. Use *reconnect* for Virtual PC and other virtual machines that destroy and re-create their pipes during a computer restart. Do not use this parameter for VMware or other virtual machines that preserve their pipes during a computer restart.

For more information about additional command-line options, see [KD Command-Line Options](#) or [WinDbg Command-Line Options](#).

Generation 2 Virtual Machines

By default, COM ports are not presented in generation 2 virtual machines. You can add COM ports through PowerShell or WMI. For the COM ports to be displayed in the Hyper-V Manager console, they must be created with a path.

To enable kernel debugging using a COM port on a generation 2 virtual machine, follow these steps:

1. Disable Secure Boot by entering this PowerShell command:

Set-VMFirmware -Vmname *VmName* -EnableSecureBoot Off

where *VmName* is the name of your virtual machine.

2. Add a COM port to the virtual machine by entering this PowerShell command:

Set-VMComPort -VMName *VmName* 1 \\\.\\pipe*PipeName*

For example, the following command configures the first COM port on virtual machine TestVM to connect to named pipe TestPipe on the local computer.

Set-VMComPort -VMName TestVM 1 \\\.\\pipe\\TestPipe

For more information, see [Generation 2 Virtual Machine Overview](#).

Remarks

If the target computer has stopped responding, the target computer is still stopped because of an earlier kernel debugging action, or you used the **-b** [command-line option](#), the debugger breaks into the target computer immediately.

Otherwise, the target computer continues running until the debugger orders it to break.

Note If you restart the virtual machine by using the VMWare facilities (for example, the reset button), exit WinDbg, and then restart WinDbg to continue debugging. During virtual machine debugging, VMWare often consumes 100% of the CPU.

Setting Up Local Kernel Debugging of a Single Computer Manually

5/26/2017 • 1 min to read • [Edit Online](#)

Debugging Tools for Windows supports *local kernel debugging*. This is kernel-mode debugging on a single computer. In other words, the debugger runs on the same computer that is being debugged. With local debugging you can examine state, but not break into kernel mode processes that would cause the OS to stop running.

The *local* `bcDEDIT` option is available in Windows 8.0 and Windows Server 2012 and later.

Setting Up Local Kernel-Mode Debugging

1. Open a Command Prompt window as Administrator. Enter **`bcDEDIT /debug on`**
2. If the computer is not already configured as the target of a debug transport, enter **`bcDEDIT /dbgsettings local`**
3. Reboot the computer.

Starting the Debugging Session

Using WinDbg

Open WinDbg as Administrator. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **Local** tab. Click **OK**.

You can also start a session with WinDbg by opening a Command Prompt window as Administrator and entering the following command:

`windbg -kl`

Using KD

Open a Command Prompt window as Administrator, and enter the following command:

`kd -kl`

Supported Ethernet NICs for Network Kernel Debugging in Windows 10

5/26/2017 • 3 min to read • [Edit Online](#)

You can do kernel debugging over an Ethernet network cable when the target computer is running Windows. The target computer must have a supported network interface card (NIC) or network adapter.

During kernel debugging, the computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*. To do [kernel debugging over a network cable](#), the target computer must have a supported network adapter. When the target computer is running Windows, the network adapters listed here are supported for kernel debugging.

Note

The list of supported adapters is for the following versions of Windows

- Windows 10, version 1703
- Windows Server 2016

Finding the vendor ID and device ID

First find the vendor ID and device ID of the network adapter on your target computer.

- On the target computer, open Device Manager (enter **devmgmt** in a Command Prompt window).
- In Device Manager, locate the network adapter that you want to use for debugging.
- Right click the network adapter node, and choose **Properties**.
- In the **Details** tab, under **Property**, select **Hardware IDs**.

The vendor and device IDs are shown as `VEN_VendorID` and `DEV_DeviceID`. For example, if you see `PCI\VEN_8086&DEV_104B`, the vendor ID is 8086, and the device ID is 104B.

Vendor ID 8086, Intel Corporation

For vendor ID 8086, these device IDs are supported:

0001 0008 000C 000D 0438 043A 043C 0440 0470 1000 1001 1004 1008 1009 100C 100D 100E 100F 1010 1011 1012 1013 1014 1015 1016 1017 1018 1019 101A 101D 101E 1026 1027 1028 1049 104A 104B 104C 104D 105E 105F 1060 1071 1075 1076 1077 1078 1079 107A 107B 107C 107D 107E 107F 108A 108B 108C 1096 1098 1099 109A 10A4 10A5 10A7 10A9 10B5 10B9 10BA 10BB 10BC 10BD 10BF 10C0 10C2 10C3 10C4 10C5 10C6 10C7 10C8 10C9 10CB 10CC 10CD 10CE 10D3 10D5 10D6 10D9 10DA 10DB 10DD 10DE 10DF 10E1 10E5 10E6 10E7 10E8 10EA 10EB 10EC 10EF 10F0 10F1 10F4 10F5 10F6 10F7 10F8 10F9 10FB 10FC 11A9 1501 1502 1503 1507 150A 150B 150C 150D 150E 150F 1510 1511 1514 1516 1517 1518 151C 1521 1522 1523 1524 1525 1526 1527 1528 1529 152A 1533 1534 1535 1536 1537 1538 1539 153A 153B 1546 154A 154D 1557 1558 1559 155A 1560 1563 156F 1570 157B 157C 15A0 15A1 15A2 15A3 15AA 15AB 15AC 15AD 15AE 15B7 15B8 17D0 1F40 1F41 1F45 1F63 1F72 211B 2159 294C 8976

Vendor ID 10EC, Realtek Semiconductor Corp.

For vendor ID 10EC, these device IDs are supported:

8136 8137 8166 8167 8168 8169

Vendor ID 14E4, Broadcom

For vendor ID 14E4, these device IDs are supported:

1600 1601 1639 163A 163B 163C 163D 163E 1641 1642 1643 1644 1645 1646 1647 1648 164A 164C 164D 164E 164F 1650 1653 1654 1655 1656 1657 1659 165A 165B 165C 165D 165E 165F 1662 1663 1665 1668 1669 166A 166B 166D 166E 1672 1673 1674 1676 1677 1678 1679 167A 167B 167C 167D 167F 168A 168D 168E 1680 1681 1682 1683 1684 1686 1687 1688 1690 1691 1692 1693 1694 1696 1698 1699 169A 169B 169D 16A0 16A1 16A2 16A4 16A5 16A6 16A7 16A8 16AA 16AC 16AE 16B0 16B1 16B2 16B3 16B4 16B5 16B6 16B7 16C6 16C7 16DD 16F7 16FD 16FF 170D 170E 170F

Vendor ID 1969, Atheros Communications

For vendor ID 1969, these device IDs are supported:

1062 1063 1073 1083 1090 1091 10A0 10A1 10B0 10B1 10C0 10C1 10D0 10D1 10E0 10E1 10F0 10F1 2060 2062 E091 E0A1 E0B1 E0C1 E0D1 E0E1 E0F1

Vendor ID 19A2, ServerEngines (Emulex)

For vendor ID 19A2, these device IDs are supported:

Supported Ethernet NICs for Network Kernel Debugging in Windows 8.1

5/26/2017 • 3 min to read • [Edit Online](#)

You can do kernel debugging over an Ethernet network cable when the target computer is running Windows 8.1. The target computer must have a supported network interface card (NIC) or network adapter.

During kernel debugging, the computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*. To do [kernel debugging over a network cable](#), the target computer must have a supported network adapter. When the target computer is running Windows 8.1, the network adapters listed here are supported for kernel debugging.

Note Support for kernel debugging over selected 10 gigabit network adapters is a new feature in Windows 8.1. Debugging over 10 gigabit network adapters is not supported in Windows 8. For a list of network adapters supported by Windows 8 for kernel debugging, see [Supported Ethernet NICs for Network Kernel Debugging in Windows 8](#).

System Requirements

Kernel debugging through Ethernet NICs requires certain low-level platform support. Windows requires that these NICs be attached via PCI/PCIe for this debugging solution. In most cases, simply plugging in one of these supported NICs will allow a robust kernel debugging experience. However, there may be cases where BIOS configuration details hinder the Windows debug path. The following platform requirement should be considered:

- System firmware should discover and configure the NIC device such that its resources do not conflict with any other devices that have been BIOS-configured.

Finding the vendor ID and device ID

First find the vendor ID and device ID of the network adapter on your target computer.

- On the target computer, open Device Manager (enter **devmgmt** in a Command Prompt window).
- In Device Manager, locate the network adapter that you want to use for debugging.
- Right click the network adapter node, and choose **Properties**.
- In the **Details** tab, under **Property**, select **Hardware IDs**.

The vendor and device IDs are shown as `VEN_VendorID` and `DEV_DeviceID`. For example, if you see `PCI\VEN_8086&DEV_104B`, the vendor ID is 8086, and the device ID is 104B.

Vendor ID 8086, Intel Corporation

For vendor ID 8086, these device IDs are supported:

0438 043A 043C 0440 1000 1001 1004 1008 1009 100C 100D 100E 100F 1010 1011 1012 1013 1014 1015
1016 1017 1018 1019 101A 101D 101E 1026 1027 1028 1049 104A 104B 104C 104D 105E 105F 1060 1075

Supported Ethernet NICs for Network Kernel Debugging in Windows 8

5/26/2017 • 3 min to read • [Edit Online](#)

You can do kernel debugging over an Ethernet network cable when the target computer is running Windows 8. The target computer must have a supported network interface card (NIC) or network adapter.

During kernel debugging, the computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*. To do [kernel debugging over a network cable](#), the target computer must have a supported network adapter. When the target computer is running Windows 8, the network adapters listed here are supported for kernel debugging.

Note For a list of network adapters supported by Windows 8.1 for kernel debugging, see [Supported Ethernet NICs for Network Kernel Debugging in Windows 8.1](#).

System Requirements

Kernel debugging through Ethernet NICs requires certain low-level platform support. Windows requires that these NICs be attached via PCI/PCIe for this debugging solution. In most cases, simply plugging in one of these supported NICs will allow a robust kernel debugging experience. However, there may be cases where BIOS configuration details hinder the Windows debug path. The following set of platform requirements should be considered:

- System firmware should discover and configure the NIC device such that its resources do not conflict with any other devices that have been BIOS-configured.
- System firmware should place the NIC's resources under address windows that are not marked prefetchable.

Finding the vendor ID and device ID

First find the vendor ID and device ID of the network adapter on your target computer.

- On the target computer, open Device Manager (enter **devmgmt** in a Command Prompt window).
- In Device Manager, locate the network adapter that you want to use for debugging.
- Right click the network adapter node, and choose **Properties**.
- In the **Details** tab, under **Property**, select **Hardware Ids**.

The vendor and device IDs are shown as `VEN_VendorID` and `DEV_DeviceID`. For example, if you see `PCI\VEN_8086&DEV_104B`, the vendor ID is 8086, and the device ID is 104B.

Vendor ID 8086, Intel Corporation

For vendor ID 8086, these device IDs are supported:

1000 1001 1004 1008 1009 100C 100D 100E 100F 1010 1011 1012 1013 1014 1015 1016 1017 1018 1019
101A 101D 101E 1026 1027 1028 1049 104A 104B 104C 104D 105E 105F 1060 1075 1076 1077 1078 1079
107A 107B 107C 107D 107E 107F 108A 108B 108C 1096 1098 1099 109A 10A4 10A5 10A7 10A9 10B5 10B9

Setting Up User-Mode Debugging in Visual Studio

5/26/2017 • 1 min to read • [Edit Online](#)

There are two user-mode debuggers available in the Microsoft Visual Studio environment. One is the Windows User-Mode Debugger, which is included in Debugging Tools for Windows. The other is the Visual Studio Debugger, which is part of the Visual Studio product. This topic describes how to get set up to use the Windows User-Mode Debugger from within the Visual Studio environment.

Debugging a User-Mode Process on the Local Computer

No special setup is required for debugging a user-mode process on the local computer. For information about attaching to a process or launching a process under the debugger, see [Debugging a User-Mode Process Using Visual Studio](#).

Debugging a User-Mode Process on a Target Computer

In some cases, two computers are used for debugging. The debugger runs on the *host computer*, and the code that is being debugged runs on the *target computer*. In Visual Studio (running on the host computer), you can use the Windows User-Mode Debugger to attach to a user-mode process on a target computer.

On the target computer, go to **Control Panel>Network and Internet>Network and Sharing Center>Advanced sharing settings**. Under **Guest or Public**, select **Turn on network discovery** and **Turn on file and printer sharing**.

You can do the rest of the configuration from the host computer:

1. On the host computer, in Visual Studio, on the **Tools** menu, choose **Attach to Process**.
2. For **Transport**, choose **Windows User Mode Debugger**.
3. To the right of the **Qualifier** box, click the **Browse** button.
4. Click the **Add** button.
5. Enter the name of the target computer.
6. To the right of **Configure Target Computer**, click the **Configure** button. The **Configure Target Computer** dialog box opens and displays the configuration progress.
7. When the configuration is complete, in the **Configure Computers** dialog box, click **OK**.

Setting Up Network Debugging of a Virtual Machine Host

5/26/2017 • 1 min to read • [Edit Online](#)

If your target computer is a virtual machine host, you can set up network debugging and still have network access for the virtual machines.

Suppose you want to set up network debugging in the following situation.

- The target computer has a single network interface card.
- You intend to install the Hyper-V role on the target computer.
- You intend to create one or more virtual machines on the target computer.

The best approach is to set up network debugging on the target computer before you install the Hyper-V role. Then the virtual machines will have access to the network.

If you decide to set up network debugging after the Hyper-V role has been installed on the target computer, you must change the network settings for your virtual machines to bridge them to the Microsoft Kernel Network Debug Adapter. Otherwise, the virtual machines will not have access to the network.

Configuring tools.ini

5/31/2017 • 3 min to read • [Edit Online](#)

The file tools.ini contains information to initialize the command-line debuggers. On startup, the debugger searches for the appropriate section header in the tools.ini file and extracts initialization information from the entries under the header. Each command-line debugger has its own section header - [CDB], [NTSD], and [KD]. The environment variable INIT must point to the directory containing the tools.ini file.

WinDbg does not use the tools.ini file. Instead, WinDbg saves initialization settings in [workspaces](#).

The tools.ini entries are shown in the following table.

Keywords must be separated from the values by white space or a colon. Keywords are not case-sensitive.

For **TRUE** or **FALSE** values, "FALSE" is the only false value. Anything else is **TRUE**.

ENTRY	DESCRIPTION
\$u0: value ... \$u9: value	Assign values to fixed-name aliases. You can specify numeric values <i>n</i> or <i>0xn</i> or any other string. See Using Aliases for details. No command-line equivalent.
DebugChildren: flag	TRUE or FALSE . If TRUE , CDB debugs the specified application as well as any child processes that it might spawn. Command-line equivalent is -o .
DebugOutput: flag	TRUE or FALSE . If TRUE , CDB sends output and receives input through a terminal. If FALSE , output goes to the user screen. The command-line option -d is similar but not identical.
IniFile: file	Specifies the name of the script file that CDB or KD takes commands from at startup. The default is the ntsd.ini file in the current directory. Command-line equivalent is -cf . For details, see Using Script Files .
LazyLoad: flag	TRUE or FALSE . If TRUE , CDB performs lazy symbol loading; that is, symbols are not loaded until required. Command-line equivalent is -s . For details, and other methods of setting this option, see Deferred Symbol Loading .
SetDll: filename	Set extension DLL. The .dll filename extension should be omitted. Default is userexts.dll. Command-line equivalent is -a . For details, and other methods of setting this default, see Loading Debugger Extension DLLs .

ENTRY	DESCRIPTION
StopFirst: <i>flag</i>	<p>TRUE or FALSE. If true, CDB stops on the breakpoint at the end of the image-loading process. Command-line equivalent is -g.</p>
StopOnProcessExit: <i>flag</i>	<p>TRUE or FALSE. If TRUE, CDB stops when it receives a process termination notification. Command-line equivalent is -G.</p>
sxd: <i>event</i> sxe: <i>event</i>	<p>Sets the debugger response and the handling status for the specified exception or event.</p> <p>Exceptions and events may be specified in the following ways:</p> <ul style="list-style-type: none"> <i>*:</i> Default exception <i>n</i>: Exception <i>n</i> (decimal) <i>0xn</i>: Exception <i>0xn</i> (hexadecimal) (other): Event code <p>See Controlling Exceptions and Events for details of this process and for other methods of controlling these settings.</p>
VerboseOutput: <i>flag</i>	<p>TRUE or FALSE. If TRUE, CDB will display detailed information about symbol handling, event notification, and other run-time occurrences. Command-line equivalent is -v.</p>
lines: <i>flag</i>	<p>TRUE or FALSE. The lines flag enables or disables support for source-line information.</p>
srcopt: <i>options</i>	<p>Sets the source line options that control source display and program stepping options. For more information see I+, I- (Set Source Options).</p>
srcpath: <i>directory</i>	<p>Sets the source file search path. For more information see .srcpath, .lsrcpath (Set Source Path).</p>
enable_unicode: <i>flag</i>	<p>TRUE or FALSE. The enable_unicode flag specifies whether the debugger displays USHORT pointers and arrays as Unicode strings.</p>
force_radix_output: <i>flag</i>	<p>TRUE or FALSE. The force_radix_output flag specifies whether integers are displayed in decimal format or in the default radix.</p>
col_mode: <i>flag</i>	<p>TRUE or FALSE. The col_mode flag controls the color mode setting. When color mode is enabled the debugger can produce colored output. By default, most colors are not set and instead default to the current console colors.</p>

ENTRY	DESCRIPTION
col: <i>name colspec</i>	<p>The <i>name</i> indicates the element that you are coloring. The <i>colspec</i> is a three-letter RGB indicator of the form [rR-][gG-][bB-]. A lower-case letter indicates darker, an upper-case letter indicates brighter and a dash indicates no color component contribution. Due to console color limitations, bright is not actually per-component, but applies to all components if any request bright. In other words, rgB is the same as RGB. For this reason, it is recommended that all caps be used if any caps are going to be used.</p> <p>Example usage:</p> <p>col: emphfg R--</p>

A sample [NTSD] section in the tools.ini file follows:

```
[NTSD]
sxe: 3c
sxe: cc
$u0: VeryLongName
VerboseOutput:true
```

Using KDbgCtrl

5/31/2017 • 5 min to read • [Edit Online](#)

The KDbgCtrl (Kernel Debugging Control, kdbgctrl.exe) tool can be used to control the kernel debugging connection from the target computer.

To use this tool, your target computer must be running Windows Server 2003 or a later version of Windows.

KDbgCtrl can control five different settings: Full Kernel Debugging, Automatic Kernel Debugging, User-Mode Error Handling, Blocking of Kernel Debugging, and the size of the DbgPrint buffer.

To use KDbgCtrl, you must have already enabled kernel debugging in the boot settings of the target computer before the last boot. KDbgCtrl cannot be used to enable kernel debugging if this was not done. See [Boot Parameters to Enable Debugging](#) for details on these boot settings.

Full Kernel Debugging

When Full Kernel Debugging is enabled, a kernel debugger running on the host computer can break into the target computer. The target computer will break into the kernel debugger if a kernel-mode exception is hit. Messages from the target to the host, such as **DbgPrint** output, symbol load messages, and redirected user-mode debuggers, are also allowed.

If this setting is disabled, all signals from the host computer will be ignored by the target.

Full Kernel Debugging is enabled by default. To check the current setting value, use **kdbgctrl -c**. To disable this setting, use **kdbgctrl -d**. To enable this setting, use **kdbgctrl -e**.

If you wish to check the current setting and use it to control execution within a batch file, you can use the **kdbgctrl -cx** command. For details on this command, see [KDbgCtrl Command-Line Options](#).

Automatic Kernel Debugging

If Full Kernel Debugging is enabled, the current setting for Automatic Kernel Debugging is immaterial -- all communication is permitted.

When Full Kernel Debugging is disabled and Automatic Kernel Debugging is enabled, only the target computer can initiate a debugging connection.

In this case, only a kernel-mode exception, breakpoint, or other kernel-mode event will cause a connection to be established. The connection will not be established for **DbgPrint** output, symbol load messages, redirected user-mode debugger input and output, or other similar messages -- these will be stored in the DbgPrint buffer instead of being sent to the kernel debugger.

If an exception or event causes the target to break into the kernel debugger, then Full Kernel Debugging will be automatically turned on, just as if you had executed **kdbgctrl -e**.

Automatic Kernel Debugging is disabled by default (although this is immaterial unless Full Kernel Debugging is disabled as well). To check the current setting value, use **kdbgctrl -ca**. To disable this setting, use **kdbgctrl -da**. To enable this setting, use **kdbgctrl -ea**.

User-Mode Error Handling

When User-Mode Error Handling is enabled, some user-mode events will cause the target computer to break into the kernel debugger.

Specifically, all **int 3** interrupts -- such as breakpoints inserted into the code by a debugger or calls to **DbgBreakPoint** -- will cause a break into the kernel debugger. However, standard exceptions -- such as access

violations and division by zero -- will usually not be sent to the kernel debugger.

If a user-mode debugger is already attached to the process, this debugger will capture all user-mode errors, and the kernel debugger will not be alerted. For the precedence ranking of the various user-mode error handlers, see [Enabling Postmortem Debugging](#).

For User-Mode Error Handling to function, either Full Kernel Debugging or Automatic Kernel Debugging must be enabled as well.

User-Mode Error Handling is enabled by default. To check the current setting value, use **kdbgctrl -cu**. To disable this setting, use **kdbgctrl -du**. To enable this setting, use **kdbgctrl -eu**.

Blocking Kernel Debugging

In some cases you might want to set up the target computer for kernel debugging, but wait to enable kernel debugging until after the target computer is started. You can do that by blocking kernel debugging.

To block kernel debugging, set up the target computer by using commands similar to the following:

```
bcdedit /debug on
bcdedit /dbgsettings 1394 channel:32 /start DISABLE /noumex
```

When you restart the target computer, it will be prepared for kernel debugging, but kernel debugging and User-Mode Error Handling will be disabled. At that point, a host computer will not be able to attach to the target computer, bug checks will not be caught by the kernel debugger, and user-mode exceptions will not cause a break in to the kernel debugger.

When you are ready, you can enable kernel debugging (without restarting the target computer) by entering the following commands.

```
kdbgctrl -db
kdbgctrl -e
```

Later, you can disable kernel debugging by entering the following commands.

```
kdbgctrl -d
kdbgctrl -eb
```

You can use **kdbgctrl -cb** to check whether kernel debugging is blocked.

The DbgPrint Buffer Size

The DbgPrint buffer stores messages that the target computer has sent to the kernel debugger.

If Full Kernel Debugging is enabled, these messages will automatically appear in the kernel debugger. But if this option is disabled, these messages will be stored in the buffer. At a later point in time, you can enable kernel debugging, connect to a kernel debugger, and use the **!dbgprint** extension to see the contents of this buffer. For more information about this buffer, see [The DbgPrint Buffer](#).

The default size of the DbgPrint buffer is 4 KB on a free build of Windows, and 32 KB on a checked build of Windows. To determine the current buffer size, use **kdbgctrl -cdb**. To change the buffer size, use **kdbgctrl -sdbSize**, where *Size* specifies the new buffer size. For syntax details, see [KDbgCtrl Command-Line Options](#).

Examples

To display all the current settings, use the following command:

```
kdbgctrl -c -ca -cu -cb -cdb
```

To restore the default settings, use the following command:

```
kdbgctrl -e -da -eu -db -sdb 0x1000
```

To lock out the host computer so that it only is contacted on exceptions, use the following command:

```
kdbgctrl -d -ea -eu
```

To disable all kernel debugging, use the following command:

```
kdbgctrl -d -da
```

If you are disabling all kernel debugging, you may also wish to increase the size of the DbgPrint buffer. This insures that all messages will be saved in case you need to see them later. If you have a megabyte of memory to spare, you might use the following command:

```
kdbgctrl -sdb 0x100000
```

Debug Universal Drivers - Step by Step Lab (Echo Kernel-Mode)

5/31/2017 • 39 min to read • [Edit Online](#)

This lab introduces the WinDbg kernel debugger. WinDbg is used to debug the echo kernel mode sample driver code.

Lab objectives

This lab includes exercises that introduce the debugging tools, teach common debugging commands, illustrate the use of break points, and show the use of the debugging extensions.

In this lab, a live kernel debug connection is used to explore the following:

- Use the Windows debugger commands
- Use standard commands (Call stacks, variables, threads, IRQL)
- Use advanced driver debugging commands (!commands)
- Use symbols
- Set breakpoints in live debugging
- View call stacks
- Display the Plug and Play device tree
- Work with thread and process context

Note When working with the Windows debugger, there are two types of debugging that can be performed - user or kernel mode debugging. *User mode* - Applications and subsystems run on the computer in user mode.

Processes that run in user mode do so within their own virtual address spaces. They are restricted from gaining direct access to many parts of the system, including system hardware, memory that was not allocated for their use, and other portions of the system that might compromise system integrity. Because processes that run in user mode are effectively isolated from the system and other user mode processes, they cannot interfere with these resources.

Kernel mode - Kernel mode is the processor access mode in which the operating system and privileged programs run. Kernel mode code has permission to access any part of the system, and is not restricted like user mode code. It can gain access to any part of any other process running in either user mode or kernel mode. Much of the core OS functionality and many hardware device drivers run in kernel mode.

This lab will focus on kernel mode debugging, as that is the method used to debug many device drivers.

This exercise covers debug commands that are frequently used during both user-mode and kernel-mode debugging. The exercise also covers debug extensions (sometimes called "!commands") that are used for kernel-mode debugging.

Lab setup

You will need the following hardware to be able to complete the lab.

- A laptop or desktop computer (host) running Windows 10
- A laptop or desktop computer (target) running Windows 10
- A network cross over cable or a network hub and network cables to connect the two PCs
- Access to the internet to download symbol files

You will need the following software to be able to complete the lab.

- Visual Studio 2015
- Windows Software Development Kit (SDK) for Windows 10
- Windows Driver Kit (WDK) for Windows 10
- The sample echo driver for Windows 10

The lab has the following eleven sections.

- [Section 1: Connect to a kernel mode WinDbg session](#)
- [Section 2: Kernel mode debugging commands and techniques](#)
- [Section 3: Download and build the KMDF Universal Echo Driver](#)
- [Section 4: Install the KMDF Echo driver sample on the target system](#)
- [Section 5: Use WinDbg to display information about the driver](#)
- [Section 6: Display Plug and Play device tree information](#)
- [Section 7: Work with breakpoints and source code](#)
- [Section 8: View variables and call stacks](#)
- [Section 9: Display processes and threads](#)
- [Section 10: IRQL, Registers and Ending the WinDbg session](#)
- [Section 11: Windows debugging resources](#)

Section 1: Connect to a kernel mode WinDbg session

In Section 1, you will configure network debugging on the host and target system.

The PCs in this lab need to be configured to use an Ethernet network connection for kernel debugging.

This lab uses two PCs. Windows debugger runs on the *host* system and the KMDF Echo driver runs on the *target* system.

The "<-Host" on the left is connected using a cross over ethernet cable to the "->Target" on the right.

The steps in the lab assume that you are using a cross over network cable, but the lab should also work if you can plug both the host and the target directly into a network hub.

To work with kernel mode applications and use WinDbg, we recommend that you use the KDNET over Ethernet transport. For information about how to use the Ethernet transport protocol, see [Getting Started with WinDbg \(Kernel-Mode\)](#). For more information about setting up the target computer, see [Preparing a Computer for Manual Driver Deployment](#) and [Setting Up Kernel-Mode Debugging over a Network Cable Manually](#).

Configure kernel-mode debugging using a crossover ethernet cable

To enable kernel mode debugging on the target system, perform the following steps.

<- On the host system

1. Open a command prompt on the host system and type **ipconfig** to determine its IP address.

```
C:\>ipconfig
Windows IP Configuration
Ethernet adapter Ethernet:
  Connection-specific DNS Suffix  . :
  Link-local IPv6 Address . . . . . : fe80::c8b6:db13:d1e8:b13b%3
  Autoconfiguration IPv4 Address. . . : 169.182.1.1
  Subnet Mask . . . . . : 255.255.0.0
  Default Gateway . . . . . :
```

2. Record the IP address of the host system: _____

-> On the target system

1. Open a command prompt on the target system and use the **ping** command to confirm network connectivity between the two systems. Use the IP address of the host system you recorded instead of the one shown in the sample output.

```
C:\> ping 169.182.1.1

Pinging 169.182.1.1 with 32 bytes of data:
Reply from 169.182.1.1: bytes=32 time=1ms TTL=255
Reply from 169.182.1.1: bytes=32 time<1ms TTL=255
Reply from 169.182.1.1: bytes=32 time<1ms TTL=255
Reply from 169.182.1.1: bytes=32 time<1ms TTL=255

Ping statistics for 169.182.1.1:
  Packets: Sent = 4, Received = 4, Lost = 0 (0% loss),
  Approximate round trip times in milli-seconds:
    Minimum = 0ms, Maximum = 1ms, Average = 0ms
```

Enable kernel mode debugging on the target system by completing the following steps.

1. On the target computer, open a Command Prompt window as Administrator. Enter this command to enable debugging.

```
C:\> bcdedit /set {default} DEBUG YES
```

2. Type this command to enable test signing.

```
C:\> bcdedit /set TESTSIGNING ON
```

3. Type this command to set the IP address of the host system. Use the IP address of the host system that you recorded earlier, not the one shown.

```
C:\> bcdedit /dbgsettings net hostip:192.168.1.1 port:50000 key:1.2.3.4
```

Warning To increase the security of the connection and decrease the risk of the random client debugger connection requests, consider using an auto generated random key. For more information, see [Setting Up Kernel-Mode Debugging over a Network Cable Manually](#).

1. Type this command to confirm that the dbgsettings they are set properly.

```
C:\> bcdeedit /dbgsettings
key          1.2.3.4
debugtype    NET
hostip       169.168.1.1
port         50000
dhcp         Yes
The operation completed successfully.
```

Note

Firewalls and debuggers

If you receive a pop-up message from the firewall, and you wish to use the debugger, unblock the types of networks that you desire.

<- On the host system

1. On the host computer, open a Command Prompt window as Administrator. Change to the WinDbg.exe directory. We will use the x64 version of WinDbg.exe from the Windows Driver Kit (WDK) that was installed as part of the Windows kit installation.

```
C:\> Cd C:\Program Files(x86)\Windows Kits\10\Debuggers\x64
```

2. Launch WinDbg with remote user debug using the following command. The value for the key and port match what we set earlier using BCDEdit on the target.

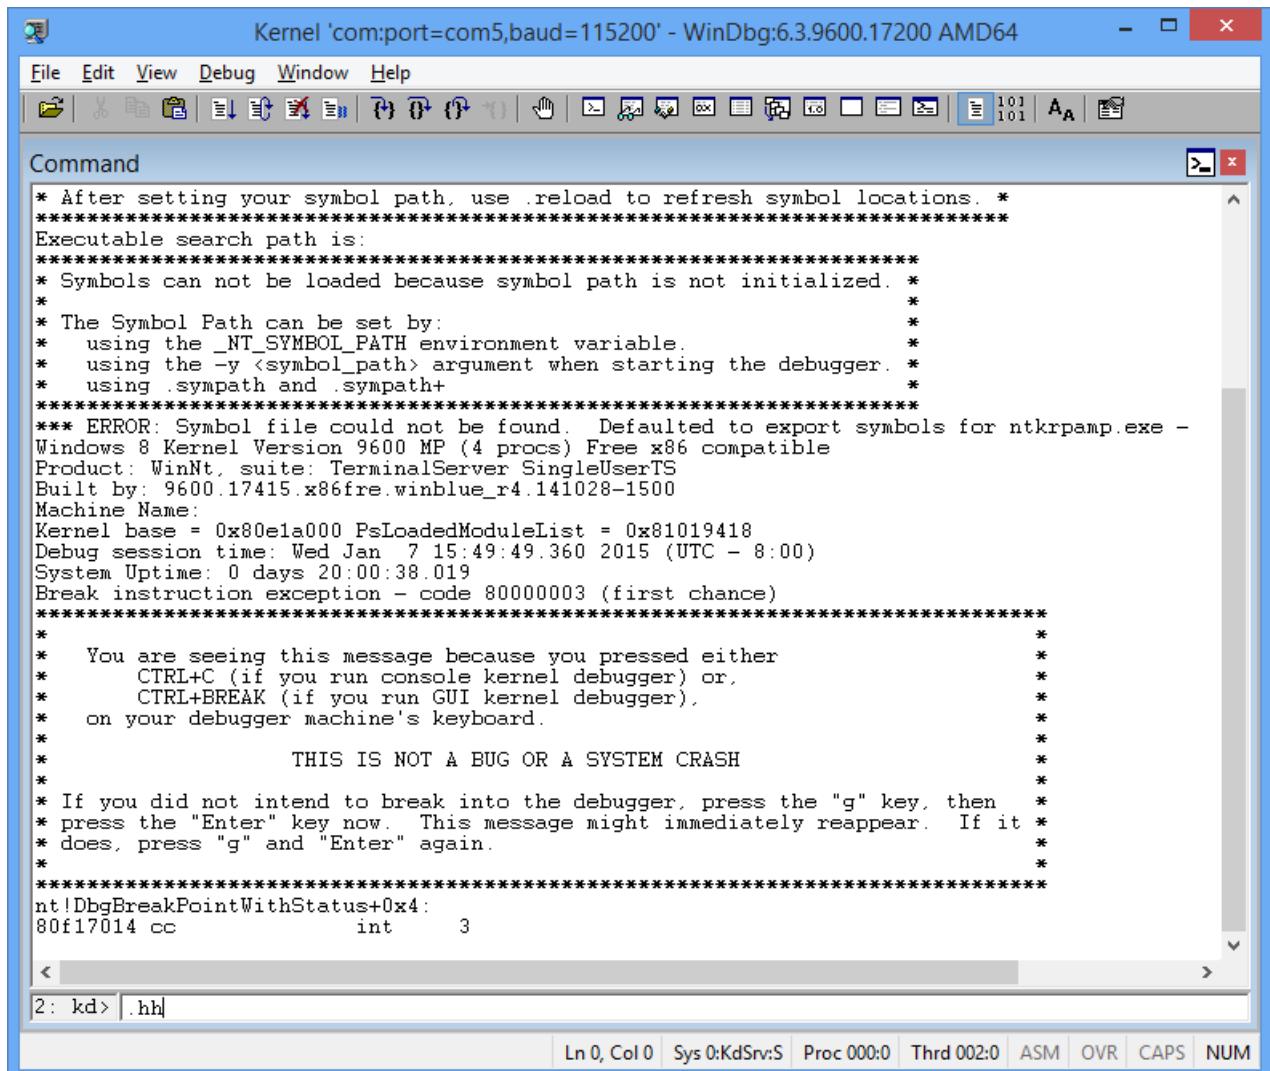

```
WinDbg -k net:port=50000,key=1.2.3.4
```

->On the target system

Reboot the target system.

<-On the host system

In a minute or two, debug output should be displayed on the host system.

```

```

The Debugger Command window is the primary debugging information window in WinDbg. You can enter debugger commands and view the command output in this window.

The Debugger Command window is split into two panes. You type commands in the smaller pane (the command entry pane) at the bottom of the window and view the command output in the larger pane at the top of the window.

In the command entry pane, use the up arrow and down arrow keys to scroll through the command history. When a command appears, you can edit it or press **ENTER** to run the command.

Section 2: Kernel mode debugging commands and techniques

In Section 2, you will use debug commands to display information about the target system.

<- On the host system

Enable Debugger Markup Language (DML) with .prefer_dml

Some debug commands display text using Debugger Markup Language that you can click on to quickly gather more information.

1. Use Ctrl+Break (Scroll Lock) in WinDbg to break into the code running on the target system. It may take a bit of time for the target system to respond.
2. Type the following command to enable DML in the Debugger Command window.

```
0: kd> .prefer_dml 1
DML versions of commands on by default
```

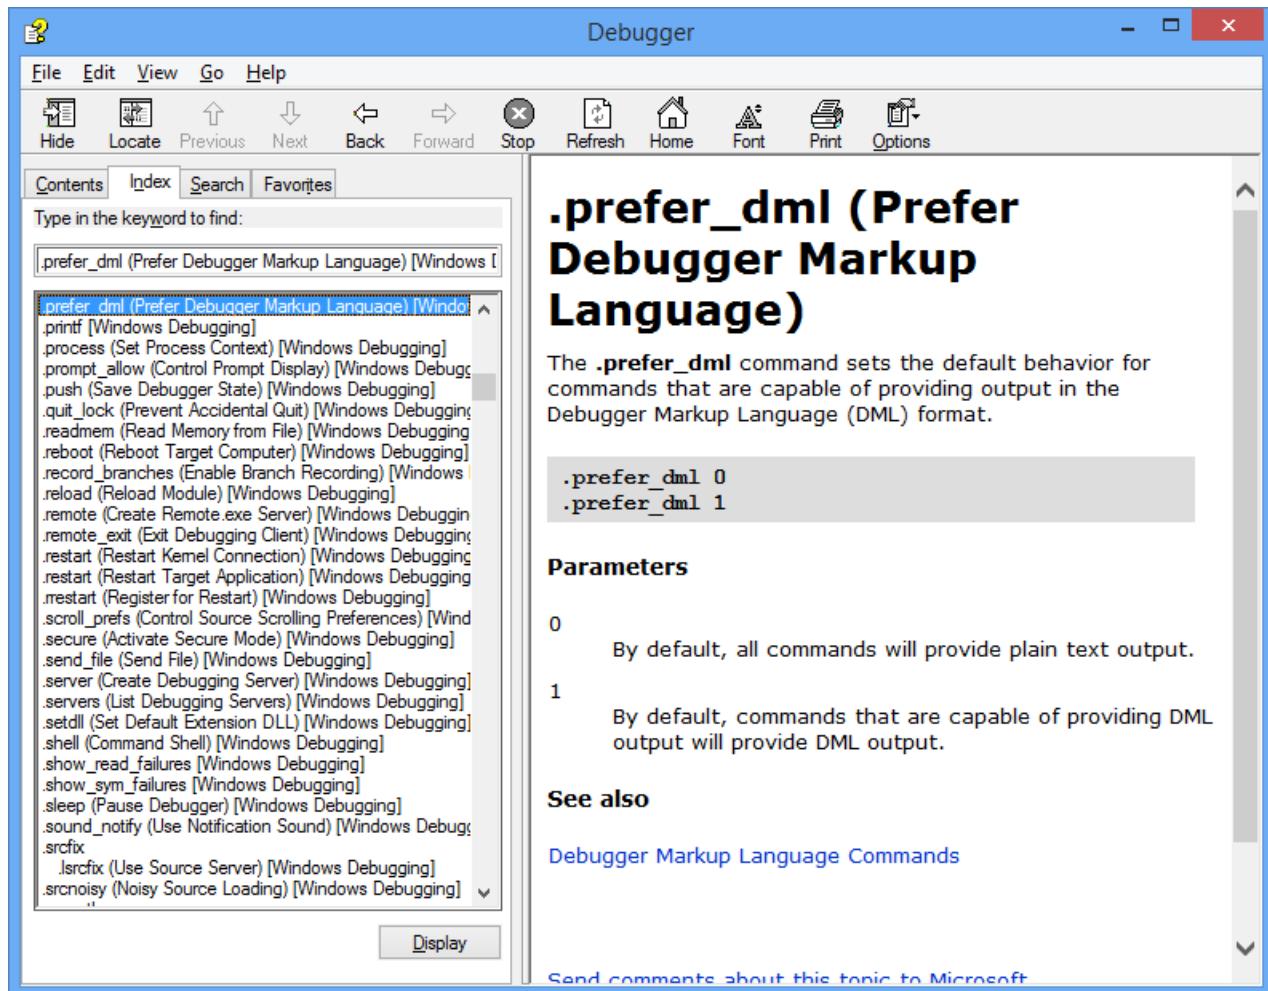

Use .hh to get help

You can access reference command help using the **.hh** command.

1. Type the following command to view the command reference help for **.prefer_dml**.

```
0: kd> .hh .prefer_dml
```

The Debugger help file will display help for the **.prefer_dml** command.

Display the version of Windows on the target system

1. Display detailed version information on the target system by typing the **vertarget (Show Target Computer Version)** command in the WinDbg window.

```
0: kd> vertarget
Windows 10 Kernel Version 9926 MP (4 procs) Free x64
Product: WinNt, suite: TerminalServer SingleUserTS
Built by: 9926.0.amd64fre.fbl_awesome1501.150119-1648
Machine Name: ""
Kernel base = 0xffff801`8d283000 PsLoadedModuleList = 0xffff801`8d58aef0
Debug session time: Fri Feb 20 10:15:17.807 2015 (UTC - 8:00)
System Uptime: 0 days 01:31:58.931
```

List the loaded modules

1. You can verify that you are working with the right kernel mode process by displaying the loaded modules by typing the **!m (List Loaded Modules)** command in the WinDbg window.

```

0: Kd> lm
start           end             module name
ffff801`09200000 fffff801`0925f000  volmgrx    (no symbols)
ffff801`09261000 fffff801`092de000  mcupdate_GenuineIntel (no symbols)
ffff801`092de000 fffff801`092ec000  werkernel   (export symbols)    werkernel.sys
ffff801`092ec000 fffff801`0934d000  CLFS        (export symbols)    CLFS.SYS

Unable to enumerate user-mode unloaded modules, Win32 error 0n30

```

1. Because we have yet to set the symbol path and loaded symbols, limited information is available in the debugger.

Section 3: Download and build the KMDF universal echo driver

In Section 3, you will download and build the KMDF universal echo driver.

Typically, you would be working with your own driver code when you use WinDbg. To become familiar with WinDbg operation, the KMDF Template "Echo" sample driver is used. With the source code available, it will also be easier to understand the information that is displayed in WinDbg. In addition, this sample is used to illustrate how you can single step through native kernel mode code. This technique can be very valuable for debugging complex kernel mode code issues.

To download and build the Echo sample audio driver, perform the following steps.

1. **Download and extract the KMDF Echo sample from GitHub**

You can use a browser to view the echo sample in GitHub here:

<https://github.com/Microsoft/Windows-driver-samples/tree/97cf5197cf5b882b2c689d8dc2b555f2edf8f418/general/echo/kmdf>

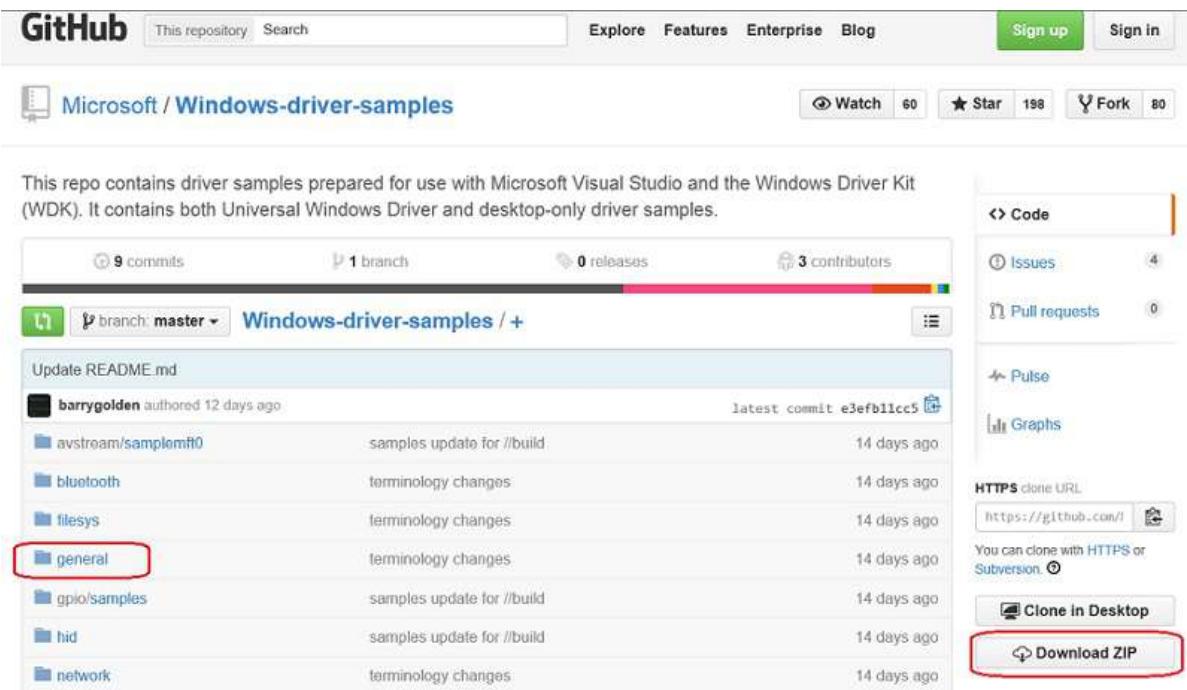

You can read about the sample here:

<https://github.com/Microsoft/Windows-driver-samples/blob/97cf5197cf5b882b2c689d8dc2b555f2edf8f418/general/echo/kmdf/ReadMe.md>

You can browse all of the universal driver samples here:

<https://github.com/Microsoft/Windows-driver-samples>

The KMDF Echo sample is located in the general folder.

This screenshot shows the GitHub repository page for `Microsoft / Windows-driver-samples`. The repository has 9 commits, 1 branch, 0 releases, and 3 contributors. The `general` folder is highlighted with a red box. The `Download ZIP` button is also highlighted with a red box.

a. This lab, shows how to download the universal driver samples in one zip file.

<https://github.com/Microsoft/Windows-driver-samples/archive/master.zip>

b. Download the master.zip file to your local hard drive.

c. Right-click `Windows-driver-samples-master.zip`, and choose **Extract All**. Specify a new folder, or browse to an existing one that will store the extracted files. For example, you could specify `C:\DriverSamples\` as the new folder into which the files are extracted.

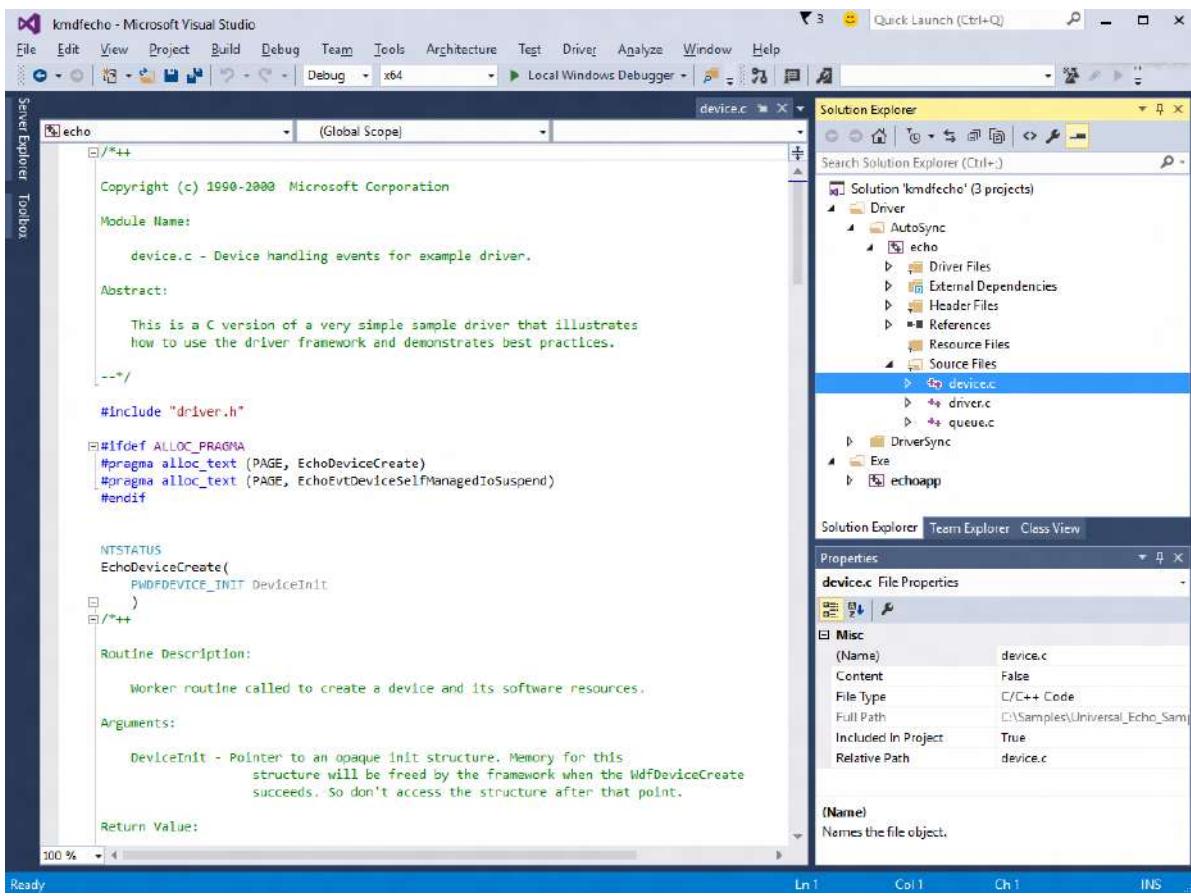

d. After the files are extracted, navigate to the following subfolder.

`C:\DriverSamples\general\echo\kmdf`

2. Open the driver solution in Visual Studio

In Microsoft Visual Studio, click **File > Open > Project/Solution...** and navigate to the folder that contains the extracted files (for example, `C:\DriverSamples\general\echo\kmdf`). Double-click the `kmdfecho` solution file to open it.

In Visual Studio, locate the Solution Explorer. (If this is not already open, choose **Solution Explorer** from the **View** menu.) In Solution Explorer, you can see one solution that has three projects.

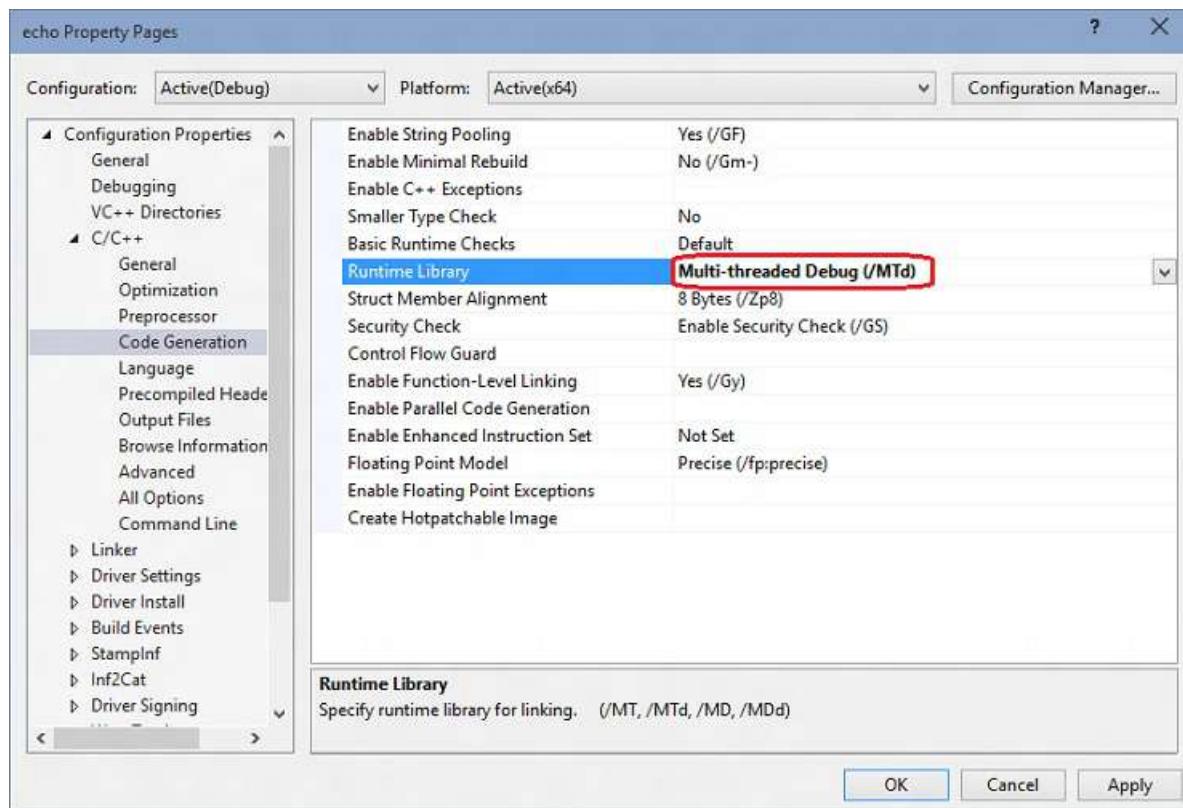

3. Set the sample's configuration and platform

In Solution Explorer, right-click **Solution 'kmdfecho' (3 projects)**, and choose **Configuration Manager**. Make sure that the configuration and platform settings are the same for the three projects. By default, the configuration is set to "Win10 Debug", and the platform is set to "Win64" for all the projects. If you make any configuration and/or platform changes for one project, you must make the same changes for the remaining three projects.

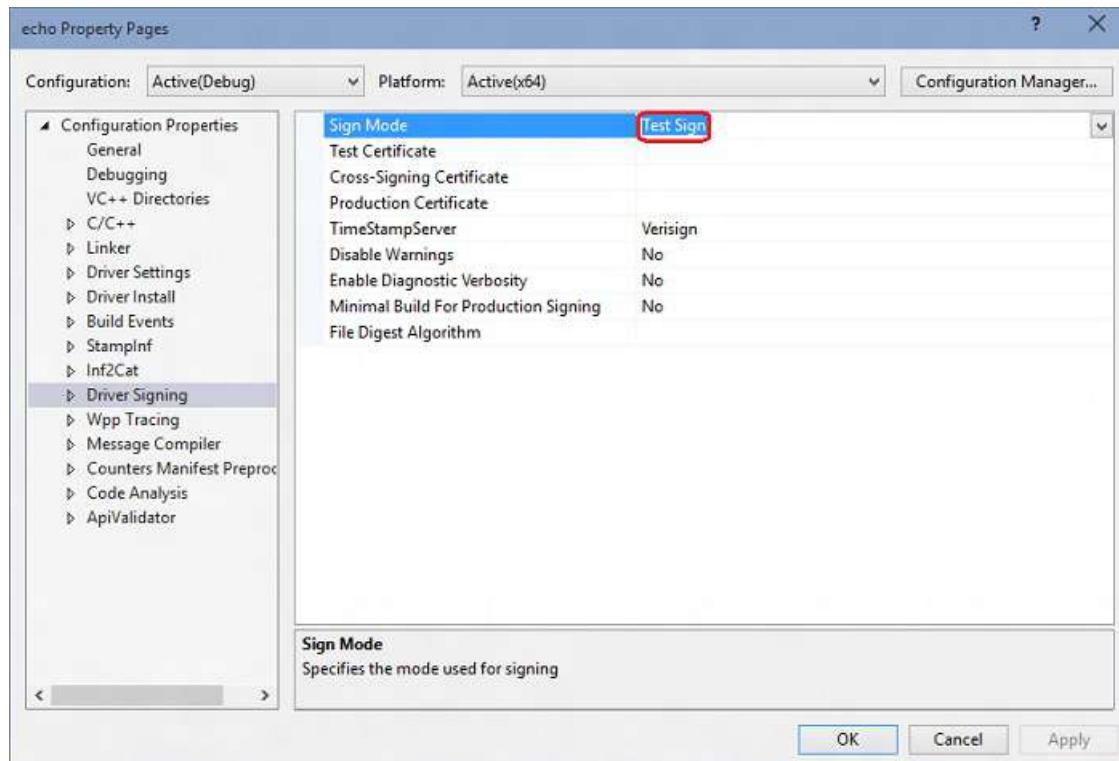

4. Set the runtime library

Set the runtime library - Change Runtime Library from DLL version to non DLL version. Without this setting, you have to install the MSVC runtime to the target computer separately.

5. Check driver signing

Open the echo driver's property page and make sure **Driver Signing > Sign Mode** is set to "Test Sign". This is required because Windows requires that drivers are signed.

6. Build the sample using Visual Studio

In Visual Studio, click **Build > Build Solution**.

If all goes well, the build windows should display a message indicating that the build for all three projects succeeded.

7. Locate the built driver files

In File Explorer, navigate to the folder that contains the extracted files for the sample. For example, you would navigate to `C:\DriverSamples\general\echo\kmdf`, if that's the folder you specified earlier. Within that folder, the location of the compiled driver files varies depending on the configuration and platform settings that you selected in the **Configuration Manager**. For example, if you left the default settings unchanged, then the compiled driver files will be saved to a folder named `\x64\Debug` for a 64 bit, debug build.

Navigate to the folder that contains the built files for the Autosync driver:

`C:\DriverSamples\general\echo\kmdf\driver\AutoSync\x64\Debug`. The folder should contain these files:

FILE	DESCRIPTION
Echo.sys	The driver file.
Echo.inf	An information (INF) file that contains information needed to install the driver.

In addition, the `echoapp.exe` file was built and it should be located here:

`*C:\\DriverSamples\\general\\echo\\kmdf\\exe\\x64\\Debug*`

File	Description
----- -----	
EchoApp.exe	A command prompt executable test file that communicates with the echo.sys driver.

1. Locate a USB thumb drive or set up a network share to copy the built driver files and the test EchoApp from the host to the target system.

In the next section, you will copy the code to the target system, and install and test the driver.

Section 4: Install the KMDF echo driver sample on the target system

In Section 4, you will use devcon to install the echo sample driver.

-> On the target system

The computer where you install the driver is called the *target computer* or the *test computer*. Typically, this is a separate computer from the computer on which you develop and build the driver package. The computer where you develop and build the driver is called the *host computer*.

The process of moving the driver package to the target computer and installing the driver is called *deploying* the driver. You can deploy the sample echo driver, automatically or manually.

Before you manually deploy a driver, you must prepare the target computer by turning on test signing. You also need to locate the DevCon tool in your WDK installation. After that you're ready to run the built driver sample.

To install the driver on the target system, perform the following steps.

Enable test signed drivers

Enable the ability to run test signed drivers:

- a. Open Windows Settings.
- b. In Update and Security, select **Recovery**.
- c. Under Advanced startup, click **Restart Now**.
- d. When the PC reboots, select **Startup options**.
- e. Select Disable driver signature enforcement by pressing the **F7** key.
- f. Reboot the target computer.

Navigate to the Tools folder in your WDK installation and locate the DevCon tool. For example, look in the following folder:

`C:\Program Files (x86)\Windows Kits\10.0\Tools\x64\devcon.exe` Create a folder on the target for the built driver

package (for example, C:\EchoDriver). Copy all the files from the built driver described earlier on the host computer and save them to the folder that you created on the target computer.

Locate the .cer certificate on the host system, it is in the same folder on the host computer in the folder that contains the built driver files. On the target computer, right-click the certificate file, and click **Install**, then follow the prompts to install the test certificate.

If you need more detailed instructions for setting up the target computer, see [Preparing a Computer for Manual Driver Deployment](#).

-> **On the target system**

Install the driver

The following instructions show you how to install and test the sample driver. Here's the general syntax for the devcon tool that you will use to install the driver:

`devcon install <INF file> <hardware ID>`

The INF file required for installing this driver is *echo.inf*. The inf file contains the hardware ID for installing the *echo.sys*. For the echo sample the hardware ID is **root\ECHO**.

On the target computer, open a Command Prompt window as Administrator. Navigate to your driver package folder, and enter the following command:

devcon install echo.inf root\ECHO If you get an error message about *devcon* not being recognized, try adding the path to the *devcon* tool. For example, if you copied it to a folder called C:\Tools, then try using the following command:

c:\tools\devcon install echo.inf root\ECHO A dialog box will appear indicating that the test driver is an unsigned driver. Click **Install this driver anyway** to proceed.

For more detailed instructions, see [Configuring a Computer for Driver Deployment, Testing, and Debugging](#).

After successfully installing the sample driver, you're now ready to test it.

Examine the driver in Device Manager

On the target computer, in a Command Prompt window, enter **devmgmt** open Device Manager. In Device Manager, on the View menu, choose Devices by type. In the device tree, locate *Sample WDF Echo Driver* in the Sample Device node.

Test the driver

Type **echoapp** to start the test echo app to confirm that the driver is functional.

```
C:\Samples\KMDF_Echo_Sample> echoapp
DevicePath: \\?\root#sample#0005#{cdc35b6e-0be4-4936-bf5f-5537380a7c1a}
Opened device successfully
512 Pattern Bytes Written successfully
512 Pattern Bytes Read successfully
Pattern Verified successfully
30720 Pattern Bytes Written successfully
30720 Pattern Bytes Read successfully
Pattern Verified successfully
```

Section 5: Use WinDbg to display information about the driver

In Section 5, you will set the symbol path and use kernel debugger commands to display information about the KMDF echo sample driver.

View information about the driver by performing the following steps.

<-On the host system

1. If you closed the debugger, open it again using the following command in the administrator command prompt window.

```
WinDbg -k net:port=50000,key=1.2.3.4
```

2. Use Ctrl+Break (Scroll Lock) to break into the code running on the target system.

Setting the symbol path

1. To set the symbols path to the Microsoft symbol server in the WinDbg environment, use the **.symfix** command.

```
0: kd> .symfix
```

2. To add your local symbol location to use your local symbols, add the path using **.sympath+** and then **.reload /f**.

```
0: kd> .sympath+ C:\DriverSamples\general\echo\kmdf
0: kd> .reload /f
```

Note The **.reload** command with the **/f** force option deletes all symbol information for the specified module and reloads the symbols. In some cases, this command also reloads or unloads the module itself.

Note You must load the proper symbols to use advanced functionality that WinDbg provides. If you do not have symbols properly configured, you will receive messages indicating that symbols are not available when you attempt to use functionality that is dependent on symbols.

```
0:000> dv
Unable to enumerate locals, HRESULT 0x80004005
Private symbols (symbols.pri) are required for locals.
Type ".hh dbgerr005" for details.
```

Note

Symbol servers

There are a number of approaches that can be used to work with symbols. In many situations, you can configure the PC to access symbols from a symbol server that Microsoft provides when they are needed. This walkthrough assumes that this approach will be used. If the symbols in your environment are in a different location, modify the steps to use that location. For additional information, see [Symbol Stores and Symbol Servers](#).

Note

Understand source code symbol requirements

To perform source debugging, you must build a checked (debug) version of your binaries. The compiler will create symbol files (.pdb files). These symbol files will show the debugger how the binary instructions correspond to the source lines. The actual source files themselves must also be accessible to the debugger.

The symbol files do not contain the text of the source code. For debugging, it is best if the linker does not optimize your code. Source debugging and access to local variables are more difficult, and sometimes nearly impossible, if the code has been optimized. If you are having problems viewing local variables or source lines, set the following build options:

```
set COMPILE_DEBUG=1
set ENABLE_OPTIMIZER=0
```

1. Type the following in the command area of the debugger to display information about the echo driver :

```
0: kd> lm m echo* v
Browse full module list
start           end             module name
fffff801`4ae80000 fffff801`4ae89000  ECHO      (private pdb symbols)
C:\Samples\KMDF_ECHO_SAMPLE\echo.pdb
    Loaded symbol image file: ECHO.sys
    Image path: \SystemRoot\system32\DRIVERS\ECHO.sys
    Image name: ECHO.sys
...
```

For information, see [lm](#).

2. Because we set `prefer_dml =1` earlier, some elements of the output are hot links that you can click on. Click on the *Browse all global symbols link* in the debug output to display information about items symbols that start with the letter "a".

```
0: kd> x /D Echo!a*
```

3. As it turns out, the echo sample doesn't contain any symbols that start with the letter "a", so to display information about all of the symbols associated with echo driver that start with Echo, type **x ECHO!Echo***.

```
0: kd> x ECHO!Echo*
fffff801`0bf95690 ECHO!EchoEvtIoQueueContextDestroy (void *)
fffff801`0bf95000 ECHO!EchoEvtDeviceSelfManagedIoStart (struct WDFDEVICE__ *)
fffff801`0bf95ac0 ECHO!EchoEvtTimerFunc (struct WDFTIMER__ *)
fffff801`0bf9b120 ECHO!EchoEvtDeviceSelfManagedIoSuspend (struct WDFDEVICE__ *)
...
```

For information, see [x \(Examine Symbols\)](#).

4. The **!lmi** extension displays detailed information about a module. Type **!lmi echo**. Your output should be similar to the text shown below.

```
0: kd> !lmi echo
Loaded Module Info: [echo]
    Module: ECHO
    Base Address: fffff8010bf94000
    Image Name: ECHO.sys
...
```

5. Use the **!dh** extension to display header information as shown below.

```
0: kd> !dh echo

File Type: EXECUTABLE IMAGE
FILE HEADER VALUES
 14C machine (i386)
 6 number of sections
54AD8A42 time date stamp Wed Jan 07 11:34:26 2015
...
```

6. Setting the debug mask

Type the following to change the default debug bit mask so that all debug messages from the target system will be displayed in the debugger.

```
0: kd> !ed nt!Kd_DEFAULT_MASK 0xFFFFFFFF
```

Some drivers will display additional information when the mask of 0xFFFFFFFF is used. Set the mask to 0x00000000 if you would like to reduce the amount of information that is displayed.

```
0: kd> !ed nt!Kd_DEFAULT_MASK 0x00000000
```

Section 6: Displaying Plug and Play device tree information

In Section 6, you will display information about the echo sample device driver and where it lives in the Plug and Play device tree.

Information about the device driver in the Plug and Play device tree can be useful for troubleshooting. For example, if a device driver is not resident in the device tree, there may be an issue with the installation of the device driver.

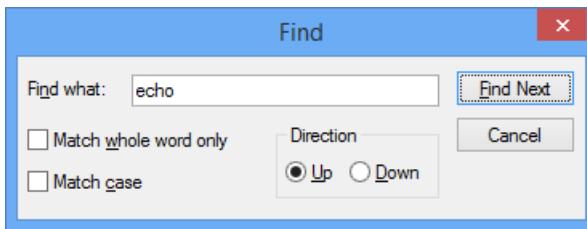

For more information about the device node debug extension, see [!devnode](#).

<-On the host system

1. To see all the device nodes in the Plug and Play device tree, enter the **!devnode 0 1** command.

```
0: kd> !devnode 0 1
Dumping IopRootDeviceNode (= 0xfffffe0005a3a8d30)
DevNode 0xfffffe0005a3a8d30 for PDO 0xfffffe0005a3a9e50
  InstancePath is "HTREE\ROOT\0"
  State = DeviceNodeStarted (0x308)
  Previous State = DeviceNodeEnumerateCompletion (0x30d)
  DevNode 0xfffffe0005a3a3d30 for PDO 0xfffffe0005a3a4e50
    InstancePath is "ROOT\volmgr\0000"
    ServiceName is "volmgr"
    State = DeviceNodeStarted (0x308)
    Previous State = DeviceNodeEnumerateCompletion (0x30d)
    DevNode 0xfffffe0005a324560 for PDO 0xfffffe0005bd95ca0...
...
```

2. Use **Ctrl+F** to search in the output that is generated to look for the name of the device driver, *echo*.

3. The echo device driver should be loaded. Use the **!devnode 0 1 echo** command to display Plug and Play information associated with our echo device driver as shown below.

```
0: Kd> !devnode 0 1 echo
Dumping IopRootDeviceNode (= 0xfffffe0007b725d30)
DevNode 0xfffffe0007b71a630 for PDO 0xfffffe0007b71a960
  InstancePath is "ROOT\SAMPLE\0000"
  ServiceName is "ECHO"
  State = DeviceNodeStarted (0x308)
  Previous State = DeviceNodeEnumerateCompletion (0x30d)
...
```

4. The output displayed in the previous command includes the PDO associated with the running instance of our driver, in this example it is *0xfffffe0007b71a960*. Enter the **!devobj< PDO address>** command to display Plug and Play information associated with the echo device driver. Use the PDO address that **!devnode** displays on your PC, not the one shown here.

```
0: kd> !devobj 0xfffffe0007b71a960
Device object (fffffe0007b71a960) is for:
  0000000e \Driver\NpManager DriverObject fffffe0007b727e60
  Current Irp 00000000 RefCount 0 Type 00000004 Flags 00001040
  Dacl fffffc102c9b36031 DevExt 00000000 DevObjExt fffffe0007b71aab0 DevNode fffffe0007b71a630
  ExtensionFlags (0x00000800) DOE_DEFAULT_SD_PRESENT
  Characteristics (0x00000180) FILE_AUTOGENERATED_DEVICE_NAME, FILE_DEVICE_SECURE_OPEN
  AttachedDevice (Upper) fffffe000801fee20 \Driver\ECHO
  Device queue is not busy.
```

5. The output displayed in the **!devnode 0 1** command includes the PDO address associated with the running instance of our driver, in this example it is *0xfffffe0007b71a960*. Enter the **!devstack< PDO address>** command to display Plug and Play information associated with the device driver. Use the PDO address that

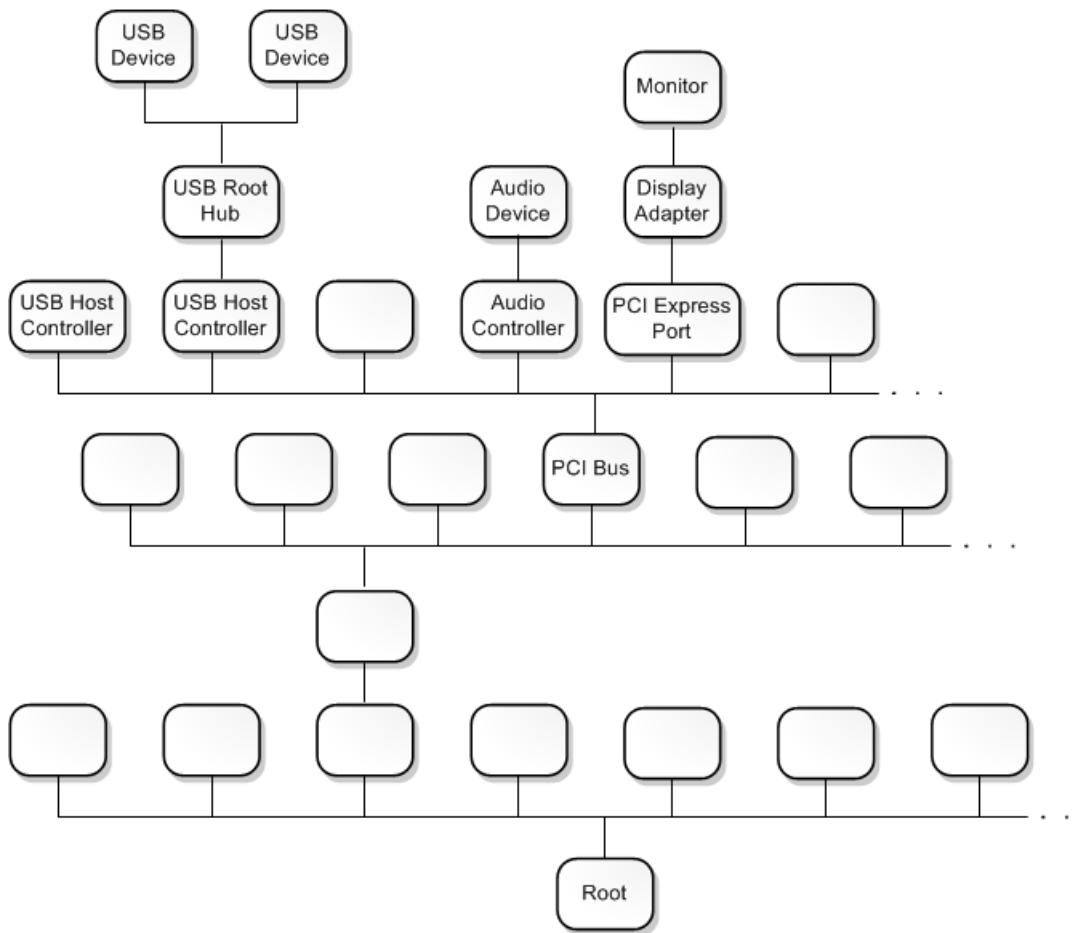

!devnode displays on your PC, not the one shown below.

```
0: kd> !devstack 0xfffffe0007b71a960
!DevObj          !DrvObj          !DevExt          ObjectName
fffffe000801fee20  \Driver\ECHO      fffffe0007f72eff0
> fffffe0007b71a960  \Driver\PnpManager 00000000  00000000
!DevNode fffffe0007b71a630 :
DeviceInst is "ROOT\SAMPLE\0000"
ServiceName is "ECHO"
```

The output shows that we have a fairly simple device driver stack. The echo driver is a child of the PnPManager node. The PnPManager is a root node.

```
\Driver\ECHO
\Driver\PnpManager
```

This diagram shows a more complex device node tree.

Note For more information about more complex driver stacks, see [Driver stacks](#) and [Device nodes and device stacks](#) on MSDN.

Section 7: Working with breakpoints and source code

In Section 7, you will set breakpoints and single step through kernel mode source code.

Note

Setting breakpoints using commands

To be able to step through code and check the values of variables in real time, we need to enable breakpoints and set a path to the source code.

Breakpoints are used to stop code execution at a particular line of code. You can then step forward in the code

from that point, to debug that specific section of code.

To set a breakpoint using a debug command, use one of the following **b** commands.

bp	Sets a breakpoint that will be active until the module it is in is unloaded.
bu	Sets a breakpoint that is unresolved when the module is unloaded and re-enables when the module reloads.
bm	Sets a breakpoint for a symbol. This command will use bu or bp appropriately and allows wildcards * to be used to set breakpoints on every symbols that matches (like all methods in a class).

For more information, see [Source Code Debugging in WinDbg](#) in the debugging reference documentation.

<-On the host system

1. Use the WinDbg UI to confirm that **Debug > Source Mode** is enabled in the current WinDbg session.
2. Add your local code location to the source path by typing the following command.

```
.srcpath+ C:\DriverSamples\KMDF_Echo_Sample\driver\AutoSync
```

3. Add your local symbol location to the symbol path by typing the following command.

```
.sympath+ C:\DriverSamples\KMDF_Echo_Sample\driver\AutoSync
```

4. We will use the **x** command to examine the symbols associated with the echo driver to determine the function name to use for the breakpoint. We can use a wild card or Ctrl+F to locate the **DeviceAdd** function name.

```
0: kd> x ECHO!EchoEvt*
8b4c7490      ECHO!EchoEvtIoQueueContextDestroy (void *)
8b4c7000      ECHO!EchoEvtDeviceSelfManagedIoStart (struct WDFDEVICE__ *)
8b4c7820      ECHO!EchoEvtTimerFunc (struct WDFTIMER__ *)
8b4cb0e0      ECHO!EchoEvtDeviceSelfManagedIoSuspend (struct WDFDEVICE__ *)
8b4c75d0      ECHO!EchoEvtIoWrite (struct WDFQUEUE__ *, struct WDFREQUEST__ *, unsigned int)
8b4cb170      ECHO!EchoEvtDeviceAdd (struct WDFDRIVER__ *, struct
...

```

The output above shows that **DeviceAdd** method for our echo driver is *ECHO!EchoEvtDeviceAdd*.

Alternatively, we could review the source code to locate the desired function name for our breakpoint.

5. Set the breakpoint with the **bm** command using the name of the driver, followed by the function name (for example **AddDevice**) where you want to set the breakpoint, separated by an exclamation mark. We will use **AddDevice** to watch the driver being loaded.

```
0: kd> bm ECHO!EchoEvtDeviceAdd
1: fffff801`0bf9b1c0 @"ECHO!EchoEvtDeviceAdd"
```

Note

You can use different syntax in conjunction with setting variables like <module>!<symbol>, <class>:<method>,'<file.cpp>:<line number>', or skip a number of times <condition> <#>. For more information, see [Conditional breakpoints in WinDbg and other Windows debuggers](#).

6. List the current breakpoints to confirm that the breakpoint was set by typing the **bl** command.

```
0: kd> bl
1 e fffff801`0bf9b1c0      0001 (0001) ECHO!EchoEvtDeviceAdd
```

The "e" in the output shown above indicates that the breakpoint number 1 is enabled to fire.

7. Restart code execution on the target system by typing the **go** command **g**.

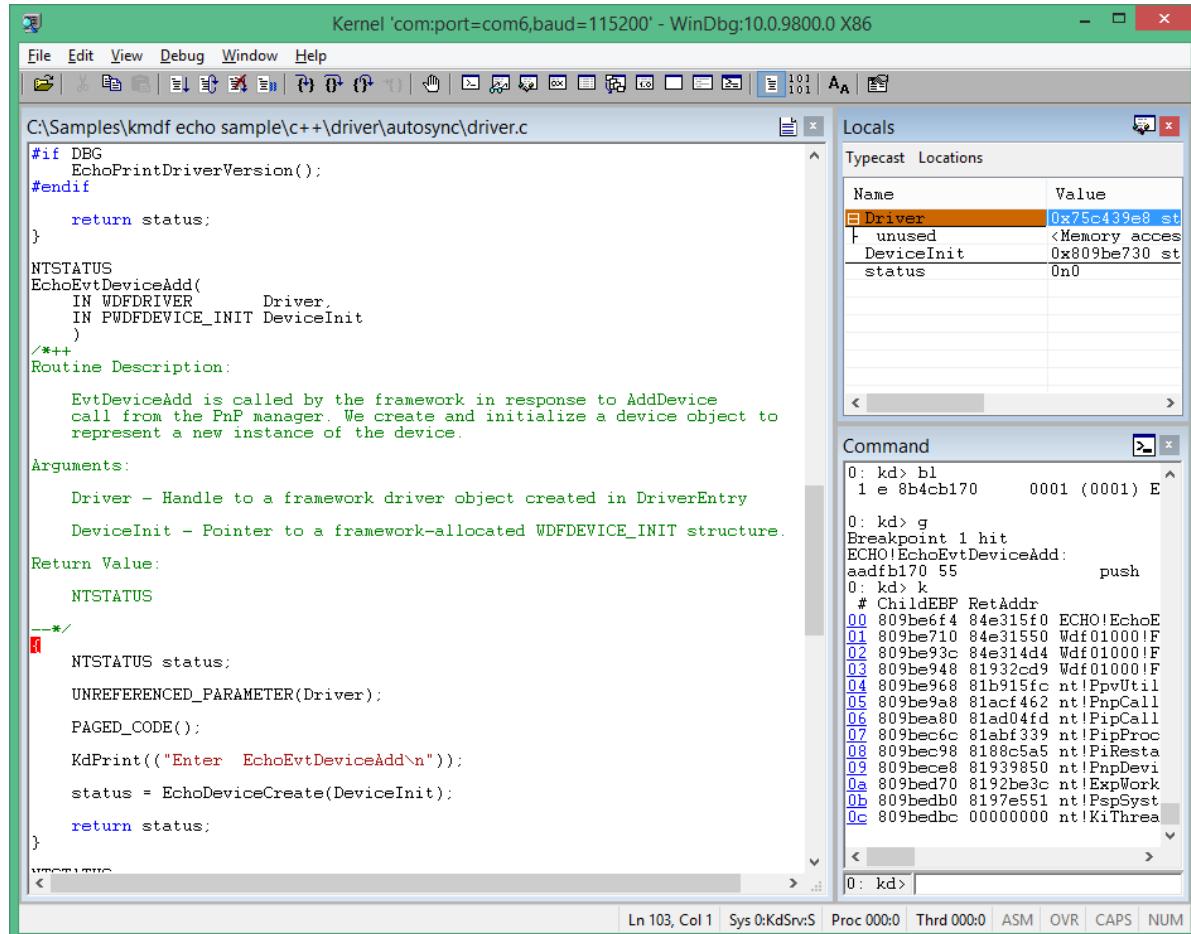

8. -> On the target system

In Windows, open **Device Manager** using the icon or by entering **mmc devmgmt.msc**. In Device Manager, expand the **Samples** node.

9. Right-click the KMDF Echo driver entry and select **Disable** from the menu.
10. Right-click the KMDF Echo driver entry again and select **Enable** from the menu.

11. <- On the host system

When the driver is enabled, the [AddDevice](#) debug breakpoint should fire, and the execution should halt. When the breakpoint is hit, the execution should be stopped at the start of the *AddDevice* routine. The debug command output will display "Breakpoint 1 hit".

12. Step through the code line-by-line by typing the **p** command or pressing F10 until you reach the following end of the [AddDevice](#) routine. The Brace character "}" will be highlighted as shown.

```

--*/
f NTSTATUS status;
UNREFERENCED_PARAMETER(Driver);
PAGED_CODE();
KdPrint(("Enter EchoEvtDeviceAdd\n"));
status = EchoDeviceCreate(DeviceInit);
return status;

```

13. In the next section, we will examine the state of the variables after the DeviceAdd code has executed.

Note

Modifying breakpoint state

You can modify existing breakpoints by using the following commands:

bl	Lists breakpoints.
bc	Clears a breakpoint from the list. Use bc * to clear all breakpoints.
bd	Disables a breakpoint. Use bd * to disable all breakpoints.
be	Enables a breakpoint. Use be * to enable all breakpoints.

Alternatively, you can also modify breakpoints by clicking **edit > breakpoints** in WinDbg. Note that the breakpoint dialog box only works with existing breakpoints. New breakpoints must be set from the command line.

Note

Setting memory access breakpoints

You can also set breakpoints that fire when a memory location is accessed. Use the **ba** (break on access) command, with the following syntax.

```
ba <access> <size> <address> {options}
```

OPTION	DESCRIPTION
e	execute (when CPU fetches an instruction from the address)
r	read/write (when CPU reads or writes to the address)
w	write (when the CPU writes to the address)

Note that you can only set four data breakpoints at any given time and it is up to you to make sure that you are aligning your data correctly or you won't trigger the breakpoint (words must end in addresses divisible by 2, dwords must be divisible by 4, and quadwords by 0 or 8).

For example, to set a read/write breakpoint on a specific memory address, you could use a command like this.

```
ba r 4 0x0003f7bf0
```

Note

Stepping through code from the Debugger Command window

The following are the commands that you can use to step through your code (with the associated keyboard short cuts shown in parentheses).

- Break in (Ctrl+Break) - This command will interrupt a system as long as the system is running and is in communication with WinDbg (the sequence in the Kernel Debugger is Ctrl+C).
- Run to cursor (F7 or Ctrl+F10) – Place the cursor in a source or disassembly window where you want the execution to break, then press F7; code execution will run to that point. Note that if the flow of code execution does not reach the point indicated by the cursor (an IF statement isn't executed), WinDbg would not break, because the code execution did not reach the indicated point.
- Run (F5) – Run until a breakpoint is encountered or an event like a bug check occurs.
- Step over (F10) – This command causes code execution to proceed one statement or one instruction at a time. If a call is encountered, code execution passes over the call without entering the called routine. (If the programming language is C or C++ and WinDbg is in source mode, source mode can be turned on or off using **Debug>Source Mode**).
- Step in (F11) – This command is like step-over, except that the execution of a call does go into the called routine.
- Step out (Shift+F11) – This command causes execution to run to and exit from the current routine (current place in the call stack). This is useful if you've seen enough of the routine.

For more information, see [Source Code Debugging in WinDbg](#) in the debugging reference documentation.

Section 8: Viewing variables and call stacks

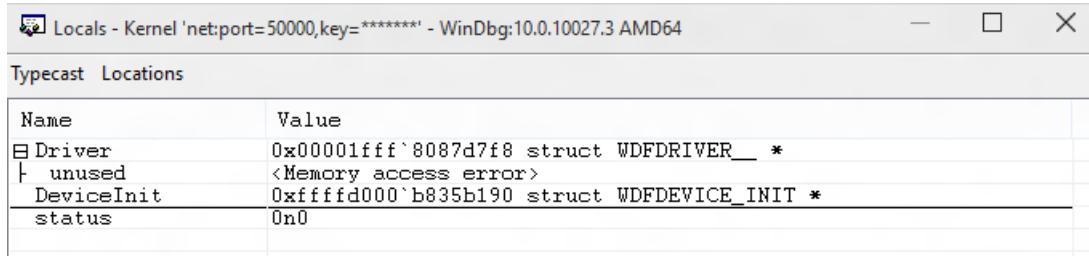

In Section 8, you will display information about variables and call stacks.

This lab assumes that you are stopped at the [AddDevice](#) routine using the process described earlier. To view the output shown here, repeat the steps described previously, if necessary.

<- On the host system

Display variables

Use the **view > local** menu item to display local variables.

Global variables

You can find the location of a global variable address by typing `? <variable name>`.

Local variables

You can display the names and values of all local variables for a given frame by typing the **dv** command.

```
0: kd> dv
    Driver = 0x00001fff`7ff9c838
    DeviceInit = 0xfffffd001`51978190
    status = 0n0
```

Callstacks

Note

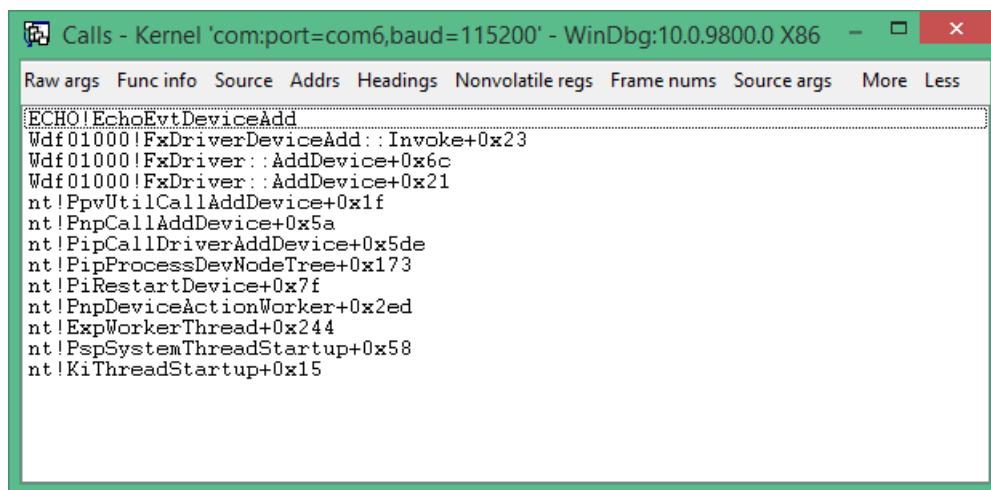

The call stack is the chain of function calls that have led to the current location of the program counter. The top function on the call stack is the current function, and the next function is the function that called the current function, and so on.

To display the call stack, use the k* commands.

kb	Displays the stack and first three parameters.
kp	Displays the stacks and the full list of parameters.
kn	Allows you to see the stack with the frame information next to it.

<-On the host system

1. If you want to keep the call stack available, you can click **view** > **call stack** to view it. Click on the columns at the top of the window to toggle the display of additional information.

```
ECHO!EchoEvtDeviceAdd
Wdf01000!FxDriverDeviceAdd::Invoke+0x23
Wdf01000!FxDriver::AddDevice+0x6c
Wdf01000!FxDriver::AddDevice+0x21
nt!PpvUtilCallAddDevice+0x1f
nt!PnpCallAddDevice+0x5a
nt!PipCallDriverAddDevice+0x5de
nt!PipProcessDevNodeTree+0x173
nt!P!RestartDevice+0x7f
nt!PnpDeviceActionWorker+0x2ed
nt!ExpWorkerThread+0x244
nt!PspSystemThreadStartup+0x58
nt!KiThreadStartup+0x15
```

1. Use the **kn** command to show the call stack while debugging the sample adapter code in a break state.

```

3: kd> kn
# Child-SP          RetAddr          Call Site
00 fffffd001`51978110 fffff801`0942f55b ECHO!EchoEvtDeviceAdd+0x66 [c:\Samples\kmdf echo
sample\c++\driver\autosync\driver.c @ 138]
01 (Inline Function) -----`----- Wdf01000!FxDriverDeviceAdd::Invoke+0x30
[d:\wbrtm\minkernel\wdf\framework\shared\inc\private\common\fxdrivercallbacks.hpp @ 61]
02 fffffd001`51978150 fffff801`eed8097d Wdf01000!FxDriver::AddDevice+0xab
[d:\wbrtm\minkernel\wdf\framework\shared\core\km\fxdriverkm.cpp @ 72]
03 fffffd001`51978570 fffff801`ef129423 nt!PpvUtilCallAddDevice+0x35
[d:\9142\minkernel\ntos\io\pnpmgr\verifier.c @ 104]
04 fffffd001`519785b0 fffff801`ef0c4112 nt!PnpCallAddDevice+0x63 [d:\9142\minkernel\ntos\io\pnpmgr\enum.c @
7397]
05 fffffd001`51978630 fffff801`ef0c344f nt!PipCallDriverAddDevice+0x6e2
[d:\9142\minkernel\ntos\io\pnpmgr\enum.c @ 3390]
...

```

The call stack shows that the kernel (nt) called into Plug and Play code (PnP), that called driver framework code (WDF) that subsequently called the echo driver **DeviceAdd** function.

Section 9: Displaying processes and threads

Processes

In Section 9, you will display information about the process and threads running in kernel mode.

Note

You can display or set process information by using the **!process** debugger extension. We will set a breakpoint to examine the process that are used when a sound is played.

1. <- On the host system

Type the **dv** command to examine the locale variables associated with the **EchoEvtIo** routine as shown.

```

0: kd> dv ECHO!EchoEvtIo*
ECHO!EchoEvtIoQueueContextDestroy
ECHO!EchoEvtIoWrite
ECHO!EchoEvtIoRead

```

2. Clear the previous breakpoints using **bc ***.

```

0: kd> bc *

```

3. a. Set a symbol breakpoint on the **EchoEvtIo** routines using the following command.

```

0: kd> bm ECHO!EchoEvtIo*
2: aade5490      @"!ECHO!EchoEvtIoQueueContextDestroy"
3: aade55d0      @"!ECHO!EchoEvtIoWrite"
4: aade54c0      @"!ECHO!EchoEvtIoRead"

```

4. List the breakpoints to confirm that the breakpoint is set properly.

```

0: kd> bl
1 e aabf0490 [c:\Samples\kmdf echo sample\c++\driver\autosync\queue.c @ 197] 0001 (0001)
ECHO!EchoEvtIoQueueContextDestroy
...

```

5. Type **g** to restart code execution.

```
0: kd> g
```

6. -> On the target system

Run the EchoApp.exe driver test program on the target system.

7. <- On the host system

When the test app runs, the I/O routine in the driver will be called. This will cause the breakpoint to fire, and execution of the driver code on the target system will halt.

```
Breakpoint 2 hit
ECHO!EchoEvtIoWrite:
fffff801`0bf95810 4c89442418      mov     qword ptr [rsp+18h],r8
```

8. Use the **!process** command to display the current process that is involved in running echoapp.exe.

```
0: kd> !process
PROCESS fffffe0007e6a7780
  SessionId: 1 Cid: 03c4 Peb: 7ff7cfec4000 ParentCid: 0f34

  THREAD fffffe00080e32080 Cid 03c4.0ec0 Peb: 00007ff7cfce000 Win32Thread: 0000000000000000
  RUNNING on processor 1
```

The output shows that the process is associated with the echoapp.exe which was running when our breakpoint on the driver write event was hit. For more information, see [!process](#).

9. Use the **!process 0 0** to display summary information for all processes. In the output, use CTRL+F to locate the same process address for the process associated with the echoapp.exe image. In the example shown below, the process address is fffffe0007e6a7780.

```
...
PROCESS fffffe0007e6a7780
  SessionId: 1 Cid: 0f68 Peb: 7ff7cf7a000 ParentCid: 0f34
  DirBase: 1f7fb9000 ObjectTable: fffffc001cec82780 HandleCount: 34.
  Image: echoapp.exe
...
```

10. Record the process ID associated with echoapp.exe to use later in this lab. You can also use CTRL+C, to copy

the address to the copy buffer for later use.

_____ (echoapp.exe process address)

11. Enter **g** as required into the debugger to run the code forward until the echoapp.exe finishes running. It will hit the breakpoint in the read and write event a number of times. When echoapp.exe finishes, break in to the debugger, by pressing CTRL+ScrLk (Ctrl+Break).
12. Use the **!process** command to confirm that you are now running a different process. In the output shown below, the process with the Image value of *System* is different from the *Echo* Image value.

```
1: kd> !process
PROCESS fffffe0007b65d900
  SessionId: none Cid: 0004 Peb: 00000000 ParentCid: 0000
  DirBase: 001ab000 ObjectTable: fffffc001c9a03000 HandleCount: 786.
  Image: System
  VadRoot fffffe0007ce45930 Vads 14 Clone 0 Private 22. Modified 131605. Locked 64.
  DeviceMap fffffc001c9a0c220
  Token fffffc001c9a05530
  ElapsedTime 21:31:02.516
  ...
...
```

The output above shows that a system process fffffe0007b65d900 was running, when we stopped the OS.

13. Now, use the **!process** command to try to look at the process ID that had been associated with echoapp.exe that you recorded earlier. Provide your echoapp.exe process address that you recorded earlier, instead of the example process address shown below.

```
0: kd> !process fffffe0007e6a7780
TYPE mismatch for process object at 82a9acc0
```

The process object is now longer available, as the echoapp.exe process is no longer running.

Threads

Note

The commands to view and set threads are very similar to those of processes. Use the **!thread** command to view threads. Use **.thread** to set the current threads.

1. <- On the host system

Enter **g** into the debugger to restart code execution on the target system.

2. -> On the target system

Run the EchoApp.exe driver test program on the target system.

3. <- On the host system

The breakpoint will be hit and code execution will halt.

```
Breakpoint 4 hit
ECHO!EchoEvtIoRead:
aade54c0 55          push    ebp
```

4. To view the threads that are running, type **!thread**. Information similar to the following should be displayed:

```
0: kd> !thread
THREAD fffffe000809a0880 Cid 0b28.1158 Peb: 00007ff7d00dd000 Win32Thread: 0000000000000000 RUNNING on
processor 0
IRP List:
fffffe0007bc5be10: (0006,01f0) Flags: 00060a30 Mdl: 00000000
Not impersonating
DeviceMap fffffc001d83c6e80
Owning Process fffffe0008096c900 Image: echoapp.exe
...
```

Note the image name of *echoapp.exe*, indicating that we are looking at the thread associated with the test app.

5. a. Use the **!process** command to determine if this is the only thread running in the process associated with *echoapp.exe*. Note that the thread number of the running thread in the process is the same thread running that the **!thread** command displayed.

```
0: kd> !process
PROCESS fffffe0008096c900

```

Call stack elements such as **KiCommitThreadWait** indicate that this thread is not running as is expected.

Note

For more information about threads and processes, see the following references on MSDN:

[Threads and Processes](#)

[Changing Contexts](#)

Section 10: IRQL, Registers and Ending the WinDbg session

Viewing the saved IRQL

In Section 10, you will display the IRQL, and the contents of the registers.

<- On the host system

The interrupt request level (IRQL) is used to manage the priority of interrupt servicing. Each processor has an IRQL setting that threads can raise or lower. Interrupts that occur at or below the processor's IRQL setting are masked and will not interfere with the current operation. Interrupts that occur above the processor's IRQL setting take precedence over the current operation. The **!irql** extension displays the interrupt request level (IRQL) on the current processor of the target computer before the debugger break occurred. When the target computer breaks into the debugger, the IRQL changes, but the IRQL that was effective just before the debugger break is saved and is displayed by **!irql**.

```
0: kd> !irql
Debugger saved IRQL for processor 0x0 -- 2 (DISPATCH_LEVEL)
```

Viewing the registers

<-On the host system

Display the contents of the registers for the current thread on the current processor by using the **r (Registers)** command.

```
0: kd> r
rax=000000000000c301 rbx=fffffe00173eed880 rcx=0000000000000001
rdx=000000d800000000 rsi=fffffe00173eed8e0 rdi=fffffe00173eed8f0
rip=fffff803bb757020 rsp=fffffd001f01f8988 rbp=fffffe00173f0b620
r8=000000000000003e r9=fffffe00167a4a000 r10=000000000000001e
r11=fffffd001f01f88f8 r12=0000000000000000 r13=fffffd001f01efdc0
r14=0000000000000001 r15=0000000000000000
iopl=0 nv up ei pl nz na pe nc
cs=0010 ss=0018 ds=002b es=002b fs=0053 gs=002b
nt!DbgBreakPointWithStatus:
fffff803`bb757020 cc int 3
```

Alternatively, you can display the contents of the registers by clicking **view > registers**. For more information see **r (Registers)**.

Viewing the contents of the registers can be helpful when stepping through assembly language code execution and in other scenarios. For more information about assembly language disassembly, see [Annotated x86 Disassembly](#) and [Annotated x64 Disassembly](#).

For information about contents of the register, see [x86 Architecture](#) and [x64 Architecture](#).

Ending the WinDbg session

<-On the host system

To end a user-mode debugging session, return the debugger to dormant mode, and set the target application to run again, enter the **qd** (Quit and Detach) command.

Be sure and use the **g** command to let the target computer run code, so that it can be used. It also a good idea to clear any break points using **bc ***, so that the target computer won't break and try to connect to the host computer debugger.

```
0: kd> qd
```

For more information, see [Ending a Debugging Session in WinDbg](#) in the debugging reference documentation.

Section 11: Windows debugging resources

Additional information is available on Windows debugging. Note that some of these books will use older versions

of Windows such as Windows Vista in their examples, but the concepts discussed are applicable to most versions of Windows.

Debug Drivers - Step by Step Lab (Sysvad Kernel Mode)

5/31/2017 • 55 min to read • [Edit Online](#)

This lab provides hands-on exercises that demonstrate how to debug the Sysvad audio kernel-mode device driver.

Microsoft Windows Debugger (WinDbg) is a powerful Windows-based debugging tool that you can use to perform user-mode and kernel-mode debugging. WinDbg provides source-level debugging for the Windows kernel, kernel-mode drivers, and system services, as well as user-mode applications and drivers.

WinDbg can step through source code, set breakpoints, view variables (including C++ objects), stack traces, and memory. Its Debugger Command window allows the user to issue a wide variety of commands.

Lab setup

You will need the following hardware to be able to complete the lab:

- A laptop or desktop computer (host) running Windows 10
- A laptop or desktop computer (target) running Windows 10
- A network cross-over cable, or a network hub and network cables to connect the two PCs
- Access to the internet to download symbol files

You will need the following software to be able to complete the lab.

- Microsoft Visual Studio 2015
- Windows Software Development Kit (SDK) for Windows 10
- Windows Driver Kit (WDK) for Windows 10
- The sample Sysvad audio driver for Windows 10

For information on downloading and installing the WDK, see [Download the Windows Driver Kit \(WDK\)](#)

Sysvad debugging walkthrough

This lab walk you through the process of debugging a kernel-mode driver. The exercises use the Syvad virtual audio driver sample. Because the Syvad audio driver doesn't interact with actual audio hardware, it can be used on most devices. The lab covers the following tasks:

- [Section 1: Connect to a kernel-mode WinDbg session](#)
- [Section 2: kernel-mode debugging commands and techniques](#)
- [Section 3: Download and build the Sysvad audio driver](#)
- [Section 4: Install the Sysvad audio driver on the target system](#)
- [Section 5: Use WinDbg to display information about the driver](#)
- [Section 6: Display Plug and Play device tree information](#)
- [Section 7: Work with breakpoints and source code](#)
- [Section 8: Look at variables](#)
- [Section 9: View call stacks](#)
- [Section 10: Display processes and threads](#)
- [Section 11: IRQL, registers and disassembly](#)
- [Section 12: Work with memory](#)

- [Section 13: Ending the WinDbg session](#)
- [Section 14: Windows debugging resources](#)

Echo driver lab

The Echo driver is a simpler driver than the Sysvad audio driver. If you are new to WinDbg, you may want to consider first completing the [Debug Universal Drivers - Step-by-Step Lab \(Echo kernel mode\)](#). This lab reuses the setup directions from that lab, so if you have completed that lab you can skip sections 1 and 2 here.

Section 1: Connect to a kernel-mode WinDbg session

In Section 1, you will configure network debugging on the host and target system.

The PCs in this lab need to be configured to use an Ethernet network connection for kernel debugging.

This lab uses two computers. WinDbg runs on the *host* system and the Sysvad driver runs on the *target* system.

The "<-Host" on the left is connected using a cross over ethernet cable to the "->Target" on the right.

The steps in the lab assume that you are using a cross over network cable, but the lab should also work if you can plug both the host and the target directly into a network hub.

To work with kernel-mode applications and use WinDbg, we recommend that you use the KDNET over Ethernet transport. For information about how to use the Ethernet transport protocol, see [Getting Started with WinDbg \(Kernel-Mode\)](#). For more information about setting up the target computer, see [Preparing a Computer for Manual Driver Deployment](#) and [Setting Up Kernel-Mode Debugging over a Network Cable Manually](#).

Configure kernel-mode debugging using a crossover ethernet cable

To enable kernel-mode debugging on the target system, perform the following steps.

<- On the host system

1. Open a command prompt on the host system and type **ipconfig /all** to determine its IP address.

```
C:\>ipconfig /all
Windows IP Configuration

Host Name . . . . . : TARGETPC
. . .

Ethernet adapter Ethernet:
  Connection-specific DNS Suffix . :
  Link-local IPv6 Address . . . . . : fe80::c8b6:db13:d1e8:b13b3
  Autoconfiguration IPv4 Address. . . : 169.182.1.1
  Subnet Mask . . . . . : 255.255.0.0
  Default Gateway . . . . . :
```

1. Record the IP address of the host System: _____

2. Record the Host Name of the host System: _____

-> On the target system

1. Open a command prompt on the target system and use the **ping** command to confirm network connectivity

between the two systems. Use the IP address of the host system you recorded instead of the one shown in the sample output.

```
C:\> ping 169.182.1.1

Pinging 169.182.1.1 with 32 bytes of data:
Reply from 169.182.1.1: bytes=32 time=1ms TTL=255
Reply from 169.182.1.1: bytes=32 time<1ms TTL=255
Reply from 169.182.1.1: bytes=32 time<1ms TTL=255
Reply from 169.182.1.1: bytes=32 time<1ms TTL=255

Ping statistics for 169.182.1.1:
    Packets: Sent = 4, Received = 4, Lost = 0 (0% loss),
    Approximate round trip times in milli-seconds:
        Minimum = 0ms, Maximum = 1ms, Average = 0ms
```

To use the KDNET utility to enable kernel-mode debugging on the target system, perform the following steps.

1. On the host system, locate the WDK KDNET directory. By default it is located here.

```
C:\Program Files (x86)\Windows Kits\10\
```

1. Locate these two files and copy them to a network share or thumb drive, so that they will be available on the target computer.

```
kdnet.exe
VerifiedNICList.xml
```

1. On the target computer, open a Command Prompt window as Administrator. Enter this command to validate that the NIC on the target PC is supported.

```
C:\KDNET>kdnet

Network debugging is supported on the following NICs:
busparams=0.25.0, Intel(R) 82579LM Gigabit Network Connection, KDNET is running on this NIC.kdnet.exe
```

1. Type this command to set the IP address of the host system. Use the IP address of the host system that you recorded earlier, not the one shown. Pick a unique port address for each target/host pair that you work with, such as 50010.

```
C:\>kdnet TARGETPC 50010

NtQuerySystemInformation cannot query SystemKernelDebuggingAllowed on this OS.
Enabling network debugging on Intel(R) 82577LM Gigabit Network Connection.
Key=2steg4fzbj2sz.23418vzkd4ko3.1g34ou07z4pev.1sp3yo9yz874p
```

1. Type this command to confirm that the dbgsettings are set properly.

```
C:\> bcdedit /dbgsettings
busparams          0.25.0
key                2steg4fzbj2sz.23418vzkd4ko3.1g34ou07z4pev.1sp3yo9yz874p
debugtype          NET
hostip             169.182.1.1
port               50010
dhcp               Yes
The operation completed successfully.
```

Copy the auto generated unique key into a text file, to avoid having to type it in on the host PC. Copy the text file with the key over to the host system. **Note**

Firewalls and debuggers

If you receive a pop-up message from the firewall, and you wish to use the debugger, unblock the types of networks that you desire.

<- On the host system

1. On the host computer, open a Command Prompt window as Administrator. Change to the WinDbg.exe directory. We will use the x64version of WinDbg.exe from the Windows Driver Kit (WDK) that was installed as part of the Windows kit installation.

```
C:\> Cd C:\Program Files (x86)\Windows Kits\10\Debuggers\x64
```

1. Launch WinDbg with remote user debug using the following command. The value for the key and port match what you set earlier using BCDEdit on the target.

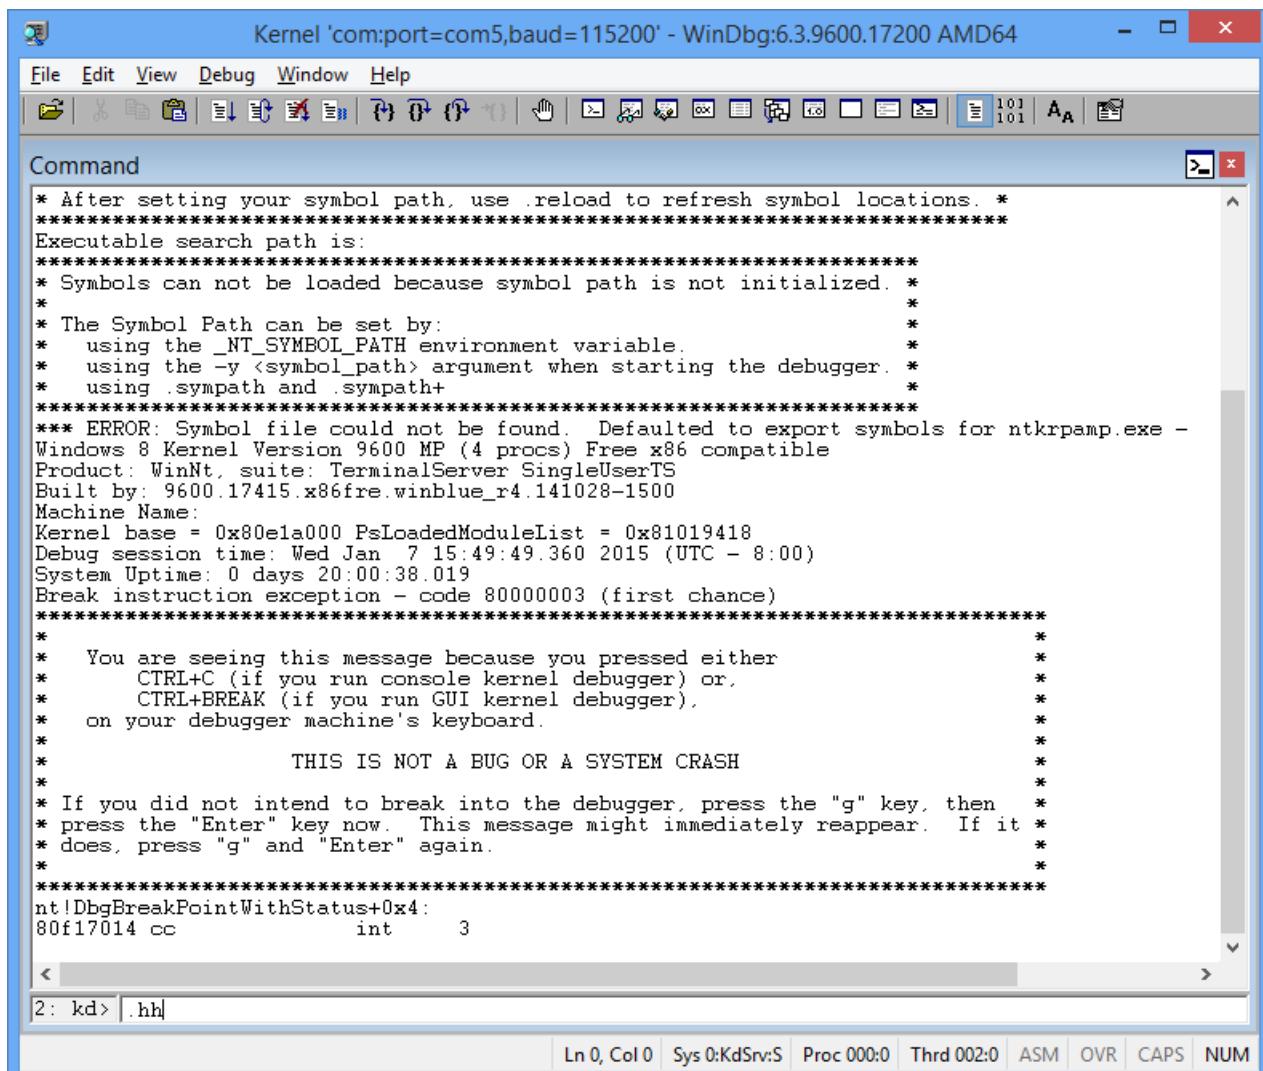

```
C:\> WinDbg -k net:port=50010,key=2steg4fzbj2sz.23418vzkd4ko3.1g34ou07z4pev.1sp3yo9yz874p
```

->On the target system

Reboot the target system.

<-On the host system

In a minute or two, debug output should be displayed on the host system.

```

```

The Debugger Command window is the primary debugging information window in WinDbg. You can enter debugger commands and view the command output in this window.

The Debugger Command window is split into two panes. You type commands in the smaller pane (the command entry pane) at the bottom of the window and view the command output in the larger pane at the top of the window.

In the command entry pane, use the up arrow and down arrow keys to scroll through the command history. When a command appears, you can edit it or press **ENTER** to run the command.

Section 2: kernel-mode debugging commands and techniques

In Section 2, you will use debug commands to display information about the target system.

<- On the host system

Enable Debugger Markup Language (DML) with .prefer_dml

Some debug commands display text using Debugger Markup Language that you can click on to quickly gather more information.

1. Use Ctrl+Break (Scroll Lock) in WinDbg to break into the code running on the target system. It may take a bit of time for the target system to respond.
2. Type the following command to enable DML in the Debugger Command window.

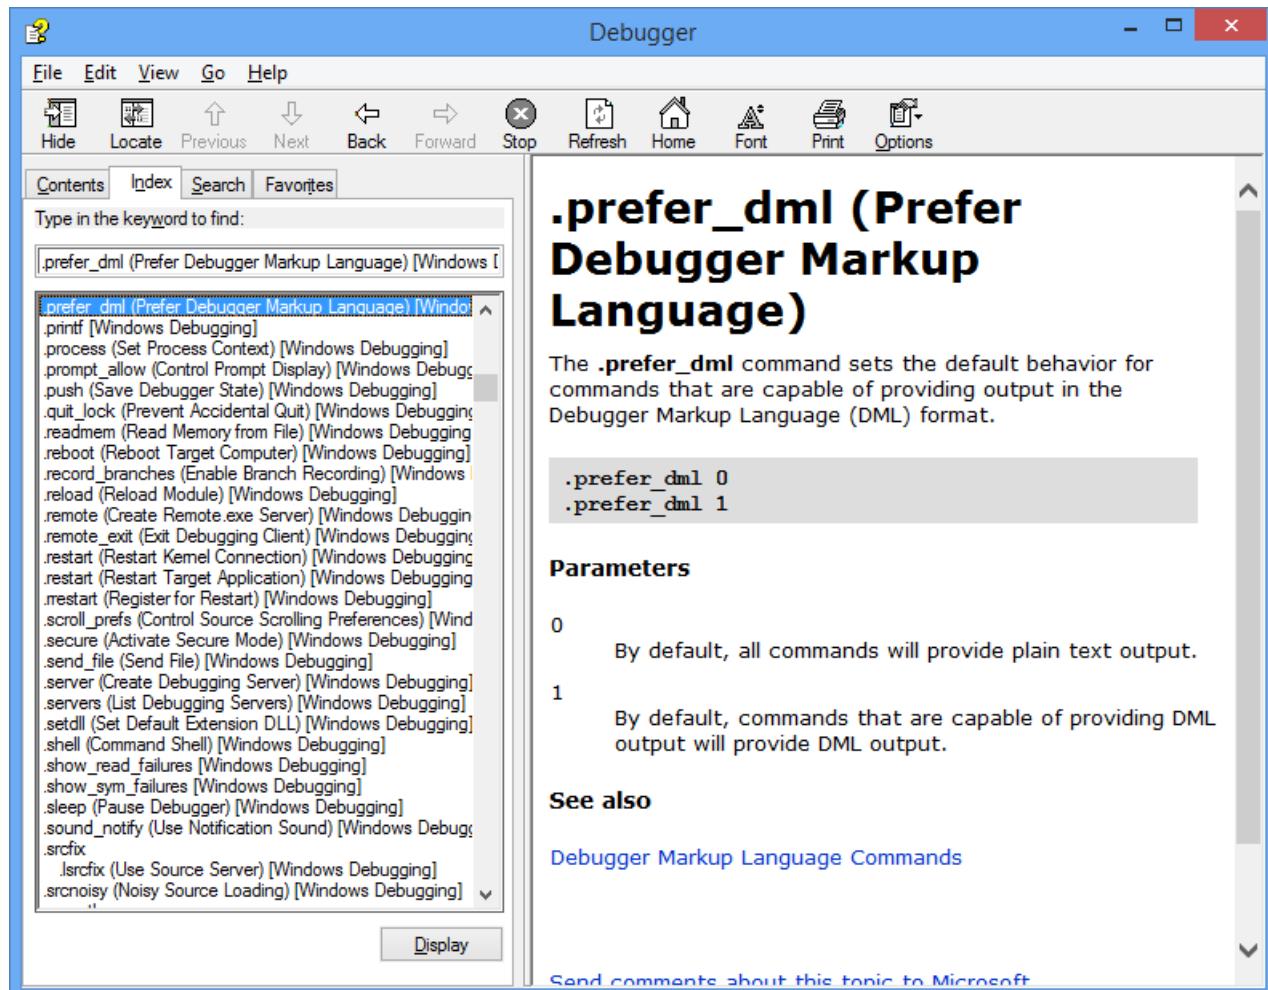

```
0: kd> .prefer_dml 1
DML versions of commands on by default
```

Use .hh to get help

You can access reference command help using the **.hh** command.

1. Type the following command to view the command reference help for **.prefer_dml**. `0: kd> .hh .prefer_dml`

The Debugger help file will display help for the **.prefer_dml** command.

Display the version of Windows on the target system

1. Display detailed version information on the target system by typing the **vertarget (Show Target Computer Version)** command in the WinDbg window.

```
0: kd> vertarget

```

List the loaded modules

1. You can verify that you are working with the right kernel-mode process by displaying the loaded modules by typing the **lm (List Loaded Modules)** command in the WinDbg window.

```

0: Kd> lm
start           end             module name
fffff801`09200000 fffff801`0925f000  volmgrx    (no symbols)
fffff801`09261000 fffff801`092de000  mcupdate_GenuineIntel (no symbols)
fffff801`092de000 fffff801`092ec000  werkernel   (export symbols)      werkernel.sys
fffff801`092ec000 fffff801`0934d000  CLFS        (export symbols)      CLFS.SYS
fffff801`0934d000 fffff801`0936f000  tm          (export symbols)      tm.sys
fffff801`0936f000 fffff801`09384000  PSCHED     (export symbols)      PSCHED.dll
fffff801`09384000 fffff801`0938e000  BOOTVID    (export symbols)      BOOTVID.dll
fffff801`0938e000 fffff801`093f7000  spaceport   (no symbols)
fffff801`09400000 fffff801`094cf000  Wdf01000   (no symbols)
fffff801`094d9000 fffff801`09561000  CI          (export symbols)      CI.dll
...

```

Note Output that has been omitted is indicated with "..." in this lab.

Because we have yet to set the symbol path and loaded symbols, limited information is available in the debugger.

Section 3: Download and build the Sysvad audio driver

In Section 3, you will download and build the Sysvad audio driver.

Typically, you would be working with your own driver code when you use WinDbg. To become familiar with debugging audio drivers, the Sysvad virtual audio sample driver is used. This sample is used to illustrate how you can single step through native kernel-mode code. This technique can be very valuable for debugging complex kernel-mode code issues.

To download and build the Sysvad sample audio driver, perform the following steps.

1. Download and extract the Sysvad audio sample from GitHub

You can use a browser to view the Sysvad sample and Readme.md file here:

<https://github.com/Microsoft/Windows-driver-samples/tree/master/audio/syvad>

This repo contains driver samples prepared for use with Microsoft Visual Studio and the Windows Driver Kit (WDK). It contains both Universal Windows Driver and desktop-only driver samples.

Branch: master	New pull request	Create new file	Upload files	Find file	Clone or download
wm1 committed on GitHub Merge pull request #125 from girishpattabiraman/master	Temporarily removing this code for rearchitecture	Clone with HTTPS	Use SSH		
audio/syvad	Ignoring specific linker warnings for RS1 and RS2	https://github.com/Microsoft/Windows-driver-samples			
avstream	Merge pull request #118 from saredd/master	Open in Desktop	Download ZIP		
biometrics	Updated for "Windows 10 Anniversary Update" (Version 1607)		8 months ago		
bluetooth	Updated for "Windows 10 Anniversary Update" (Version 1607)		8 months ago		
filesys	Fix build failures		29 days ago		
general	Fix build failures		29 days ago		

This lab, shows how to download the universal driver samples in one zip file.

a. Download the master.zip file to your local hard drive.

<https://github.com/Microsoft/Windows-driver-samples/archive/master.zip>

b. Right-click **Windows-driver-samples-master.zip**, and choose **Extract All**. Specify a new folder, or browse to an existing one that will store the extracted files. For example, you could specify **C:\WDK_Samples** as the new folder into which the files are extracted.

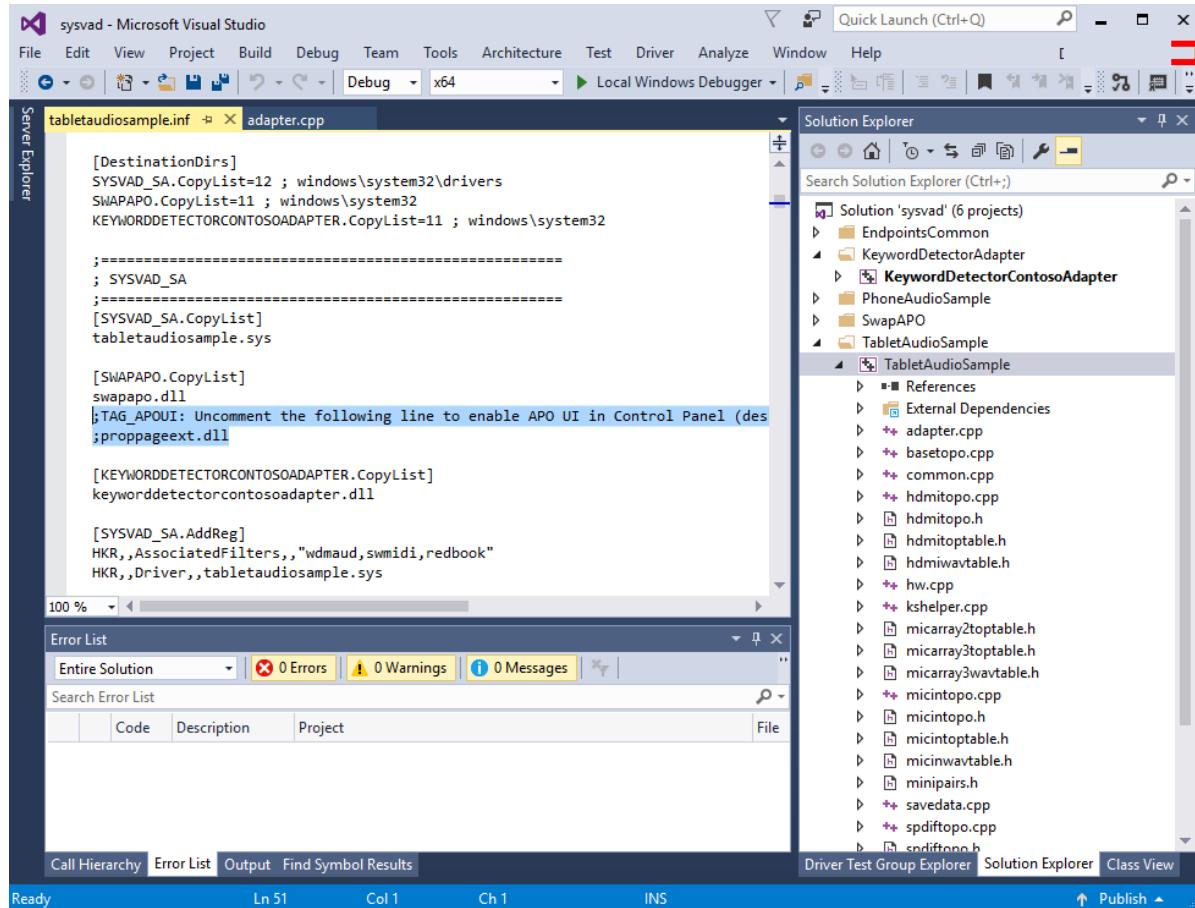

c. After the files are extracted, navigate to the following subfolder.

C:\WDK_Samples\Sysvad

2. Open the driver solution in Visual Studio

In Visual Studio, click **File > Open > Project/Solution...** and navigate to the folder that contains the extracted files (for example, **C:\WDK_Samples\Sysvad**). Double-click the **Syvad** solution file.

In Visual Studio locate the Solution Explorer. (If this is not already open, choose **Solution Explorer** from the **View** menu.) In Solution Explorer, you can see one solution that has four (4) projects. Note that the project titled **SwapAPO** is actually a folder that contains two projects - **APO** and **PropPageExtensions**.

3. Set the sample's configuration and platform

In Solution Explorer, right-click **Solution 'sysvad' (6 projects)**, and choose **Configuration Manager**.

Make sure that the configuration and platform settings are the same for the four projects. By default, the configuration is set to "Win10 Debug", and the platform is set to "Win64" for all the projects. If you make any configuration and/or platform changes for one project, you must make the same changes for the remaining three projects.

Note This lab assumes that 64 bit Windows is being used. If you are using 32 bit Windows, build the driver for 32 bit.

4. Check driver signing

Locate the **TabletAudioSample**. Open the **Sysvad** driver's property page and make sure **Driver Signing > Sign Mode** is set to *Test Sign*.

5. Build the sample using Visual Studio

In Visual Studio, click **Build > Build Solution**.

The build windows should display a message indicating that the build for all six projects succeeded.

6. Locate the built driver files

In File Explorer, navigate to the folder that contains the extracted files for the sample. For example, you would navigate to `C:\WDK_Samples\Sysvad`, if that's the folder you specified earlier. Within that folder, the location of the compiled driver files varies depending on the configuration and platform settings that you selected in the **Configuration Manager**. For example, if you left the default settings unchanged, then the compiled driver files will be saved to a folder named `\x64\Debug` for a 64-bit, debug build.

Navigate to the folder that contains the built files for the `TabletAudioSample` driver:

`C:\WDK_Samples\Sysvad\TabletAudioSample\x64\Debug`. The folder will contain the `TabletAudioSample.SYS` driver, symbol `pdb` file and the `inf` file. You will also need to locate the `SwapAPO`, `PropPageExt` and `KeywordDetectorContosoAdapter` dlls and symbol files.

To install the driver, you will need the following files.

TabletAudioSample.sys	The driver file.
TabletAudioSample.pdb	The driver symbol file.
tabletaudiosample.inf	An information (INF) file that contains information needed to install the driver.
KeywordDetectorContosoAdapter.dll	A sample keyword detector.
KeywordDetectorContosoAdapter.pdb	The sample keyword detector symbol file.
ISwapAPO.dll	A sample driver extension for a UI to manage APOs.
ISwapAPO.pdb	The APO UI symbol file.
PropPageExt.dll	A sample driver extension for a property page.
PropPageExt.pdb	The property page symbol file.
TabletAudioSample.cer	The <code>TabletAudioSample</code> certificate file.

7. Locate a USB thumb drive or set up a network share to copy the built driver files from the host to the target system.

In the next section, you will copy the code to the target system, and install and test the driver.

Section 4: Install the Sysvad audio driver sample on the target system

In Section 4, you will use devcon to install the Sysvad audio driver.

-> On the target system

The computer where you install the driver is called the *target computer* or the *test computer*. Typically, this is a separate computer from the computer on which you develop and build the driver package. The computer where

you develop and build the driver is called the *host computer*.

The process of moving the driver package to the target computer and installing the driver is called *deploying* the driver. You can deploy the sample Sysvad driver, automatically or manually.

Before you manually deploy a driver, you must prepare the target computer by turning on test signing. You also need to locate the DevCon tool in your WDK installation. After that you're ready to run the built driver sample on the target system.

To install the driver on the target system, perform the following steps.

1. **Enable test signed drivers**

To enable the ability to run test signed drivers:

- a. Open Windows Settings.
- b. In **Update and Security**, select **Recovery**.
- c. Under **Advanced startup**, click **Restart Now**.
- d. When the PC restarts, select **Troubleshoot**.
- e. Then select **Advanced options**, **Startup Settings** and then click **Restart**.
- f. Select Disable driver signature enforcement by pressing the **F7** key.
- g. The PC will start with the new values in place.

2. <- On the host system

Navigate to the Tools folder in your WDK installation and locate the DevCon tool. For example, look in the following folder:

C:\Program Files (x86)\Windows Kits\10\Tools\x64\devcon.exe

3. -> On the target system

Install the driver

The following instructions show you how to install and test the sample driver.

The INF file required for installing this driver is *TabletAudioSample.inf*. On the target computer, open a Command Prompt window as Administrator. Navigate to your driver package folder, right-click the *TabletAudioSample.inf* file, and then select **Install**.

A dialog box will appear indicating that the test driver is an unsigned driver. Click **Install this driver anyway** to proceed.

[!TIP] If you have any issues with the installation, check the following file for more information.

%windir%\inf\setupapi.dev.log

For more detailed instructions, see [Configuring a Computer for Driver Deployment, Testing, and Debugging](#).

The INF file contains the hardware ID for installing the *tabletaudiosample.sys*. For the Sysvad sample, the hardware ID is: `root\\sysvad_TabletAudioSample`

On the target computer, open a Command Prompt window as Administrator. Navigate to your driver package folder, and enter the following command: `devcon status root\\sysvad_TabletAudioSample`

Status information is displayed during the devcon install.

1. Examine the driver in Device Manager

On the target computer, in a Command Prompt window, enter **devmgmt** to open Device Manager. In Device Manager, on the View menu, select **Devices by type**.

In the device tree, locate *Virtual Audio Device (WDM) - Tablet Sample* in the Audio Device node. This is typically under the **Sound, video and game controllers** node. Confirm that it is installed and active.

Highlight the driver for the actual hardware on the PC in Device Manager. Then right-click the driver and click disable to disable the driver.

Confirm in Device Manager that audio hardware driver, displays the a down arrow, indicating that it is disabled.

```
>  Security devices
>  Sensors
>  Software devices
▽  Sound, video and game controllers
   Realtek High Definition Audio
   Virtual Audio Device (WDM) - Tablet Sample
>  Storage controllers
>  System devices
>  Universal Serial Bus controllers
```

After successfully installing the sample driver, you're now ready to test it.

Test the Sysvad audio driver

1. On the target computer, in a Command Prompt window, enter **devmgmt** to open Device Manager. In Device Manager, on the **View** menu, select **Devices by type**. In the device tree, locate *Virtual Audio Device (WDM) - Tablet Sample*.
2. Open Control Panel and navigate to **Hardware and Sound > Manage audio devices**. In the Sound dialog box, select the speaker icon labeled as *Virtual Audio Device (WDM) - Tablet Sample*, and then click **Set Default**, but do not click **OK**. This will keep the Sound dialog box open.
3. Locate an MP3 or other audio file on the target computer and double-click to play it. Then in the Sound dialog box, verify that there is activity in the volume level indicator associated with the *Virtual Audio Device (WDM) - Tablet Sample* driver.

Section 5: Use WinDbg to display information about the driver

In Section 5, you will set the symbol path and use kernel debugger commands to display information about the Sysvad sample driver.

Symbols allow for WinDbg to display additional information such as variable names, that can be invaluable when debugging. WinDbg uses the Microsoft Visual Studio debug symbol formats for source-level debugging. It can access any symbol or variable from a module that has PDB symbol files.

To load the debugger, perform the following steps.

<-On the host system

1. If you closed the debugger, open it again using the following command in the administrator command prompt window. Replace the key and port with what you previously configured.

```
C:\> WinDbg -k net:port=50010,key=2steg4fzbj2sz.23418vzkd4ko3.1g34ou07z4pev.1sp3yo9yz874p
```

2. Use Ctrl+Break (Scroll Lock) to break into the code running on the target system.

Set the symbol path

1. To set the symbols path to the Microsoft symbol server in the WinDbg environment, use the **.symfix** command.

```
0: kd> .symfix
```

2. To add your local symbol location to use your local symbols, add the path using **.sympath+** and then **.reload /f**.

```
0: kd> .sympath+ C:\WDK_Samples\Sysvad
0: kd> .reload /f
```

Note The **.reload** command with the **/f** force option deletes all symbol information for the specified module and reloads the symbols. In some cases, this command also reloads or unloads the module itself.

Note You must load the proper symbols to use advanced functionality that WinDbg provides. If you do not have symbols properly configured, you will receive messages indicating that symbols are not available when you attempt to use functionality that is dependent on symbols.

```
0:000> dv
Unable to enumerate locals, HRESULT 0x80004005
Private symbols (symbols.pri) are required for locals.
Type ".hh dbgerr005" for details.
```

Note

Symbol servers

There are a number of approaches that can be used to work with symbols. In many situations, you can configure the PC to access symbols from a symbol server that Microsoft provides when they are needed. This walkthrough assumes that this approach will be used. If the symbols in your environment are in a different location, modify the steps to use that location. For additional information, see [Symbol Stores and Symbol Servers](#).

Note

Understand source code symbol requirements

To perform source debugging, you must build a checked (debug) version of your binaries. The compiler will create symbol files (.pdb files). These symbol files will show the debugger how the binary instructions correspond to the source lines. The actual source files themselves must also be accessible to the debugger.

The symbol files do not contain the text of the source code. For debugging, it is best if the linker does not optimize your code. Source debugging and access to local variables are more difficult, and sometimes nearly impossible, if the code has been optimized. If you are having problems viewing local variables or source lines, set the following build options.

```
set COMPILE_DEBUG=1
set ENABLE_OPTIMIZER=0
```

1. Type the following in the command area of the debugger to display information about the Sysvad driver.

```
0: kd> lm m tabletaudiosample v
Browse full module list
start           end             module name
fffff801`14b40000 fffff801`14b86000  tabletaudiosample  (private pdb symbols)
C:\Debuggers\sym\TabletAudioSample.pdb\5395F0C5AE504C56AD31DD5473BD318F1\TabletAudioSample.pdb
    Loaded symbol image file: tabletaudiosample.sys
    Image path: \SystemRoot\system32\drivers\tabletaudiosample.sys
    Image name: tabletaudiosample.sys
    Browse all global symbols  functions  data
    Timestamp:      Thu Dec 10 12:20:26 2015 (5669DE8A)
    CheckSum:       0004891E
    ...
...
```

For more information, see [!m](#).

2. Click the **Browse all global symbols** link in the debug output to display information about items symbols that start with the letter a.
3. Because DML is enabled, some elements of the output are hot links that you can click on. Click on the *data* link in the debug output to display information about items symbols that start with the letter a.

```
0: kd> x /D /f tabletaudiosample!a*
A B C D E F G H I J K L M N O P Q R S T U V W X Y Z

fffff806`9adb1000 tabletaudiosample!AddDevice (struct _DRIVER_OBJECT *, struct _DEVICE_OBJECT *)
```

For information, see [x \(Examine Symbols\)](#).

4. The **!lmi** extension displays detailed information about a module. Type **!lmi tabletaudiosample**. Your output should be similar to the text shown below.

```
0: kd> !lmi tabletaudiosample
Loaded Module Info: [tabletaudiosample]
    Module: tabletaudiosample
    Base Address: fffff8069ad90000

  Executable
  App can handle >2gb addresses
...
```

Section 6: Displaying Plug and Play device tree information

In Section 6, you will display information about the Sysvad sample device driver and where it lives in the Plug and Play device tree.

Information about the device driver in the Plug and Play device tree can be useful for troubleshooting. For example, if a device driver is not resident in the device tree, there may be an issue with the installation of the device driver.

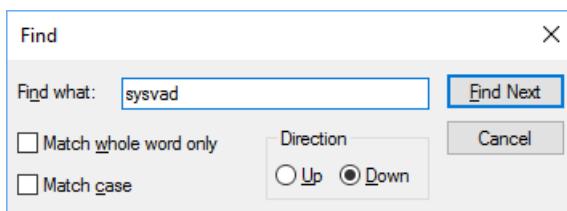

For more information about the device node debug extension, see [!devnode](#).

<-On the host system

1. To see all the device nodes in the Plug and Play device tree, enter the **!devnode 0 1** command. This command can take a minute or two to run. During that time, "*Busy" will be displayed in the status area of WinDbg.

```
0: kd> !devnode 0 1
Dumping IopRootDeviceNode (= 0xfffffe0005a3a8d30)
DevNode 0xfffffe0005a3a8d30 for PDO 0xfffffe0005a3a9e50
  InstancePath is "HTREE\ROOT\0"
  State = DeviceNodeStarted (0x308)
  Previous State = DeviceNodeEnumerateCompletion (0x30d)
  DevNode 0xfffffe0005a3a3d30 for PDO 0xfffffe0005a3a4e50
    InstancePath is "ROOT\volmgr\0000"
    ServiceName is "volmgr"
    State = DeviceNodeStarted (0x308)
    Previous State = DeviceNodeEnumerateCompletion (0x30d)
    DevNode 0xfffffe0005a324560 for PDO 0xfffffe0005bd95ca0...
...
```

2. Use **Ctrl+F** to search in the output that is generated to look for the name of the device driver, *sysvad*.

A device node entry with a name of *sysvad_TabletAudioSample* will be present in the **!devnode** output for Syvad.

```

DevNode 0xfffffe00086e68190 for PDO 0xfffffe00089c575a0
  InstancePath is "ROOT\sysvad_TabletAudioSample\0000"
  ServiceName is "sysvad_tabletaudiosample"
  State = DeviceNodeStarted (0x308)
...

```

Note that the PDO address and the DevNode address are displayed.

3. Use the **!devnode 0 1 sysvad_TabletAudioSample** command to display Plug and Play information associated with our Sysvad device driver.

```

0: kd> !devnode 0 1 sysvad_TabletAudioSample
Dumping IopRootDeviceNode (= 0xfffffe00082df8d30)
DevNode 0xfffffe00086e68190 for PDO 0xfffffe00089c575a0
  InstancePath is "ROOT\sysvad_TabletAudioSample\0000"
  ServiceName is "sysvad_tabletaudiosample"
  State = DeviceNodeStarted (0x308)
  Previous State = DeviceNodeEnumerateCompletion (0x30d)
  DevNode 0xfffffe000897fb650 for PDO 0xfffffe00089927e30
    InstancePath is "SWD\MMDEVAPI\{0.0.0.00000000\.\{64097438-cdc0-4007-a19e-62e789062e20\}"
    State = DeviceNodeStarted (0x308)
    Previous State = DeviceNodeStartPostWork (0x307)
  DevNode 0xfffffe00086d2f5f0 for PDO 0xfffffe0008993ae0
    InstancePath is "SWD\MMDEVAPI\{0.0.0.00000000\.\{78880f4e-9571-44a4-a9df-960bde446487\}"
    State = DeviceNodeStarted (0x308)
    Previous State = DeviceNodeStartPostWork (0x307)

    InstancePath is "SWD\MMDEVAPI\{0.0.1.00000000\.\{0894b831-c9fe-4c56-86a6-092380fc5628\}"
    State = DeviceNodeStarted (0x308)
    Previous State = DeviceNodeStartPostWork (0x307)
  DevNode 0xfffffe000893dbb70 for PDO 0xfffffe00089d68060
    InstancePath is "SWD\MMDEVAPI\{0.0.1.00000000\.\{15eb6b5c-aa54-47b8-959a-0cff2c1500db\}"
    State = DeviceNodeStarted (0x308)
    Previous State = DeviceNodeStartPostWork (0x307)
  DevNode 0xfffffe00088e6f250 for PDO 0xfffffe00089f6e990
    InstancePath is "SWD\MMDEVAPI\{0.0.1.00000000\.\{778c07f0-af9f-43f2-8b8d-490024f87239\}"
    State = DeviceNodeStarted (0x308)
    Previous State = DeviceNodeStartPostWork (0x307)
  DevNode 0xfffffe000862eb4b0 for PDO 0xfffffe000884443a0
    InstancePath is "SWD\MMDEVAPI\{0.0.1.00000000\.\{e4b72c7c-be50-45df-94f5-0f2922b85983\}"
    State = DeviceNodeStarted (0x308)
    Previous State = DeviceNodeStartPostWork (0x307)

```

4. The output displayed in the previous command includes the PDO associated with the running instance of our driver, in this example it is *0xfffffe00089c575a0*. Enter the **!devobj< PDO address>** command to display Plug and Play information associated with the Sysvad device driver. Use the PDO address that **!devnode** displays on your PC, not the one shown here.

```
0: kd> !devobj 0xfffffe00089c575a0
Device object (fffffe00089c575a0) is for:
0000004e \Driver\PnpManager DriverObject fffffe00082d47e60

```

6. Enter the **!devstack< PDO address>** command to display Plug and Play information associated with the device driver. The output displayed in the **!devnode 0 1** command includes the PDO address associated with the running instance of our driver. In this example it is `0xfffffe00089c575a0`. Use the PDO address that **!devnode** displays on your PC, not the one shown below.

```
0: kd> !devstack 0xfffffe00089c575a0
!DevObj           !DrvObj           !DevExt           ObjectName
fffffe00088d212e0  \Driver\ksthunk   fffffe00088d21430  0000007b
fffffe00088386a50  \Driver\sysvad_tabletaudiosamplefffffe00088386ba0  0000007a
> fffffe00089c575a0  \Driver\PnPManager 00000000  0000004e
!DevNode fffffe00086e68190 :
DeviceInst is "ROOT\sysvad_TabletAudioSample\0000"
ServiceName is "sysvad_tabletaudiosample"
```

The output shows that we have a fairly simple device driver stack. The sysvad_TabletAudioSample driver is a child of the PnPManager node. The PnPManager is a root node.

This diagram shows a more complex device node tree.

Note For more information about more complex driver stacks, see [Driver stacks](#) and [Device nodes and device stacks](#).

Section 7: Working with breakpoints

In Section 7, you will work with breakpoints to stop code execution at specific points.

Setting breakpoints using commands

Breakpoints are used to stop code execution at a particular line of code. You can then step forward in the code from that point, to debug that specific section of code.

To set a breakpoint using a debug command, use one of the following **b** commands.

bp	Sets a breakpoint that will be active until the module it is in is unloaded.
----	--

bu	Sets a breakpoint that is unresolved when the module is unloaded and re-enables when the module reloads.
bm	Sets a breakpoint for a symbol. This command will use bu or bp appropriately and allows wildcards * to be used to set breakpoints on every symbols that matches (like all methods in a class).

1. Use the WinDbg UI to confirm that **Debug > Source Mode** is enabled in the current WinDbg session.

2. Add your local code location to the source path by typing the following command.

```
.sympath+ C:\WDK_Samples\Sysvad
```

3. Add your local symbol location to the symbol path by typing the following command.

```
.sympath+ C:\WDK_Samples\Sysvad
```

4. Set the debug mask

As you are working with a driver it can be handy to see all of the messages that it may display. Type the following to change the default debug bit mask so that all debug messages from the target system will be displayed in the debugger.

```
0: kd> ed nt!Kd_DEFAULT_MASK 0xFFFFFFFF
```

5. Set the breakpoint with the **bm** command using the name of the driver, followed by the function name (AddDevice) where you want to set the breakpoint, separated by an exclamation mark.

```
0: kd> bm tableaudiosample!AddDevice
breakpoint 1 redefined
1: fffff801`14b5f000 @!"tableaudiosample!AddDevice"
```

You can use different syntax in conjunction with setting variables like <module>!<symbol>, <class>:<method>,<file.cpp>:<line number>, or skip a number of times <condition> <#>. For more information, see [Using Breakpoints](#).

6. List the current breakpoints to confirm that the breakpoint was set by typing the **bl** command.

```
0: kd> bl
1 e fffff801`14b5f000      0001 (0001) tableaudiosample!AddDevice
```

7. Restart code execution on the target system by typing the go command **g**.

8. ->On the target system

In Windows, open Device Manager by using the icon or by entering **mmc devmgmt.msc**. In **Device Manager** expand the **Sound, video and game controllers** node. Right click the virtual audio driver entry and select **Disable** from the menu.

9. Right click the virtual audio driver entry again and select **Enable** from the menu.

10. <- On the host system

This should cause Windows to reload the driver, which calls AddDevice. This will cause the AddDevice debug breakpoint to fire and the execution of the driver code on the target system should halt.

```
Breakpoint 1 hit
tabletaudiosample!AddDevice:
fffff801`14baf000 4889542410      mov     qword ptr [rsp+10h],rdx
```

If your source path is set properly, you should stop at the AddDevice routine in adapter.cpp

```
{
    PAGED_CODE();

    NTSTATUS          ntStatus;
    ULONG             maxObjects;

    DPF(D_TERSE, ("[AddDevice]"));

    maxObjects = g_MaxMinports;

    #ifdef SYSVAD_BTH_BYPASS
    //
    // Allow three (3) Bluetooth hands-free profile devices.
    //
    maxObjects += g_MaxBthHfpMinports * 3;
    #endif // SYSVAD_BTH_BYPASS

    // Tell the class driver to add the device.
    //
    ntStatus =
        PcAddAdapterDevice
    (
        DriverObject,
        PhysicalDeviceObject,
        PCPFNSTARTDEVICE(StartDevice),
        maxObjects,
        0
    );
}
```

- ```
return ntStatus;
} // AddDevice
```

  1. Step line-by-line through the code by typing the p command or pressing F10. You can step forward out of the sysvad AddDevice code to PpvUtilCall, PnpCallAddDevice and then to the PipCallDriverAddDevice Windows code. You can provide a number to the p command to step forward multiple lines, for example p 5.
  2. When you are done stepping through the code, use the go command g to restart execution on the target system.
```

Setting memory access breakpoints

You can also set breakpoints that fire when a memory location is accessed. Use the **ba** (break on access) command, with the following syntax.

```
ba <access> <size> <address> {options}
```

OPTION	DESCRIPTION
e	execute (when CPU fetches an instruction from the address)
r	read/write (when CPU reads or writes to the address)
w	write (when the CPU writes to the address)

Note that you can only set four data breakpoints at any given time and it is up to you to make sure that you are aligning your data correctly or you won't trigger the breakpoint (words must end in addresses divisible by 2, dwords must be divisible by 4, and quadwords by 0 or 8)

For example, to set a read/write breakpoint on a specific memory address, use a command like this.

```
ba r 4 fffff800`7bc9eff0
```

Modifying breakpoint state

You can modify existing breakpoints by using the following commands.

bl	Lists breakpoints.
bc	Clears a breakpoint from the list. Use bc * to clear all breakpoints.
bd	Disables a breakpoint. Use bd * to disable all breakpoints.
be	Enables a breakpoint. Use be * to enable all breakpoints.

Alternatively, you can also modify breakpoints by clicking **edit > breakpoints**. Note that the breakpoint dialog box only works with existing breakpoints. New breakpoints must be set from the command line.

Set a breakpoint on MixerVolume

Different parts of the audio driver code is called to respond to various events, after the device driver is loaded. In the next section, we set a breakpoint that will fire when the user adjusts the volume control for the virtual audio driver.

To set a breakpoint on MixerVolume, perform the following steps.

1. <- On the host system

To locate the method that changes the volume, use the x command to list the symbols in CAdapterCommon, that contain the string volume.

```
kd> x tabletaudiosample!CAdapterCommon::*
...
fffff800`7bce26a0 tabletaudiosample!CAdapterCommon::MixerVolumeWrite (unsigned long, unsigned long,
long)
...
```

Use CTRL+F to search upward in the output for volume and locate the MixerVolumeWrite method.

2. Clear the previous breakpoints using `bc *`.
3. Set a symbol breakpoint on the `CAdapterCommon::MixerVolumeWrite` routine using the following command.

```
kd> bm tabletaudiosample!CAdapterCommon::MixerVolumeWrite
1: fffff801`177b26a0 @"!tabletaudiosample!CAdapterCommon::MixerVolumeWrite"
```

4. List the breakpoints to confirm that the breakpoint is set properly.

```
kd> bl
1 e fffff801`177b26a0 [c:\WDK_Samples\audio\sysvad\common.cpp @ 1668] 0001 (0001)
tabletaudiosample!CAdapterCommon::MixerVolumeWrite
```

5. Restart code execution on the target system by typing the `go` command **g**.
6. In Control Panel select **Hardware and Sound > Sound**. Right click **Sink Description Sample** and select **Properties**. Select the **Levels** tab. Adjust the slider volume.
7. This should cause the `SetMixerVolume` debug breakpoint to fire and execution of the driver code on the target system should halt.

```
kd> g
Breakpoint 1 hit
tabletaudiosample!CAdapterCommon::MixerVolumeWrite:
fffff801`177b26a0 44894c2420    mov     dword ptr [rsp+20h],r9d
```

You should stop at this line in `common.cpp`

```
{
    if (_pHW)
    {
        _pHW->SetMixerVolume(Index, Channel, Value);
    }
} // MixerVolumeWrite
```

8. Use the `dv` command to display the current variables and their values. More information on variables is provided in the next section of this lab.

```
2: kd> dv
    this = 0x00000000`00000010
    ulNode = 0x344
    ulChannel = 0x210a45f8
    lVolume = 0n24
```

9. Press **F10** to single step through the code.
10. Press **F5** to finish the execution of the `MixerVolumeWrite` code.

Summary - Stepping through code from the Debugger Command window

The following are the commands that you can use to step through your code (with the associated keyboard short cuts shown in parentheses).

- Break in (Ctrl+Break) - This command will interrupt a system as long as the system is running and is in communication with WinDbg (the sequence in the Kernel Debugger is Ctrl+C).
- Step over (F10) – This command causes code execution to proceed one statement or one instruction at a time. If a call is encountered, code execution passes over the call without entering the called routine. (If the programming language is C or C++ and WinDbg is in source mode, source mode can be turned on or off using **Debug>Source Mode**).
- Step in (F11) – This command is like step-over, except that the execution of a call does go into the called routine.
- Step out (Shift+F11) – This command causes execution to run to and exit from the current routine (current place in the call stack). This is useful if you've seen enough of the routine.
- Run to cursor (F7 or Ctrl+F10) – Place the cursor in a source or disassembly window where you want the execution to break, then press F7; code execution will run to that point. Note that if the flow of code execution does not reach the point indicated by the cursor (e.g., an IF statement isn't executed), WinDbg would not break, because the code execution did not reach the indicated point.
- Run (F5) – Run until a breakpoint is encountered or an event like a bug check occurs.

Advanced options

- Set instruction to the current line (Ctrl+Shift+I) – In a source window, you can place your cursor on a line, enter this keyboard shortcut, and code execution will start from that point as soon as you let it proceed (for example using F5 or F10). This is handy if you want to retry a sequence, but it requires some care. For example, registers and variables are not set to what they would be if code execution had reached that line naturally.
- Direct setting of the eip register -- You can put a value into the eip register, and as soon as you press F5 (or F10, F11, etc.), execution commences from that address. This is similar to setting instruction to the cursor-designated current line, except that you specify the address of an assembly instruction.

It can be easier to step through UI rather than from the command line so this method is recommended. If necessary, the following commands can be used to step through a source file at the command line:

- .lines - Enable source line information.
- bp main - Set the initial breakpoint at the beginning of your module.
- l+t - Stepping will be done by source line.
- Select **Debug>Source Mode** to enter source mode; the `L+t` command is not sufficient.
- l+s - Source lines will be displayed at prompt.
- g - Run program until "main" is entered.
- p - Execute one source line.

For more information, see [Source Code Debugging in WinDbg](#) in the debugging reference documentation.

Set breakpoints in code

You can set a breakpoint in code by adding the `DebugBreak()` statement and rebuilding the project and re-installing the driver. This breakpoint will fire each time the driver is enabled, so it would be a technique to be used

in the early development stages, not in production code. This technique is not as flexible as dynamically setting breakpoints using the breakpoint commands.

Tip: You may want to keep a copy of the Sysvad driver with out the breakpoint added for further lab work.

1. Set a break to occur each time the AddDevice method is run by adding the `DebugBreak()` statement to the sample code.

```
...
// Insert the DebugBreak() statement before the  PcAddAdapterDevice is called.
//  
  
DebugBreak()  
  
// Tell the class driver to add the device.  
//  
ntStatus =  
    PcAddAdapterDevice  
(  
    DriverObject,  
    PhysicalDeviceObject,  
    PCP_FN_STARTDEVICE(StartDevice),  
    maxObjects,  
    0  
)  
  
return ntStatus;  
} // AddDevice
```

2. Follow all of the steps previously described to rebuild the driver in Microsoft Visual Studio and re-install it to the target machine. Be sure to uninstall the existing driver before installing the updated driver.
3. Clear any previous breakpoints and make sure that the debugger is attached to the target PC.
4. When the code runs and reaches the `DebugBreak()` statement, execution will stop and a message will be displayed.

```
KERNELBASE!DebugBreak:  
77b3b770 defe    __debugbreak
```

Section 8: Display variables

In Section 8, you will use debugger commands to display variables.

It can be useful to examine variables as the code executes to confirm that the code is working as expected. This lab examines variables as the audio driver produces sound.

1. Use the `dv` command to examine the locale variables associated with the `tabletaudiosample!CMiniportWaveRT::New*`.

```
kd> dv tabletaudiosample!CMiniportWaveRT::New*
```

2. Clear the previous breakpoints

```
bc *
```

3. Set a symbol breakpoint on the `CMiniportWaveCyclicStreamMSVAD` routines using the following

command.

```
0: kd> bm tabletaudiosample!CMiniportWaveRT::NewStream
1: fffff801`177dffc0 @!"tabletaudiosample!CMiniportWaveRT::NewStream"
```

4. Restart code execution on the target system by typing the go command **g**.

5. -> On the target system

Locate a small media file (such as Windows notification sound file with a .wav file extension) and click the file to play it. For example you can use Ring05.wav located in the Windows\Media directory.

6. <- On the host system

When the media file is played, the breakpoint should fire, and execution of the driver code on the target system should halt.

```
Breakpoint 1 hit
tabletaudiosample!CMiniportWaveRT::NewStream:
fffff801`177dffc0 44894c2420      mov      dword ptr [rsp+20h],r9d
```

The source code Window should be highlighting the brace on the entrance to the NewStream function.

```
/*++

Routine Description:

    The NewStream function creates a new instance of a logical stream
    associated with a specified physical channel. Callers of NewStream should
    run at IRQL PASSIVE_LEVEL.

Arguments:

    OutStream -
    OuterUnknown -
    Pin -
    Capture -
    DataFormat -

Return Value:

    NT status code.

--*/
{
```

7. Local variables

You can display the names and values of all local variables for a given frame by typing the **dv** command.

```
0: kd> dv
    this = 0xfffffe000`4436f8e0
    OutStream = 0xfffffe000`49d2f130
    OuterUnknown = 0xfffffe000`4436fa30
    Pin = 0
    Capture = 0x01 '
    DataFormat = 0xfffffe000`44227790
    signalProcessingMode = {487E9220-E000-FFFF-30F1-D24900E0FFFF}
    ntStatus = 0n1055
    stream = 0x00000000`00000200
```

8. Use DML to Display Variables

To use DML to explore variables, click the underlined elements. The click action builds a [dx \(Display NatVis Expression\)](#) command that allows you to drill down on nested data structures.

```
0: kd> dx -r1 (*((tabletaudiosample!CMiniportWaveRT *)0xfffffe001d10b8380))
(*((tabletaudiosample!CMiniportWaveRT *)0xfffffe001d10b8380)) : [Type: CMiniportWaveRT]
    [+0x020] m_lRefCount      : 0
    [+0x028] m_pUnknownOuter  : 0xfffffe001d1477e50 : [Type: IUnknown *]
    [+0x030] m_ulLoopbackAllocated : 0x2050
    [+0x034] m_ulSystemAllocated : 0x180
    [+0x038] m_ulOffloadAllocated : 0x0
    [+0x03c] _dwCaptureAllocatedModes : 0x0

0: kd> dx -r1 (*((tabletaudiosample!_GUID *)0xfffffd001c8acd348))
(*((tabletaudiosample!_GUID *)0xfffffd001c8acd348)) : {487E9220-E000-FFFF-30F1-D24900E0FFFF} [Type: _GUID]
    [<Raw View>]

0: kd> dx -r1 -n (*((tabletaudiosample!_GUID *)0xfffffd001c8acd348))
(*((tabletaudiosample!_GUID *)0xfffffd001c8acd348)) : [Type: _GUID]
    [+0x000] Data1          : 0x487e9220
    [+0x004] Data2          : 0xe000
    [+0x006] Data3          : 0xffff
    [+0x008] Data4          : [Type: unsigned char [8]]
```

```
0: kd> dx -r1 -n (*((tabletaudiosample!unsigned char (*)[8])0xfffffd001c8acd350))
(*((tabletaudiosample!unsigned char (*)[8])0xfffffd001c8acd350)) : [Type: unsigned char [8]]
    [0]          : 0x30
    [1]          : 0xf1
    [2]          : 0xd2
    [3]          : 0x49
    [4]          : 0x0
    [5]          : 0xe0
    [6]          : 0xff
    [7]          : 0xff
    ...
    ``
```

1. Global variables

You can find the memory location of a global variable by typing `? <variable name>`.

```
0: kd> ? signalProcessingMode
Evaluate expression: -52768896396472 = fffffd001`c8acd348
```

2. This returns the memory location of the variable, in this case `ffffd001`c8acd348`. You can view the contents

of the memory location by dumping the value of that location typing the **dd** command using the memory location returned by the previous command.

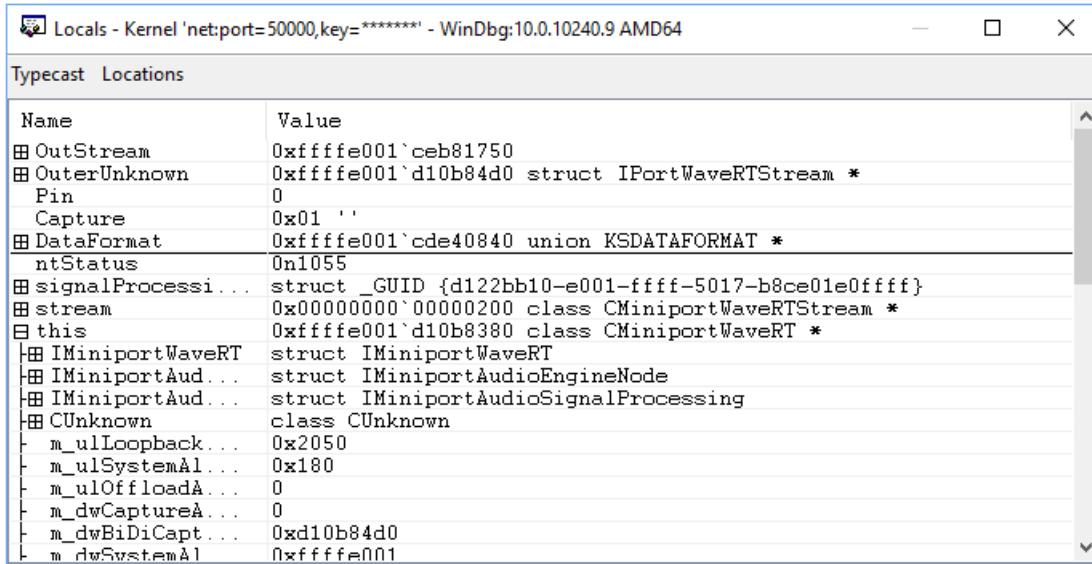

```
0: kd> dd fffffd001`c8acd348
fffffd001`c8acd348 487e9220 fffffe000 49d2f130 fffffe000
fffffd001`c8acd358 4837c468 fffffe000 18221570 fffffc000
fffffd001`c8acd368 4436f8e0 fffffe000 487e9220 fffffe000
fffffd001`c8acd378 18ab145b fffff801 4837c420 fffffe000
fffffd001`c8acd388 4436f8e0 fffffe000 49d2f130 fffffe000
fffffd001`c8acd398 4436fa30 fffffe000 00000000 00000000
fffffd001`c8acd3a8 00000001 00000000 44227790 fffffe000
fffffd001`c8acd3b8 18adc7f9 fffff801 495972a0 fffffe000
```

3. You can also use variable names with the **dd** command.

```
0: kd> dd signalProcessingMode
fffffd001`c8acd348 487e9220 fffffe000 49d2f130 fffffe000
fffffd001`c8acd358 4837c468 fffffe000 18221570 fffffc000
fffffd001`c8acd368 4436f8e0 fffffe000 487e9220 fffffe000
fffffd001`c8acd378 18ab145b fffff801 4837c420 fffffe000
fffffd001`c8acd388 4436f8e0 fffffe000 49d2f130 fffffe000
fffffd001`c8acd398 4436fa30 fffffe000 00000000 00000000
fffffd001`c8acd3a8 00000001 00000000 44227790 fffffe000
fffffd001`c8acd3b8 18adc7f9 fffff801 495972a0 fffffe000
```

4. Display variables

Use the **View> Locals** menu item to display local variables. This interface also provides this ability to drill down on more complex data structures.

5. Use p or F10 to step forward about 10 lines in the code until you are highlighting the ntStatus = IsFormatSupported(Pin, Capture, DataFormat); line of code.

```

PAGED_CODE();

ASSERT(OutStream);
ASSERT(DataFormat);

DPF_ENTER("[CMiniportWaveRT::NewStream]");

NTSTATUS ntStatus = STATUS_SUCCESS;
PCMiniportWaveRTStream stream = NULL;
GUID signalProcessingMode = AUDIO_SIGNALPROCESSINGMODE_DEFAULT;

*OutStream = NULL;

//
// If the data format attributes were specified, extract them.
//
if ( DataFormat->Flags & KSDATAFORMAT_ATTRIBUTES )
{
    // The attributes are aligned (QWORD alignment) after the data format
    PKSMULTIPLE_ITEM attributes = (PKSMULTIPLE_ITEM) (((PBYTE)DataFormat) + ((DataFormat-
>FormatSize + FILE_QUAD_ALIGNMENT) & ~FILE_QUAD_ALIGNMENT));
    ntStatus = GetAttributesFromAttributeList(attributes, attributes->Size, &signalProcessingMode);
}

// Check if we have enough streams.
//
if (NT_SUCCESS(ntStatus))
{
    ntStatus = ValidateStreamCreate(Pin, Capture, signalProcessingMode);
}

// Determine if the format is valid.
//
if (NT_SUCCESS(ntStatus))
{
    ntStatus = IsFormatSupported(Pin, Capture, DataFormat);
}

...

```

6. Use the **dv** command to display the names and values of all local variables for a given frame. Note that, as expected, the values are different from the last time we ran this command, as additional code has been run that changes the local variables and some variables are now not in the current frame or their values have changed.

```

2: kd> dv
    this = 0xfffffe001`d1182000
    OutStream = 0xfffffe001`d4776d20
    OuterUnknown = 0xfffffe001`d4776bc8
    Pin = 0
    Capture = 0x00 '
    DataFormat = 0xfffffe001`cd7609b0
    signalProcessingMode = {4780004E-7133-41D8-8C74-660DADD2C0EE}
    ntStatus = 0n0
    stream = 0x00000000`00000000

```

Section 9: View call stacks

In Section 9, you will view call stacks to examine caller/callee code.

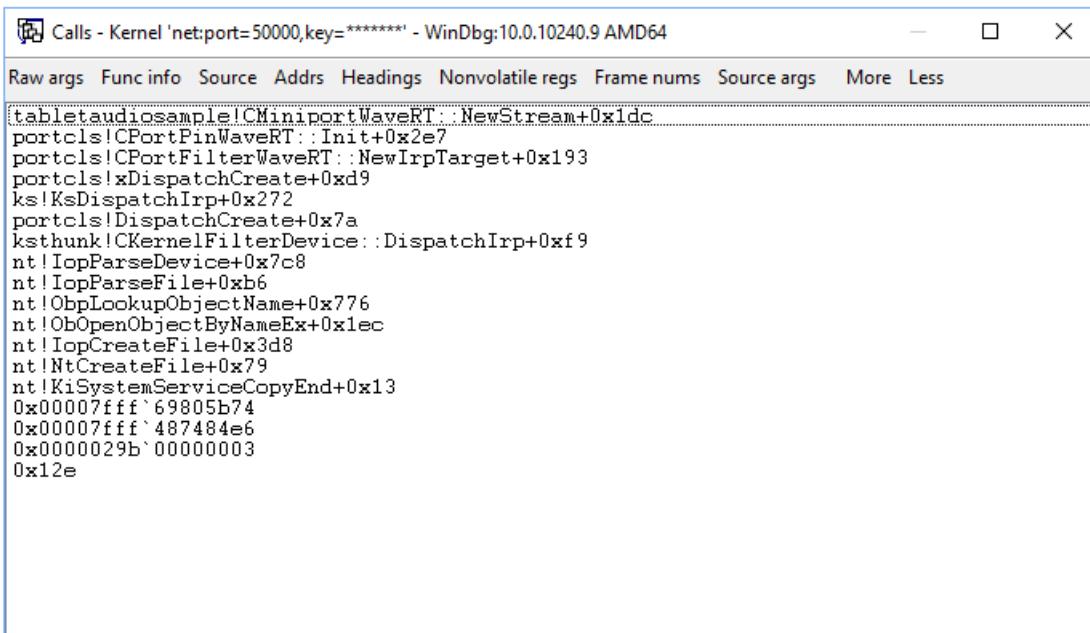

The call stack is the chain of function calls that have led to the current location of the program counter. The top function on the call stack is the current function, and the next function is the function that called the current

function, and so on.

To display the call stack, use the k* commands:

kb	Displays the stack and first three parameters.
kp	Displays the stacks and the full list of parameters.
kn	Allows you to see the stack with the frame information next to it.

If you want to keep the call stack available, you can click **View> Call stack** to view it. Click the columns at the top of the window to toggle the display of additional information.

The screenshot shows the WinDbg Call stack window titled 'Calls - Kernel 'net:port=50000,key=*****' - WinDbg:10.0.10240.9 AMD64'. The window lists a series of kernel stack frames, starting with 'tabletaudiosample!CMiniportWavERT::NewStream+0x1dc' and ending with '0x12e'. The frames are listed in a vertical stack, with each frame showing its address and the address of the previous frame.

```
tabletaudiosample!CMiniportWavERT::NewStream+0x1dc

```

Section 10: Display processes and threads

In Section 10, you will use debugger commands to display processes and threads.

Process

To change the current process context, use the `.process <process>` command. The following example

demonstrates how to identify a process and switch context to it.

- Use the `!process` command to display the current process that is involved in playing the sound.

For more information see [!process](#)

The output shows that the process is associated with audiodg.exe. If you are still at the breakpoint described in the previous section of this topic, the current process should be associated with the audiodg.exe image.

<- On the host system

```
0: kd> !process

processor 2
```

Note that one of the threads associated with this process is in the RUNNING state. This thread was supporting the playing of the media clip when the breakpoint was hit.

Use the `!process 0 0` command to display summary information for all processes. In the command output use

CTRL+F to locate the process ID for the process associated with the audiodg.exe image. In the example shown below, the process ID is *fffffe001d147c840*.

Record the process ID associated with audiodg.exe on your PC to use later in this lab. _____

```
...
PROCESS fffffe001d147c840
SessionId: 0 Cid: 10f0 Peb: ee6cf8a000 ParentCid: 0434
DirBase: d2122000 ObjectTable: fffffc0001f191ac0 HandleCount: <Data Not Accessible>
Image: audiodg.exe
...
```

Enter g into the debugger to run the code forward until the media clip is done playing. Then break in to the debugger, by pressing Ctrl+ScrLk (Ctrl+Break) Use the !process command to confirm that you are now running a different process.

```
!process

```

The output above shows that a different system process of *fffffe001cd0ad040* is running. The image name shows System, not audiodg.exe.

Now use the !process command to switch to the process that was associated with audiodg.exe. In the example, the process ID is *fffffe001d147c840*. Substitute the process ID in the example with your process ID, that you recorded earlier.

Because this code is not active, all of the threads are in WAIT state, as expected.

Threads

The commands to view and set threads are very similar to those of processes. Use the **!thread** command to view threads. Use **.thread** to set the current threads.

To explore threads associated with the media player, play the media clip again. If the breakpoint described in the previous section is still in place, you will stop in the context of audiodg.exe.

Use the **!thread -1 0** to display brief information for the current thread. This shows the thread address, the thread and process IDs, the thread environment block (TEB) address, the address of the Win32 function (if any) the thread was created to run, and the thread's scheduling state.

```
0: kd> !thread -1 0
THREAD fffffe001d3a27040  Cid 10f0.17f4  Teb: 000000ee6cf9d000 Win32Thread: 0000000000000000 RUNNING on
processor 0
```

To view more information about the thread that is running, type **!thread**. Information similar to the following should be displayed.

```

0: kd> !thread
THREAD fffffe001d3a27040  Cid 10f0.17f4  Teb: 000000ee6cf9d000 Win32Thread: 0000000000000000 RUNNING on
processor 0

```

The image name is rundll32.exe, which is indeed not the image name associated with playing the media clip.

Note

To set the current thread, type .thread <thread number>.

For more information about threads and processes, see the following references on MSDN:

[Threads and Processes](#)

Section 11: IRQL, registers, and disassembly

View the saved IRQL

In Section 11, you will display the IRQL, and the contents of the registers.

<- On the host system

The interrupt request level (IRQL) is used to manage the priority of interrupt servicing. Each processor has an IRQL setting that threads can raise or lower. Interrupts that occur at or below the processor's IRQL setting are masked and will not interfere with the current operation. Interrupts that occur above the processor's IRQL setting take precedence over the current operation. The **!irql** extension displays the interrupt request level (IRQL) on the current processor of the target computer before the debugger break occurred. When the target computer breaks into the debugger, the IRQL changes, but the IRQL that was effective just before the debugger break is saved and is displayed by **!irql**.

```
0: kd> !irql
Debugger saved IRQL for processor 0x0 -- 2 (DISPATCH_LEVEL)
```

<View the registers and disassembly

View the registers

Display the contents of the registers for the current thread on the current processor by using the **r (Registers)** command.

```
0: kd> r
rax=000000000000c301 rbx=fffffe00173eed880 rcx=0000000000000001

For more information about assembly language disassembly, see [Annotated x86 Disassembly](#) and [Annotated x64 Disassembly](#).

Section 12: Work with memory

In Section 12, you will use debugger commands to display the contents of memory.

View memory

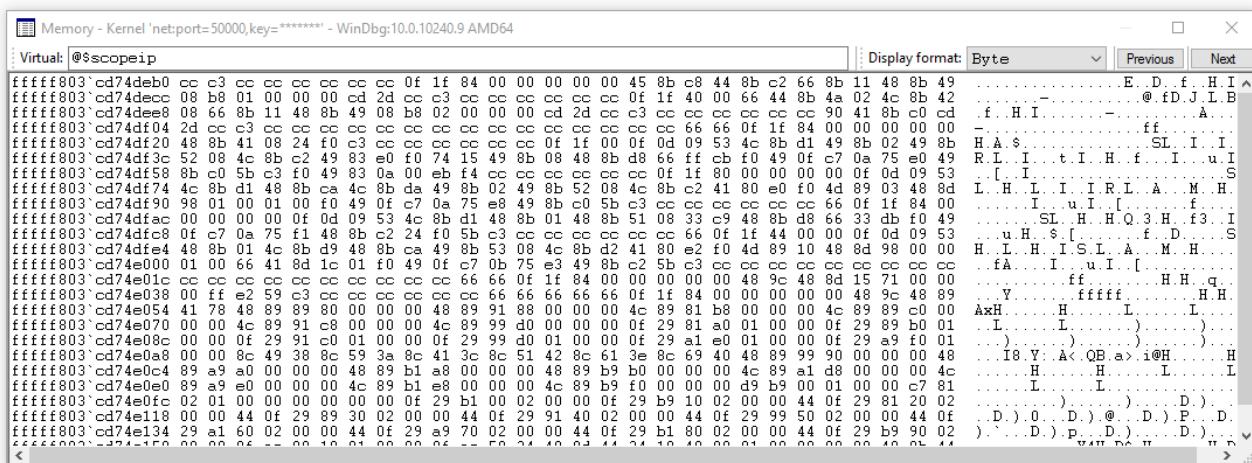

You may need to examine memory to identify an issue or to inspect variables, pointers, and so on. You can display memory by typing one of the following **d* <address>** commands.

db	Displays data in byte values and ASCII characters.
dd	Displays data as double wide words (4 bytes).
du	Displays data as Unicode characters.
dw	Displays data as word values (2 bytes) and ASCII characters.

Note

If you attempt to display an invalid address, its contents are shown as question marks (?).

Alternatively, you can view the memory by clicking **View > Memory**. Use the **Display format** pull down to change how the memory is displayed.

1. To view data associated with the volume control, set a breakpoint to fire on the `PropertyHandlerAudioEngineVolumeLevel` routine using the `bm` command. Before we set the new breakpoint, we will clear all of the previous breakpoints using `bc *`.

```
kd> bc *
```

2. Set a breakpoint to fire on the `PropertyHandlerAudioEngineVolumeLevel` routine using the `bm` command.

```
kd> bm tabletudiosample!CMiniportWaveRT::SetDeviceChannelVolume
1: fffff80f`02c3a4b0 @"!tabletudiosample!CMiniportWaveRT::SetDeviceChannelVolume"
```

3. List the breakpoints to confirm that the breakpoint is set properly.

```
kd> bl
1: fffff80f`02c3a4b0 @!"tabletaudiosample!CMiniportWaveRT::SetDeviceChannelVolume"
```

4. Use the **g** command to restart code execution.

On the target system adjust the volume in the system tray. This will cause the breakpoint to fire.

```
Breakpoint 1 hit
tabletaudiosample!CMiniportWaveRT::SetDeviceChannelVolume:
fffff80f`02c3a4b0 44894c2420    mov     dword ptr [rsp+20h],r9d
```

5. Use the **View> Local** menu item to display local variables. Note the current value of the **lVolume** variable.
6. You can display the data type and the current value for the **lVolume** variable in the sample code by typing the **dt** command and the name of the variable.

```
kd> dt lVolume
Local var @ 0xa011ea50 Type long
0n-6291456
```

7. The breakpoint is hit on entering **SetDeviceChannelVolume**.

```
STDMETHODIMP_(NTSTATUS) CMiniportWaveRT::SetDeviceChannelVolume(_In_ ULONG _ulNodeId, _In_ UINT32
 _uiChannel, _In_ LONG _Volume)
{
    NTSTATUS ntStatus = STATUS_INVALID_DEVICE_REQUEST;

    PAGED_CODE ();

    DPF_ENTER("[CMiniportWaveRT::SetDeviceChannelVolume]");

    IF_TRUE_ACTION_JUMP(_ulNodeId != KSNODE_WAVE_AUDIO_ENGINE, ntStatus =
 STATUS_INVALID_DEVICE_REQUEST, Exit);

    // Snap the volume level to our range of steppings.
    LONG lVolume = VOLUME_NORMALIZE_IN_RANGE(_Volume);

    ntStatus = SetChannelVolume(_uiChannel, lVolume);

Exit:
    return ntStatus;
}
```

8. Attempt to display the value at the memory location of **lVolume** by using the **dt (Display Type)** command.

```
kd> dt dt lVolume
Local var @ 0xfffffb780b7eee664 Type long
0n0
```

Because the variable is yet to be defined, it does not contain information.

9. Press F10 to run forward to the last line of code in **SetDeviceChannelVolume**.

```
return ntStatus;
```

10. Display the value at the memory location of **lVolume** by using the **dt (Display Type)** command.

```
kd> dt lVolume
Local var @ 0xfffffb780b7eee664 Type long
0n-6291456
```

Now that the variable is active, a value of 6291456 is displayed in this example.

11. You can also display the memory location of lVolume by using the [? \(Evaluate Expression\)](#) command.

```
kd> ? lVolume
Evaluate expression: -79711507126684 = fffffb780`b7eee664
```

12. The address shown, `ffffb780`b7eee664` is the address of the lVolume variable. Use the dd command to display the contents of memory at that location.

```
kd> dd fffffb780`b7eee664
fffffb780`b7eee664 ffa00000 00000018 00000000 c52d7008
fffffb780`b7eee674 fffffc98e e0495756 ffffff80e c52d7008
fffffb780`b7eee684 fffffc98e 00000000 ffffff80e 00000000
fffffb780`b7eee694 fffffc98e ffa00000 fffffb780 b7eee710
fffffb780`b7eee6a4 fffffb780 00000000 00000000 c7477260
fffffb780`b7eee6b4 fffffc98e b7eee7a0 fffffb780 b7eee6f0
fffffb780`b7eee6c4 fffffb780 e04959ca ffffff80e 00000000
fffffb780`b7eee6d4 00000000 00000028 00000000 00000002
```

13. You can display the first four bytes of an address by specifying the range parameter L4.

```
kd> dd fffffb780`b7eee664 14
fffffb780`b7eee664 ffa00000 00000018 00000000 c52d7008
```

14. To see the different types of memory output displayed, type the **du**, **da** and **db** commands.

```
kd> du fffffb780`b7eee664
fffffb780`b7eee664 ""

kd> a fffffb780`b7eee664
fffffb780`b7eee664 ""

kd> db 0xfffffae015ff97664
fffffae01`5ff97664 00 80 bc ff 18 00 00 00-00 00 00 08 50 e0 51 .....P.Q
fffffae01`5ff97674 00 c0 ff ff 56 57 da 56-0e f8 ff ff 08 50 e0 51 .....V.W.V.....P.Q
fffffae01`5ff97684 00 c0 ff ff 00 00 00 00-0e f8 ff ff 00 00 00 00 .....W.-
fffffae01`5ff97694 00 c0 ff ff aa 80 bc ff-01 ae ff ff 10 77 f9 5f .....W.-
fffffae01`5ff976a4 01 ae ff ff 40 00 00 00-00 e6 ff ff 10 dc 30 55 .....@.....0U
fffffae01`5ff976b4 00 c0 ff ff a0 77 f9 5f-01 ae ff ff f0 76 f9 5f .....W.-----V.-
fffffae01`5ff976c4 01 ae ff ff ca 59 da 56-0e f8 ff ff 00 00 00 00 .....Y.V.-----
fffffae01`5ff976d4 00 00 00 00 28 00 00 00-00 00 00 02 00 00 00 .....(.....
```

Use the df float option to display data as single-precision floating-point numbers (4 bytes).

```
df fffffb780`b7eee664
fffffb780`b7eee664 -1.#QNAN 3.3631163e-044 0 -2775.002
fffffb780`b7eee674 -1.#QNAN -5.8032637e+019 -1.#QNAN -2775.002
fffffb780`b7eee684 -1.#QNAN 0 -1.#QNAN 0
fffffb780`b7eee694 -1.#QNAN -1.#QNAN -1.#QNAN -2.8479408e-005
```

Write to memory

Similar to the commands that are used for reading memory, you can use the **e*** commands to change memory contents.

COMMAND	DESCRIPTION
ea	ASCII string (not NULL-terminated)
eu	Unicode string (not NULL-terminated)
ew	Word values (2 bytes)
eza	NULL-terminated ASCII string
ezu	NULL-terminated Unicode string
eb	Byte values
ed	Double-word values (4 bytes)

The following example shows how to overwrite memory.

1. First, locate the address of the **lVolume** that is used in the sample code.

```
kd> ? lVolume
Evaluate expression: -79711507126684 = fffffb780`b7eee664
```

2. Overwrite that memory address with new characters using the **eb** command.

```
kd> eb 0xfffffb780`b7eee664 11 11 11 11
```

3. Display the memory location to confirm that the characters have been overwritten by typing the **db** command.

```
kd> db 0xfffffb780`b7eee664
fffffb780`b7eee664 11 11 11 11 00 00 00-00 00 00 00 08 70 2d c5 .....p-.
fffffb780`b7eee674 8e c9 ff ff 56 57 49 e0-0e f8 ff ff 08 70 2d c5 ....VWI.....p-.
fffffb780`b7eee684 8e c9 ff ff 00 00 00 00-0e f8 ff ff 00 00 00 00 ..... .
fffffb780`b7eee694 8e c9 ff ff 00 00 a0 ff-80 b7 ff ff 10 e7 ee b7 ..... .
fffffb780`b7eee6a4 80 b7 ff ff 00 00 00 00-00 00 00 60 72 47 c7 .....`nG.
fffffb780`b7eee6b4 8e c9 ff ff a0 e7 ee b7-80 b7 ff ff f0 e6 ee b7 ..... .
fffffb780`b7eee6c4 80 b7 ff ff ca 59 49 e0-0e f8 ff ff 00 00 00 00 .....YI..... .
fffffb780`b7eee6d4 00 00 00 00 28 00 00 00-00 00 00 02 00 00 00 .....(..... .
```

Alternatively, you can modify the contents of the memory in a watch or locals window. For the watch window, you may see variables that are out of context of the current frame. Modifying them is not relevant if they are not in context.

Section 13: End the WinDbg session

<-On the host system

To end a user-mode debugging session, return the debugger to dormant mode, and set the target application to run again, enter the **qd** (Quit and Detach) command.

Be sure and use the **g** command to let the target computer run code, so that it can be used. It also a good idea to clear any break points using **bc ***, so that the target computer won't break and try to connect to the host computer debugger.

```
0: kd> qd
```

For more information, see [Ending a Debugging Session in WinDbg](#) in the debugging reference documentation.

Section 14: Windows debugging resources

Additional information is available on Windows debugging. Note that some of these books will use older versions of Windows such as Windows Vista in their examples, but the concepts discussed are applicable to most versions of Windows.

Books

- *Advanced Windows Debugging* by Mario Hewardt and Daniel Pravat
- *Inside Windows Debugging: A Practical Guide to Debugging and Tracing Strategies in Windows®* by Tarik Soulami
- *Windows Internals* by Mark E. Russinovich, David A. Solomon and Alex Ionescu

Debugging Resources

5/26/2017 • 1 min to read • [Edit Online](#)

Use Debugging Tools for Windows to debug drivers, applications, and services on Windows systems. The core debugging engine in the tool set is called the Windows debugger. Starting with Windows 8, you can use Visual Studio as your interface to the Windows debugger. You can also use the traditional interfaces (WinDbg, CDB, and NTSD), which are included in Debugging Tools for Windows.

Debugging Tools for Windows: New for Windows 10

5/26/2017 • 1 min to read • [Edit Online](#)

For Windows 10, Debugging Tools for Windows includes these new features.

Windows 10, version 1703

This section describes new debugging tools in Windows 10, version 1703.

- Eight new JavaScript topics including [JavaScript Debugger Scripting](#)
- Updates to the **dx (Display Debugger Object Model Expression)** command, to include new command capabilities.
- New **dtx (Display Type - Extended Debugger Object Model Information)** command.
- New **!ioctldecode** command.
- Updated [Debugger Engine Reference](#) to include additional interfaces and structures.
- Updates to [Configuring tools.ini](#) to document additional options for the command line debuggers.
- Published 75 previously undocumented stop codes in [Bug Check Code Reference](#).
- New [Supported Ethernet NICs for Network Kernel Debugging in Windows 10](#) topic.

Windows 10, version 1607

This section describes new debugging tools in Windows 10, version 1607.

- New topic about [Debugging a UWP app using WinDbg](#).
- Updates to the 30 most-viewed developer bug check topics in [Bug Check Code Reference](#).

Windows 10

- **.settings (Set Debug Settings)** - New command that allows you to set, modify, display, load and save settings in the Debugger.Settings namespace.
- **dx (Display NatVis Expression)** - Describes the new dx debugger command, which displays object information using the NatVis extension model and LINQ support.
- New commands that work with the NatVis visualization files in the debugger environment.
 - **.nvlist (NatVis List)**
 - **.nvload (NatVis Load)**
 - **.nvunload (NatVis Unload)**
 - **.nvunloadall (NatVis Unload All)**
- Bluetooth Extensions (Bthkd.dll)
- Storage Kernel Debugger Extensions
- New Symproxy information including [SymProxy Automated Installation](#). In addition the following topics are updated to cover new SymProxy functionality:
 - [HTTP Symbol Stores](#)
 - [SymProxy](#)
 - [Installing SymProxy](#)
 - [Configuring the Registry](#)
 - [Configuring IIS for SymProxy](#)
- **CDB Command-Line Options** - Updated to include new command line options.

- [!analyze](#) - Updated to include information about using this extension with UMDF 2.15.
- [!wdfkd.wdfcrashdump](#)- Updated to include information about using this extension with UMDF 2.15
- [!irp](#) - Updated. Starting with Windows 10 the IRP major and minor code text is displayed in command output.
- [Using Debugger Markup Language](#) - Updated to describe new right click behavior available in the Debugger Markup Language (DML).
- [Crash dump analysis using the Windows debuggers \(WinDbg\)](#) - Performance has increased in taking a memory dump over KDNET.
- [Debug Universal Drivers - Step by Step Lab \(Echo Kernel-Mode\)](#)- New step by step lab that shows how to use WinDbg to debug the sample KMDF echo driver.

[Send comments about this topic to Microsoft](#)

Tools Included in Debugging Tools for Windows

5/26/2017 • 2 min to read • [Edit Online](#)

Debugging Tools for Windows includes several tools in addition to the debugging engine and the [Debugging Environments](#). The tools are in the [installation directory](#) of Debugging Tools for Windows.

[ADPlus](#)

Automatically create memory dump files and log files with debug output from one or more processes.

[DumpChk](#)

Validate a memory dump file.

[GFlags](#)

Control registry keys and other settings.

[Kill](#)

Terminate a process.

[Logger and LogViewer](#)

Record and display function calls and other actions of a program.

[PLMDebug](#)

Use the Windows debugger to debug Windows app, which run under Process Lifecycle Management (PLM). With PLMDebug, you can take manual control of suspending, resuming, and terminating a Windows app.

[Remote Tool](#)

Remotely control any console program, including KD, CDB, and NTSD. See [Remote Debugging Through Remote.exe](#).

[TList](#)

List all running processes.

[UMDH](#)

Analyze heap allocations.

[USBView](#)

Display USB host controllers and connected devices.

[DbgRpc \(DbgRPC.exe\)](#)

Display Microsoft Remote Procedure Call (RPC) state information. See [RPC Debugging](#) and [Using the DbgRpc Tool](#).

[KDbgCtrl \(Kernel Debugging Control, KDbgCtrl.exe\)](#)

Control and configure the kernel debugging connection. See [Using KDbgCtrl](#).

[SrcSrv](#)

A source server that can be used to deliver source files while debugging.

[SymSrv](#)

A symbol server that the debugger can use to connect to a symbol store.

[SymProxy](#)

Create a single HTTP symbol server on your network that all your debuggers can point to. This has the benefit of pointing to multiple symbol servers (both internal and external) with a single symbol path, handling all authentication, and increasing performance via symbol caching. Symproxy.dll is in the SymProxy folder in the

[installation directory](#).

[SymChk](#)

Compare executable files to symbol files to verify that the correct symbols are available.

[SymStore](#)

Create a symbol store. See [Using SymStore](#).

[AgeStore](#)

Removes old entries in the downstream store of a symbol server or a source server.

[DBH](#)

Display information about the contents of a symbol file.

[PDBCopy](#)

Remove private symbol information from a symbol file, and control which public symbols are included in the file.

[DbgSrv](#)

A process server used for remote debugging. See [Process Servers \(User Mode\)](#).

[KdSrv](#)

A KD connection server used for remote debugging. See [KD Connection Servers \(Kernel Mode\)](#).

[DbEngPrx](#)

A repeater (small proxy server) used for remote debugging. See [Repeaters](#).

[Breakin \(Breakin.exe\)](#)

Causes a user-mode break to occur in a process. For help, open a Command Prompt window, navigate to the [installation directory](#), and enter **breakin /?**.

[List \(File List Utility\) \(List.exe\)](#)

For help, open a Command Prompt window, navigate to the [installation directory](#), and enter **list /?**.

[RTList \(Remote Task List Viewer\) \(Rtlist.exe\)](#)

List running processes via a DbgSrv process server. For help, open a Command Prompt window, navigate to the [installation directory](#), and enter **rtlist /?**.

Installation Directory

The default installation directory for 64 bit OS installs for the debugging tools is C:\Program Files (x86)\Windows Kits\10\Debuggers\. If you have a 32-bit OS, you can find the Windows Kits folder under C:\Program Files. To determine if you should use the 32 bit or 64 bit tools, see [Choosing the 32-Bit or 64-Bit Debugging Tools](#).

ADPlus

5/31/2017 • 1 min to read • [Edit Online](#)

ADPlus V7.0 is a total rewrite of ADPlus. ADPlus V7.0 is written in managed code, which allows us to easily add new features. ADPlus.exe keeps the basic functionality of ADPlus.vbs and adds some additional features. Also, there is a new companion called ADPlusManager, which extends ADPlus to a distributed environment like an HPC computer cluster.

Where to get ADPlus

ADPlus is included in [Debugging Tools for Windows](#).

For ADPlus V7.0 documentation, see adplus.doc in the installation folder for Debugging Tools for Windows.

[Tools Included in Debugging Tools for Windows](#)

[Send comments about this topic to Microsoft](#)

DumpChk

5/31/2017 • 4 min to read • [Edit Online](#)

DumpChk (the Microsoft Crash Dump File Checker tool) is a program that performs a quick analysis of a crash dump file. This enables you to see summary information about what the dump file contains. If the dump file is corrupt in such a way that it cannot be opened by a debugger, DumpChk reveals this fact.

Where to get DumpChk

DumpChk.exe is included in [Debugging Tools for Windows](#).

DumpChk command-line options

```
DumpChk [-y SymbolPath] DumpFile
```

Parameters

-y *SymbolPath*

SymbolPath specifies where DumpChk is to search for symbols. Symbol information may be necessary for some dump files. It can also help to improve the information shown in the dump file by allowing symbol names to be resolved.

DumpFile

DumpFile specifies the crash dump file that is to be analyzed. This may include an absolute or relative directory path or universal naming convention (UNC) path. If *DumpFile* contains spaces, it must be enclosed in quotation marks.

Using DumpChk

Here is an example in which the dump file is corrupt. The error shown at the end,

```
DebugClient cannot open DumpFile
```

```
C:\Debuggers> dumpchk c:\mydir\dumpfile2.dmp

Loading dump file c:\mydir\dumpfile2.dmp

Microsoft (R) Windows Debugger Version 6.9.0003.113 X86
Copyright (C) Microsoft. All rights reserved.

Loading Dump File [c:\mydir\dumpfile2.dmp]
Could not match Dump File signature - invalid file format
Could not open dump file [c:\mydir\dumpfile2.dmp], HRESULT 0x80004002
    "No such interface supported"
**** DebugClient cannot open DumpFile - error 80004002
```

Because this display does not end with the words `Finished dump check`, the dump file is corrupt. The error message at the end explains that the dump file could not be opened.

Note that other errors may be listed, some of which are actually benign. For example, the following error message does not represent a problem:

```
error 3 InitTypeRead( nt!_PEB at 7ffd5000)
```

Here is an example of DumpChk run on a healthy user-mode minidump. The display begins with an overall summary of the dump file, and then gives detailed information about what data is contained in the dump file:

```
C:\Debuggers> dumpchk c:\mydir\dumpfile1.dmp

Loading dump file c:\mydir\dumpfile1.dmp

Microsoft (R) Windows Debugger Version 6.9.0003.113 X86

        RoxioCentral=C:\Program Files\Common Files\Roxio Shared\9.0\Roxio Central33\
        SESSIONNAME=Console
        SystemDrive=C:
        SystemRoot=C:\Windows
        USERDNSDOMAIN=NORTHSIDE.COMPANY.COM
        USERDOMAIN=NORTHSIDE
        USERNAME=myname
        USERPROFILE=C:\Users\myname
        WINDBG_DIR=C:\DTFW\200804~2.113
        windir=C:\Windows
        WINLAYTEST=200804~2.113
        _NT_SOURCE_PATH=C:\mysources
        _NT_SYMBOL_PATH=C:\mysymbols
Finished dump check
```

The output begins by identifying the characteristics of the dump file - in this case, a user-mode minidump with full memory information, including application data but not operating-system data. This is followed by the symbol path being used by DumpChk, and then a summary of the dump file contents.

Because this display ends with the words `Finished dump check`, the dump file is probably not corrupt, and can be opened by a debugger. However, more subtle forms of corruption might still be present in the file.

GFlags

5/31/2017 • 2 min to read • [Edit Online](#)

GFlags (the Global Flags Editor), gflags.exe, enables and disables advanced debugging, diagnostic, and troubleshooting features. It is most often used to turn on indicators that other tools track, count, and log.

Where to get GFlags

GFlags is included in [Debugging Tools for Windows](#).

Overview of GFlags

Driver developers and testers often use GFlags to turn on debugging, logging and test features, either directly, or by including GFlags commands in a test script. The page heap verification features can help you to identify memory leaks and buffer errors in kernel-mode drivers.

GFlags has both a dialog box and a command-line interface. Most features are available from both interfaces, but some features are accessible from only one of the interfaces. (See [GFlags Details](#).)

Features

- Page heap verification. GFlags now includes the functions of PageHeap (pageheap.exe), a tool that enables heap allocation monitoring. PageHeap was included in previous versions of Windows.
- No reboot required for the Special Pool feature. On Windows Vista and later versions of Windows, you can enable, disable, and configure the Special Pool feature without restarting ("rebooting") the computer. For information, see [Special Pool](#).
- Object Reference Tracing. A new flag enables tracing of object referencing and object dereferencing in the kernel. This new feature of Windows detects when an object reference count is decremented too many times or not decremented even though an object is no longer used. This flag is supported only in Windows Vista and later versions of Windows.
- New dialog box design. The GFlags dialog box has tabbed pages for easier navigation.

Requirements

To use most GFlags features, including setting flags in the registry or in kernel mode, or enabling page heap verification, you must be a member of the Administrators group on the computer. However, prior to Windows Vista, users with at least Guest account access can launch a program from the **Global Flags** dialog box.

When features do not work, or work differently, on particular operating system versions, the differences are explained in the description of the feature.

This topic includes:

[GFlags Overview](#)

[GFlags Details](#)

[GFlags Commands](#)

[GFlags Flag Table](#)

[GFlags and PageHeap](#)

[Global Flags Dialog Box](#)

[GFlags Examples](#)

[Global Flag Reference](#)

Note Incorrect use of this tool can degrade system performance or prevent Windows from starting, requiring you to reinstall Windows.

Important Pool tagging is permanently enabled on Windows Server 2003 and later versions of Windows, including Windows Vista. On these systems, the **Enable pool tagging** check box on the **Global Flags** dialog box is dimmed and commands to enable or disable pool tagging fail.

GFlags Overview

5/26/2017 • 2 min to read • [Edit Online](#)

GFlags (gflags.exe), the Global Flags Editor, enables and disables advanced internal system diagnostic and troubleshooting features. You can run GFlags from a Command Prompt window or use its graphical user interface dialog box.

Use GFlags to activate the following features:

Registry

Set system-wide debugging features for all processes running on the computer. These settings are stored in the **GlobalFlag** registry entry (**HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\GlobalFlag**). They take effect when you restart Windows and remain effective until you change them and restart again.

Kernel flag settings

Set debugging features for this session. These settings are effective immediately, but are lost when Windows shuts down. The settings affect all processes started after this command completes.

Image file settings

Set debugging features for a particular program. These settings are stored in a GlobalFlag registry entry for each program (**HKEY_LOCAL_MACHINE\ SOFTWARE\ Microsoft\ Windows NT\ CurrentVersion\ Image File Execution Options\ ImageFileName\ GlobalFlag**). They take effect when you restart the program and remain effective until you change them.

Debugger

Specify that a particular program always runs in a debugger. This setting is stored in the registry. It is effective immediately and remains effective until you change it. (This feature is available only in the **Global Flags** dialog box.)

Launch

Run a program with the specified debugging settings. The debugging settings are effective until the program stops. (This feature is available only from the **Global Flags** dialog box.)

Special Pool

Request that allocation with a specified pool tag or of a specified size are filled from the special pool. This feature helps you to detect and identify the source of errors in kernel pool use, such as writing beyond the allocated memory space, or referring to memory that has already been freed.

Beginning in Windows Vista, you can enable, disable, and configure the special pool feature (**Kernel Special Pool Tag**) as a kernel flags setting, which does not require a reboot, or as a registry setting, which requires a reboot.

Page heap verification

Enable, disable, and configure page heap verification for a program. When enabled, page heap monitors dynamic heap memory operations, including allocation and free operations, and causes a debugger break when it detects a heap error.

Silent process exit

Enable, disable, and configure monitoring and reporting of silent exits for a process. You can specify actions that occur when a process exits silently, including notification, event logging, and creation of dump files. For more information, see [Monitoring Silent Process Exit](#).

[Send comments about this topic to Microsoft](#)

GFlags Details

5/26/2017 • 2 min to read • [Edit Online](#)

GFlags enables and disables system features by editing the Windows registry and internal settings. This section explains the operation of GFlags in detail and includes tips for using GFlags most efficiently.

General Information

- To display the GFlags dialog box, at the command line, type **gflags** (with no parameters).
- On Windows Server 2003 and earlier versions of Windows, to set flags in the registry or in kernel mode, you must be a member of the Administrators group on the computer. However, users with at least Guest account access can launch a program from the GFlags dialog box.
- GFlags system-level registry settings appear in the registry immediately, but do not take effect until you restart the system.
- GFlags image file registry settings appear in the registry immediately, but do not take effect until you restart the process.
- The debugger and launch features in the GFlags dialog box are program specific. You can only set them on one image file at a time.

Flag Details

- To clear all flags, set the flag to -FFFFFFF. Setting the flag to 0 adds 0 to the current flag value.
- When you set the flags for an image file to FFFFFFFF (0xFFFFFFFF), Windows clears all flags for the image file and deletes the **GlobalFlag** entry in the image file registry key. The image file registry key is retained.

Dialog Box and Command Line

You can run GFlags by using its handy dialog box or from the command line. Most features are available in both forms, with the following exceptions.

Dialog box only

- Launch. Start a program using the specified flags.
- Run the program in a debugger.
- **Special Pool** on systems prior to Windows Vista. On Windows Vista and later versions of Windows, you can configure the Special Pool feature at the command line or in the GFlags dialog box.

Command line only

- Set the size of the user mode stack trace database (/tracedb).
- Set page heap verification options.

Registry Information

GFlags settings that are saved between sessions are stored in the registry. You can use the registry APIs, Regedit, or reg.exe to query or change these values. The following table lists the types of settings and where they are stored in the registry.

Systemwide settings ("Registry")	HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session ManagerGlobalFlag
Program-specific settings ("Image file") for all users of the computer.	HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution OptionsImageFileNameGlobalFlag
Silent exit settings for a specific program ("Silent Process Exit") for all users of the computer.	HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\SilentProcessExitImageFileName
Page heap options for an image file for all users of the computer	HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution OptionsImageFileNamePageHeapFlags
User mode stack trace database size (tracedb)	HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution OptionsImageFileNameStackTraceDatabaseSizeInMb
Create user mode stack trace database (ust, 0x1000) for an image file	Windows adds the image file name to the value of the USTEEnabled registry entry (HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution OptionsUSTEnabled).
Load image using large pages if possible	HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution OptionsImageFileNameUseLargePages.
Special Pool (Kernel Special Pool Tag)	HKLM\SYSTEM\CurrentControlSet\Control\Session Manager\Memory ManagementPoolTag
Verify Start / Verify End	HKLM\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management\PoolTagOverruns. The Verify Start option sets the value to 0. The Verify End option sets the value to 1.
Debugger for an image file	HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution OptionsImageFileNameDebugger
Object Reference Tracing	HKLM\SYSTEM\CurrentControlSet\Control\Session Manager\KernelObTraceProcessName, ObTracePermanent and ObTracePoolTags

GFlags Commands

5/31/2017 • 14 min to read • [Edit Online](#)

To use GFlags, type the following commands at the command line.

You can use the GFlags commands and the [Global Flags Dialog Box](#) interchangeably.

To open the GFlags dialog box:

```
gflags
```

To set or clear global flags in the registry:

```
gflags /r [{+ | -}Flag [{+ | -}Flag...]]
```

To set or clear global flags for the current session:

```
gflags /k [{+ | -}Flag [{+ | -}Flag...]]
```

To set or clear global flags for an image file:

```
gflags /i ImageFile [{+ | -}Flag [{+ | -}Flag...]]  
gflags /i ImageFile /tracedb SizeInMB
```

To set or clear the Special Pool feature (Windows Vista and later)

```
gflags {/r | /k} {+ | -}spp {PoolTag | 0xSize}
```

To enable or disable the Object Reference Tracing feature (Windows Vista and later)

```
gflags {/ro | /ko} [/p] [/i ImageFile | /t PoolTag;[PoolTag...]]
```

```
gflags {/ro | /ko} /d
```

To enable and configure page heap verification:

```
gflags /p /enable ImageFile [ /full [/backwards] | /random Probability | /size SizeStart SizeEnd | /address  
AddressStart AddressEnd | /dlls DLL [DLL...]]  
[/debug ["DebuggerCommand"] | /kdebug] [/unaligned] [/notraces] [/fault Rate [TimeOut]] [/leaks] [/protect]  
[/no_sync] [/no_lock_checks]
```

To disable page heap verification:

```
gflags /p [/disable ImageFile] [/?]
```

To display help:

```
gflags /?
```

Parameters

Flag

Specifies a three-letter abbreviation (*FlagAbbr*) or hexadecimal value (*FlagHex*) that represents a debugging feature. The abbreviations and hexadecimal values are listed in the [GFlags Flag Table](#).

Use one of the following flag formats:

FORMAT	DESCRIPTION
{+ -}FlagAbbr	Sets (+) or clears (-) the flag represented by the flag abbreviation. Without a plus (+) or minus (-) symbol, the command has no effect.
[+ -]FlagHex	Adds (+) or subtracts (-) the hexadecimal value of a flag. A flag is set when its value is included in the sum. Add (+) is the default. Enter a hexadecimal value (without 0x) that represents a single flag or enter the sum of hexadecimal values for multiple flags.

ImageFile

Specifies the name of an executable file, including the file name extension (for example, notepad.exe or mydll.dll).

/r

Registry. Displays or changes system-wide debugging flags stored in the registry. These settings take effect when you restart Windows and remain effective until you change them.

With no additional parameters, **gflags /r** displays the system-wide flags set in the registry.

/k

Kernel flag settings. Displays or changes system-wide debugging flags for this session. These settings are effective immediately, but are lost when Windows shuts down. The settings affect processes started after this command completes.

With no additional parameters, **gflags /k** displays system-wide flags set for the current session.

/i

Image file settings. Displays or changes debugging flags for a particular process. These settings are stored in the registry. They are effective for all new instances of this process and they remain effective until you change them.

With no additional parameters, **gflags /i ImageFile** displays the flags set for the specified process.

/tracedb SizeInMB

Sets the maximum size of the user-mode stack trace database for the process. To use this parameter, the [Create user mode stack trace database](#) (ust) flag must be set for the process.

SizeInMB is a whole number representing the number of megabytes in decimal units. The default value is the minimum size, 8 MB; there is no maximum size. To revert to the default size, set *SizeInMB* to 0.

spp

(Windows Vista and later.) Sets or clears the [Special Pool](#) feature. For an example, see [Example 14: Configuring Special Pool](#).

PoolTag

(Windows Vista and later.) Specifies a pool tag for the [Special Pool](#) feature. Use only with the **spp** flag.

Enter a four-character pattern for *PoolTag*, such as Tag1. It can include the ? (substitute for any single character) and * (substitute for multiple characters) wildcard characters. For example, Fat* or Av?4. Pool tags are always case-sensitive.

0xSize

(Windows Vista and later.) Specifies a size range for the Special Pool feature. Use only with the **spp** flag. For guidance on selecting a size value, see "Selecting an Allocation Size" in [Special Pool](#).

/ro

Enables, disables, and displays [Object Reference Tracing](#) settings in the registry. To make a change to this setting effective, you must restart Windows.

Without additional parameters, **/ro** displays the Object Reference Tracing settings in the registry.

To enable Object Reference Tracing, you must include at least one pool tag (**/t PoolTag**) or one image file (**/i ImageFile**) in the command. For details, see [Example 15: Using Object Reference Tracing](#).

The following table lists the subparameters that are valid with **/ro**.

/t PoolTags	<p>Limits the trace to objects with the specified pool tags. Use a semicolon (;) to separate tag names. Enter up to 16 pool tags.</p> <p>Enter a four-character pattern for <i>PoolTags</i>, such as Tag1.</p> <p>If you specify more than one pool tag, Windows traces objects with any of the specified pool tags .</p> <p>If you do not specify any pool tags, Windows traces all objects that are created by the image.</p>
/i ImageFile	<p>Limits the trace to objects that are created by processes with the specified image file. You can specify only one image file with the /i parameter.</p> <p>Enter an image file name, such as notepad.exe, with up to 64 characters. "System" and "Idle" are not valid image names.</p> <p>If you do not specify an image file, Windows traces all objects with the specified pool tags. If you specify both an image file (/i) and one or more pool tags (/t), Windows traces objects with any of the specified pool tags that are created by the specified image.</p>
/d	<p>Clears the Object Reference Tracing feature settings. When used with /ro, it clears the settings in the registry.</p>
/p	<p>Permanent. The trace data is retained until Object Reference Tracing is disabled, or the computer is shut down or restarted. By default, the trace data for an object is discarded when the object is destroyed.</p>

/ko

Enables, disables, and displays kernel flag (run time) [Object Reference Tracing](#) settings. Changes to this setting are effective immediately, but are lost when the system is shut down or restarted. For details, see [Example 15: Using Object Reference Tracing](#).

Without additional parameters, **/ko** displays the kernel flag (run time) Object Reference Tracing settings.

To enable Object Reference Tracing, you must include at least one pool tag (**/t PoolTag**) or one image file (**/i ImageFile**) in the command.

The following table lists the subparameters that are valid with **/ko**.

/t PoolTags	Limits the trace to objects with the specified pool tags. Use a semicolon (;) to separate tag names. Enter up to 16 pool tags. Enter a four-character pattern for <i>PoolTags</i> , such as Tag1. If you specify more than one pool tag, Windows traces objects with any of the specified pool tags. If you do not specify any pool tags, Windows traces all objects that are created by the image.
/i ImageFile	Limits the trace to objects that are created by processes with the specified image file. You can specify only one image file with the /i parameter. If you do not specify an image file, Windows traces all objects with the specified pool tags. If you specify both an image file (/i) and one or more pool tags (/t), Windows traces objects with any of the specified pool tags that are created by the specified image.
/d	Clears the Object Reference Tracing feature settings. When used with /ro , it clears the settings in the registry.
/p	Permanent. The trace data is retained until Object Reference Tracing is disabled, or the computer is shut down or restarted. By default, the trace data for an object is discarded when the object is destroyed.

/p

Sets page heap verification options for a process.

With no additional parameters, **gflags /p** displays a list of image files for which page heap verification is enabled.

Page heap verification monitors dynamic heap memory operations, including allocate operations and free operations, and causes a debugger break when it detects a heap error.

/disable ImageFile

Turns off page heap verification (standard or full) for the specified image file.

This command is equivalent to turning off the [Enable page heap](#) (hpa) flag for a process (**gflags /i ImageFile -hpa**). You can use the commands interchangeably.

/enable ImageFile

Turns on page heap verification for the specified image file.

By default, the **/enable** parameter turns on *standard* page heap verification for the image file. To enable *full* page heap verification for the image file, add the **/full** parameter to the command or use the **/i** parameter with the **+hpa** flag.

/full

Turns on full page heap verification for the process. Full page heap verification places a zone of reserved virtual memory at the end of each allocation.

Using this parameter is equivalent to turning on the [Enable page heap](#) (hpa) flag for a process (**gflags /i ImageFile +hpa**). You can use the commands interchangeably.

/backwards

Places the zone of reserved virtual memory at the beginning of an allocation, rather than at the end. As a result, the debugger traps overruns at the beginning of the buffer, instead of those at the end of the buffer. Valid only with the **/full** parameter.

/random Probability

Chooses full or standard page heap verification for each allocation, based on the specified probability.

Probability is a decimal integer from 0 through 100 representing the probability of full page heap verification. A probability of 100 is the same as using the **/full** parameter. A probability of 0 is the same as using standard page heap verification.

/size SizeStart SizeEnd

Enables full page heap verification for allocations within the specified size range and enables standard page heap verification for all other allocations by the process.

SizeStart and *SizeEnd* are decimal integers. The default is standard page heap verification for all allocations.

/address AddressStart AddressEnd

Enables full page heap verification for memory allocated while a return address in the specified address range is on the run-time call stack. It enables standard page heap verification for all other allocations by the process.

To use this feature, specify a range that includes the addresses of all functions that call the function with the suspect allocation. The address of the calling function will be on the call stack when the suspect allocation occurs.

AddressStart and *AddressEnd* specify the address range searched in allocation stack traces. The addresses are specified in hexadecimal format, such as, 0xAABBCCDD.

On Windows Server 2003 and earlier systems, the **/address** parameter is valid only on x86-based computers. On Windows Vista, it is valid on all supported architectures.

/dlls DLL[, DLL...]

Enables full page heap verification for allocations requested by the specified DLLs and standard page heap verification for all other allocations by the process.

DLL is the name of a binary file, including its file name extension. The specified file must be a function library that the process loads during execution.

/debug

Automatically launches the process specified by the **/enable** parameter under a debugger.

By default, this parameter uses the NTSD debugger with the command line **ntsd -g -G -x** and with page heap enabled, but you can use the *DebuggerCommand* variable to specify a different debugger and command line.

For information about NTSD, see [Debugging Using CDB and NTSD](#).

This option is useful for programs that are difficult to start from a command prompt and those that are started by other processes.

"DebuggerCommand"

Specifies a debugger and the command sent to the debugger. This quoted string can include a fully qualified path to the debugger, the debugger name, and command parameters that the debugger interprets. The quotation marks are required.

If the command includes a path to the debugger, the path cannot contain any other quotation marks. If other quotation marks appear, the command shell (`cmd.exe`) will misinterpret the command.

/kdebug

Automatically launches the process specified by the **/enable** parameter under the NTSD debugger with the command line `ntsd -g -G -x`, with page heap enabled, and with control of NTSD redirected to the kernel debugger.

For information about NTSD, see [Debugging Using CDB and NTSD](#).

/unaligned

Aligns the end of each allocation at an end-of-page boundary, even if doing so means that the starting address is not aligned on an 8-byte block. By default, the heap manager guarantees that the starting address of an allocation is aligned on an 8-byte block.

This option is used to detect off-by-one-byte errors. When this parameter is used with the **/full** parameter, the zone of reserved virtual memory begins just after the last byte of the allocation and an immediate fault occurs when a process tries to read or write even one byte beyond the allocation.

/decommit

This option is no longer valid. It is accepted, but ignored.

The PageHeap program (`pageheap.exe`) included in Windows 2000 implemented full page heap verification by placing an inaccessible page after an allocation. In that tool, the **/decommit** parameter substituted a zone of reserved virtual memory for the inaccessible page. In this version of GFlags, a zone of reserved virtual memory is always used to implement full page heap verification.

/notraces

Specifies that run-time stack traces are not saved.

This option improves performance slightly, but it makes debugging much more difficult. This parameter is valid, but its use is not recommended.

/fault

Forces the program's memory allocations to fail at the specified rate and after the specified time-out.

This parameter inserts heap allocation errors into the image file being tested (a practice known as "fault injection") so that some memory allocations fail, as might occur when the program runs in low memory conditions. This test helps to detect errors in handling allocation failure, such as failing to release resources.

<i>Rate</i>	Specifies a decimal integer from 1 (.01%) through 10000 (100%) representing the probability that an allocation will fail. The default is 100 (1%).
<i>TimeOut</i>	Determines the time interval between the start of the program and the start of the fault injection routines. <i>TimeOut</i> is measured in seconds. The default is 5 (seconds).

/leaks

Checks for heap leaks when a process ends.

The **/leaks** parameter disables full page heap. When **/leaks** is used, the **/full** parameter and parameters that modify the **/full** parameter, such as **/backwards**, are ignored, and GFlags performs standard page heap verification with a leak check.

/protect

Protects heap internal structures. This test is used to detect random heap corruptions. It can make execution significantly slower.

/no_sync

Checks for unsynchronized access. This parameter causes a break if it detects that a heap created with the HEAP_NO_SERIALIZE flag is accessed by different threads.

Do not use this flag to debug a program that includes a customized heap manager. Functions that synchronize heap access cause the page heap verifier to report synchronization faults that do not exist.

/no_lock_checks

Disables the critical section verifier.

/?

Displays help for GFlags. With **/p**, **/?** displays help for the page heap verification options in GFlags.

Comments

Typing **gflags** without parameters opens the **Global Flags** dialog box.

Typing **gflags /p** without additional parameters displays a list of programs that have page heap verification enabled.

To clear all flags, set *Flag* to **-FFFFFFFFFF**. (Setting *Flag* to 0 adds zero to the current flag value. It does not clear all flags.)

When you set *Flag* for an image file to **FFFFFFFFFF**, Windows clears all flags and deletes the GlobalFlag entry in the registry subkey for the image file. The subkey remains.

The **/full**, **/random**, **/size**, **/address**, and **/dlls** parameters for the page heap **/enable** operation determine which allocations are subject to page heap verification and the verification method used. You can use only one of these parameters in each command. The default is standard page heap verification of all allocations of the process. The remaining parameters set options for page heap verification.

The page heap features in GFlags only monitor heap memory allocations that use the standard Windows heap manager functions (**HeapAlloc**, **GlobalAlloc**, **LocalAlloc**, **malloc**, **new**, **new[]**, or their corresponding deallocation functions), or those that use custom operations that call the standard heap manager functions.

To determine whether full or standard page heap verification is enabled for a program, at the command line, type **gflags /p**. In the resulting display, **traces** indicates that standard page heap verification is enabled for the program and **full traces** indicates that full page heap verification is enabled for the program.

The **/enable** parameter sets the [Enable page heap](#) (hpa) flag for the image file in the registry. However, the **/enable** parameter turns on *standard* heap verification for the image file by default, unlike the **/i** parameter with the **+hpa** flag, which turns on *full* heap verification for an image file.

Standard page heap verification places random patterns at the end of an allocation and examines the patterns when a heap block is freed. *Full* page heap verification places a zone of reserved virtual memory at the end of each allocation.

Full page heap verification can consume system memory quickly. To enable full page heap verification for memory-intensive processes, use the **/size** or **/dlls** parameter.

After using global flags for debugging, submit a **gflags /p /disable** command to turn off the page heap verification and delete associated registry entries. Otherwise, entries that the debugger reads remain in the registry. You cannot use the **gflags /i hpa** command for this task, because it turns off page heap verification, but does not delete the registry entries.

By default, on Windows Vista and later versions of Windows, program-specific settings (image file flags and page heap verification settings) are stored in the current user account.

This version of GFlags includes the **-v** options, which enable features being developed for GFlags. However, these features are not yet complete and, therefore, are not documented.

GFlags Flag Table

5/26/2017 • 2 min to read • [Edit Online](#)

The following table lists the flags that GFlags changes, the hexadecimal value and abbreviation for each flag, and the destination (R for registry, K for kernel, I for image file) in which the flag is valid.

For a detailed description of each flag, see the [Global Flag Reference](#).

For information about using GFlags, see [GFlags Overview](#) and [GFlags Details](#).

Important Pool tagging is permanently enabled in Windows Server 2003 and later versions of Windows. On these systems, the **Enable pool tagging** check box on the **Global Flags** dialog box is dimmed, and commands to enable or disable pool tagging fail.

Note The symbolic name of each flag is provided for reference only. Because symbolic names change, they are not a reliable identifier of a global flag.

DESCRIPTION	SYMBOLIC NAME	HEXADECIMAL VALUE	ABBREVIATION	DESTINATION
Buffer DbgPrint Output	FLG_DISABLE_DB GPRINT	0x08000000	ddp	R,K
Create kernel mode stack trace database	FLG_KERNEL_STACK_TRACE_DB	0x2000	kst	R
Create user mode stack trace database	FLG_USER_STACK_TRACE_DB	0x1000	ust	R,K,I

GFlags and PageHeap

5/26/2017 • 1 min to read • [Edit Online](#)

This version of GFlags includes the functionality of PageHeap (pageheap.exe), a tool that enables heap allocation monitoring in Windows. PageHeap enables Windows features that reserve memory at the boundary of each allocation to detect attempts to access memory beyond the allocation.

The page heap options in GFlags let you select *standard heap verification*, which writes fill patterns at the end of each heap allocation and examines the patterns when the allocations are freed, or *full-page heap verification*, which places an inaccessible page at the end of each allocation so that the program stops immediately if it accesses memory beyond the allocation. Because full heap verification uses a full page of memory for each allocation, its widespread use can cause system memory shortages.

- To enable standard page heap verification for all processes, use **gflags /r +hpa** or **gflags /k +hpa**.
- To enable standard page heap verification for one process, use **gflags /p /enable ImageFileName**.
- To enable full page heap verification for one process, use **gflags /i ImageFileName +hpa** or **gflags /p /enable ImageFileName /full**.

All page heap settings, except for **/k**, are stored in the registry and remain effective until you change them.

Use care in interpreting the **Enable page heap** check box for an image file in the GFlags dialog box. It indicates that page heap verification is enabled for an image file, but it does not indicate whether it is full or standard page heap verification. If the check results from selecting the check box, then full page heap verification is enabled for the image file. However, if the check results from use of the command-line interface, then the check can represent the enabling of either full or standard page heap verification for the image file.

To determine whether full or standard page heap verification is enabled for a program, at the command line, type **gflags /p**. In the resulting display, **traces** indicates that standard page heap verification is enabled for the program and **full traces** indicates that full page heap verification is enabled for the program.

Monitoring Silent Process Exit

5/26/2017 • 5 min to read • [Edit Online](#)

Beginning with Windows 7, you can use the **Silent Process Exit** tab in GFlags to enter the name of a process that you want to monitor for silent exit.

In the context of this monitoring feature, we use the term *silent exit* to mean that the monitored process terminates in one of the following ways.

Self termination

The monitored process terminates itself by calling **ExitProcess**.

Cross-process termination

A second process terminates the monitored process by calling **TerminateProcess**.

The monitoring feature does not detect normal process termination that happens when the last thread of the process exits. The monitoring feature does not detect process termination that is initiated by kernel-mode code.

To register a process for silent exit monitoring, open the **Silent Process Exit** tab in GFlags. Enter the process name as the **Image** and press the **Tab** key. Check the **Enable Silent Process Exit Monitoring** box, and click **Apply**. This sets the `FLG_MONITOR_SILENT_PROCESS_EXIT` flag in the following registry entry.

HKLM\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\ProcessName\GlobalFlag

For more information about this flag, see [Enable silent process exit monitoring](#).

For more information about using the **Silent Process Exit** tab in GFlags, see [Configuring Silent Process Exit Monitoring](#).

In the **Silent Process Exit** tab of GFlags, you can configure the actions that will take place when a monitored process exits silently. You can configure notification, event logging, and creation of dump files. You can specify a process that will be launched when silent exit is detected, and you can specify a list of modules that the monitor will ignore. Several of these settings are available both globally and for individual applications. Global settings apply to all processes that you register for silent exit monitoring. Application settings apply to an individual process and override global settings.

Global settings are stored in the registry under the following key.

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\SilentProcessExit

Application settings are stored in the registry under the following key.

HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\SilentProcessExit*ProcessName*

Reporting Mode

The **Reporting Mode** setting is available as an application setting, but not as a global setting. You can use the following check boxes to set the reporting mode.

Launch monitor process **Enable dump collection** **Enable notification** The **ReportingMode** registry entry is a bitwise OR of the following flags.

FLAG	VALUE	MEANING
LAUNCH_MONITORPROCESS	0x1	When silent exit is detected, the monitor process (specified in the Monitor Process box) is launched.
LOCAL_DUMP	0x2	When silent exit is detected, a dump file is created for the monitored process. In the case of cross-process termination, a dump file is also created for the process that caused the termination.
NOTIFICATION	0x4	When silent exit is detected, a pop-up notification is displayed.

Ignore Self Exits

The **Ignore Self Exits** setting is available as an application setting, but not as a global setting. You can use the **Ignore Self Exits** check box to specify whether self exits are ignored.

The **IgnoreSelfExits** registry entry has one of the following values.

VALUE	MEANING
0x0	Detect and respond to both self termination and cross-process termination.
0x1	Ignore self termination. Detect and respond to cross-process termination.

Monitor Process

You can specify a monitor process by entering a process name, along with command line parameters, in the **Monitor Process** text box. You can use the following variables in your command line.

VARAIBLE	MEANING
%e	ID of the exiting process. This is the monitored process that exited silently.
%i	ID of the initiating process. In the case of self termination, this is the same as the exiting process. In the case of cross-process termination, this is the ID of the process that caused the termination.
%t	ID of the initiating thread. This is the tread that caused the termination.
%c	The status code passed to ExitThread or TerminateThread .

For example, the following value for **Monitor Process** specifies that on silent exit, WinDbg is launched and attached to the exiting process.

windbg -p %e

The **Monitor Process** command line is stored in the **MonitorProcess** registry entry.

Dump Folder Location

You can use the **Dump folder location** text box to specify a location for the dump files that are written when a silent exit is detected.

The string that you enter for **Dump folder location** is stored in the **LocalDumpFolder** registry entry.

If you do not specify a dump folder location, dump files are written to the default location, which is %TEMP%\Silent Process Exit.

Dump Folder Size

You can use the **Dump folder size** text box to specify the maximum number of dump files that can be written to the dump folder. Enter this value as a decimal integer.

The value that you enter for **Dump folder size** is stored in the **MaximumNumberOfDumpFiles** registry entry.

By default, there is no limit to the number of dump files that can be written.

Dump Type

You can use the **Dump Type** drop-down list to specify the type of dump file (Micro, Mini, Heap, or Custom) that is written when a silent exit is detected.

The dump type is stored in the **DumpType** registry entry, which is a bitwise OR of the members of the **MINIDUMP_TYPE** enumeration. This enumeration is defined in dbghelp.h, which is included in the Debugging Tools for Windows package.

For example, suppose you chose a dump type of **Micro**, and you see that the **DumpType** registry entry has a value of 0x88. The value 0x88 is a bitwise OR of the following two **MINIDUMP_TYPE** enumeration values.

MiniDumpFilterModulePaths	0x00000080
MiniDumpFilterMemory	0x00000008

If you choose a dump type of **Custom**, enter your own bitwise OR of **MINIDUMP_TYPE** enumeration values in the **Custom Dump Type** box. Enter this value as a decimal integer.

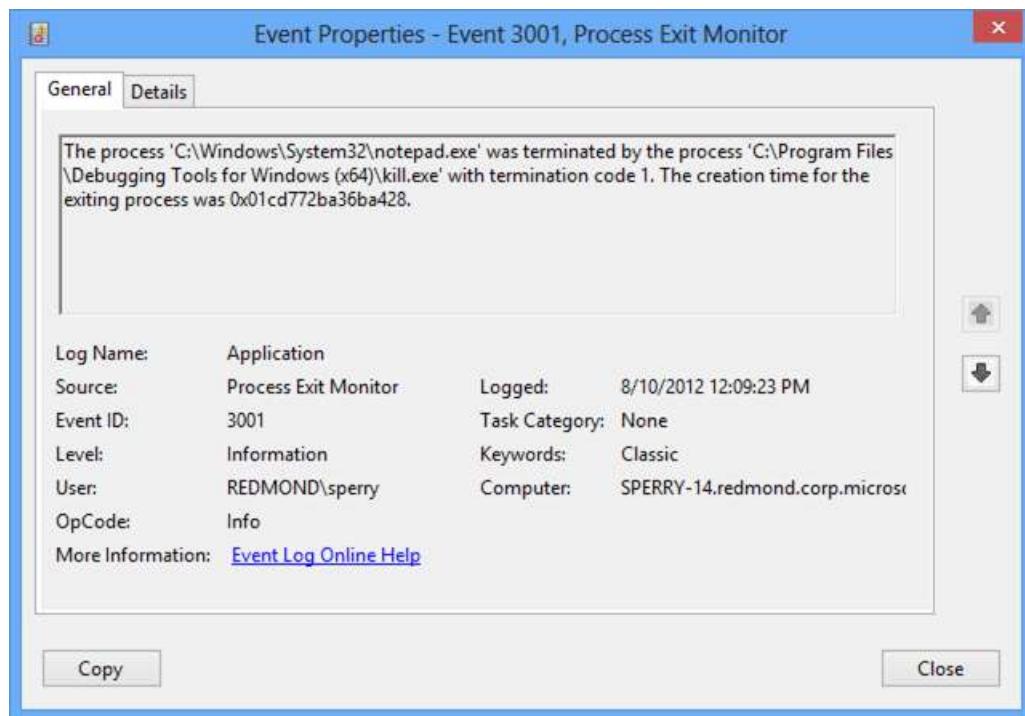

Module Ignore List

You can use the **Module Ignore List** box to specify a list of modules that will be ignored when a silent exit is detected. If the monitored process is terminated by one of the modules in this list, the silent exit is ignored.

The list of modules that you enter in the **Module Ignore List** box is stored in the **ModuleIgnoreList** registry entry.

Reading Process Exit Reports in Event Viewer

When a monitored process exits silently, the monitor creates an entry in Event Viewer. To open Event Viewer, enter the command **eventvwr.msc**. Navigate to **Windows Logs > Application**. Look for log entries that have a **Source** of Process Exit Monitor.

Send comments about this topic to Microsoft

Global Flags Dialog Box

5/26/2017 • 1 min to read • [Edit Online](#)

You can use the **Global Flags** dialog box to set and clear global flags from a user interface that lists all flags by name. There is no need to look up flag abbreviations or hexadecimal values.

Also, the dialog box provides access to the following features that are not available from the command line:

- **Debugger** – Specifies that a particular program always runs in a debugger.
- **Launch** – Runs a program with the specified debugging settings.
- **Kernel Special Pool Tag** – Configures the Special Pool feature.

This topic includes instructions for the following procedures:

[Opening the Dialog Box](#)

[Setting and Clearing System-wide Flags](#)

[Setting and Clearing Kernel Flags](#)

[Setting and Clearing Image File Flags](#)

[Launching a Program with Flags](#)

[Running a Program in a Debugger](#)

[Configuring Special Pool](#)

[Configuring Object Reference Tracing](#)

Pool tagging is permanently enabled on Windows Server 2003 and later versions of Windows. On these systems, the **Enable pool tagging** check box on the **Global Flags** dialog box is dimmed, and commands to enable or disable pool tagging fail.

Use care in interpreting the **Enable page heap** check box for an image file in the **Global Flags** dialog box. This check box indicates that page heap verification is enabled for an image file, but it does not indicate whether it is full or standard page heap verification. If the check results from selecting the check box, then full page heap verification is enabled for the image file. However, if the check results from use of the command-line interface, then the check can represent the enabling of either full or standard page heap verification for the image file.

To determine whether a full or standard page heap verification is enabled for a program, at the command line, type **gflags /p**. In the resulting display, **traces** indicates that standard page heap verification is enabled for the program and **full traces** indicates that full page heap verification is enabled for the program.

[Send comments about this topic to Microsoft](#)

Opening the Dialog Box

5/26/2017 • 1 min to read • [Edit Online](#)

To open the Global Flags dialog box

- Double-click the **gflags.exe** icon or, at the command line, or in the **Run** dialog box, type **gflags** (without parameters).
 - OR
- Click **Start**, point to **All Programs**, point to **Debugging Tools for Windows**, and then click **Global Flags**.

On Windows Vista, click **Start**, click **All Programs**, click **Debugging Tools for Windows**, right-click **Global Flags** and then click **Run as administrator**. If you omit this step, Windows displays the **System Registry**

Gflags Error: 5. The Gflags dialog box opens, but Gflags commands fail.

[Send comments about this topic to Microsoft](#)

Setting and Clearing System-wide Flags

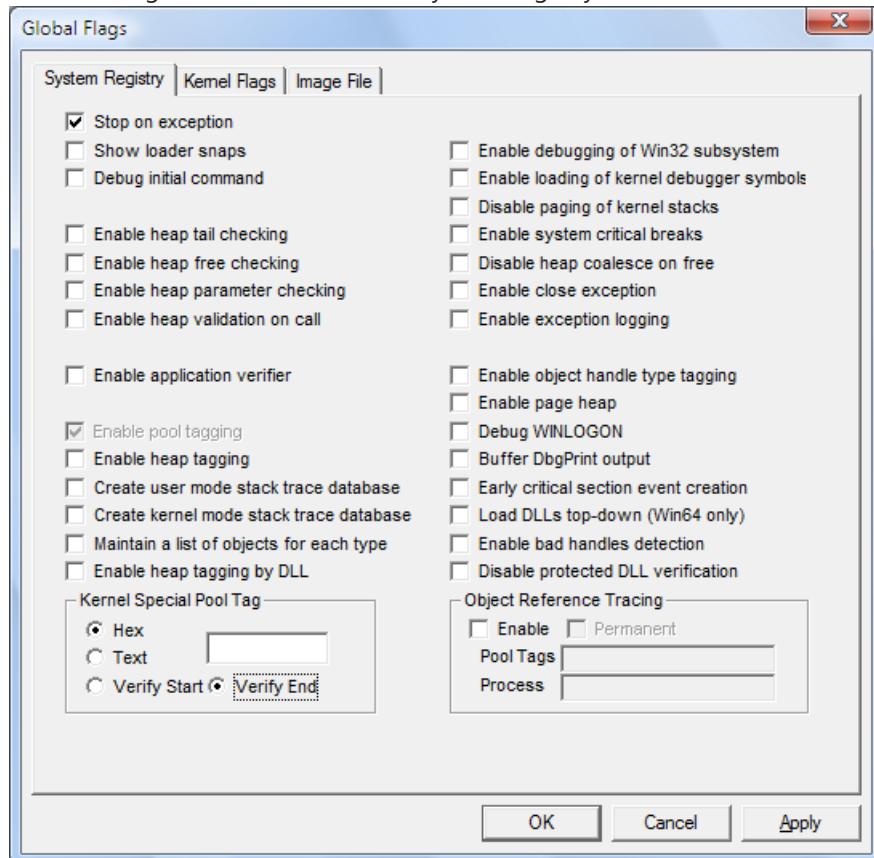

5/26/2017 • 1 min to read • [Edit Online](#)

System-wide registry settings affect all processes running on Windows. They are saved in the registry and remain effective until you change them.

To set and clear system-wide registry flags

1. Click the **System Registry** tab.

The following screen shot shows the System Registry tab in Windows Vista.

2. Set or clear a flag by selecting or clearing the check box associated with the flag.
3. When you have selected or cleared all of the flags that you want, click **Apply**.
4. Restart Windows to make the changes effective.

[Send comments about this topic to Microsoft](#)

Setting and Clearing Kernel Flags

5/26/2017 • 1 min to read • [Edit Online](#)

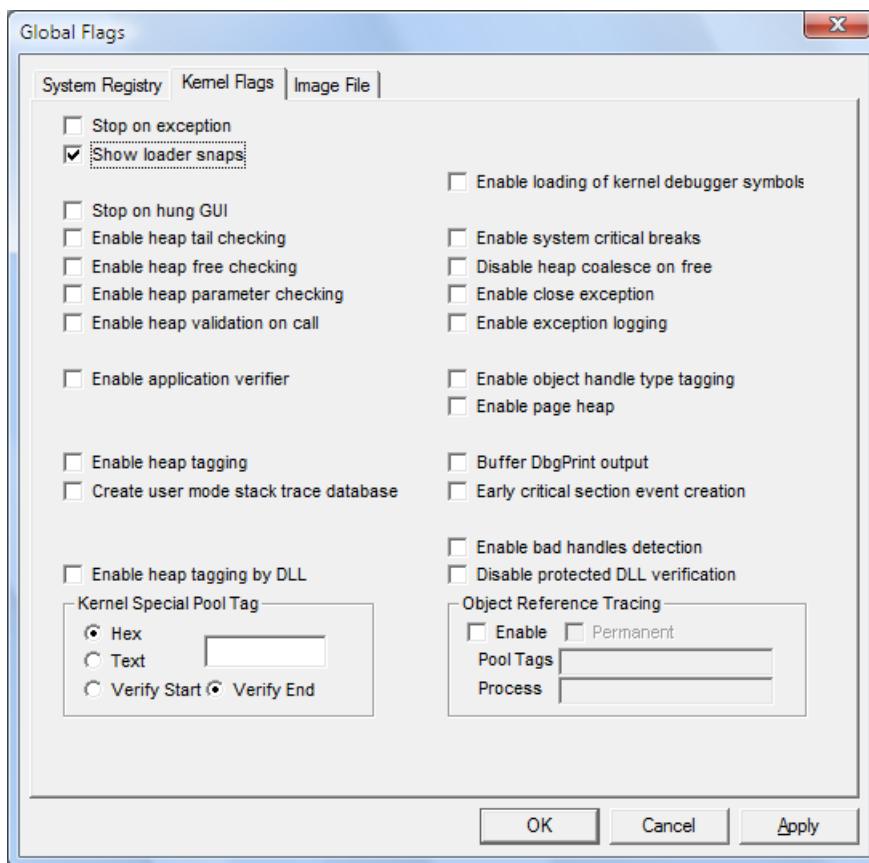

Kernel flag settings, also known as "run-time settings," affect the entire system. They take effect immediately without rebooting, but they are lost if you shut down or restart the system.

Kernel settings take precedence over registry settings during run time, but when you shut down or restart the system, the kernel flag settings are lost and the registry settings are effective again.

To set and clear kernel flags

1. Click the **Kernel Flags** tab.

The following screen shot shows the **Kernel Flags** tab in Windows Vista.

2. Set or clear a flag by selecting or clearing the check box associated with the flag.
3. When you have selected or cleared all of the flags that you want, click **Apply**.

[Send comments about this topic to Microsoft](#)

Setting and Clearing Image File Flags

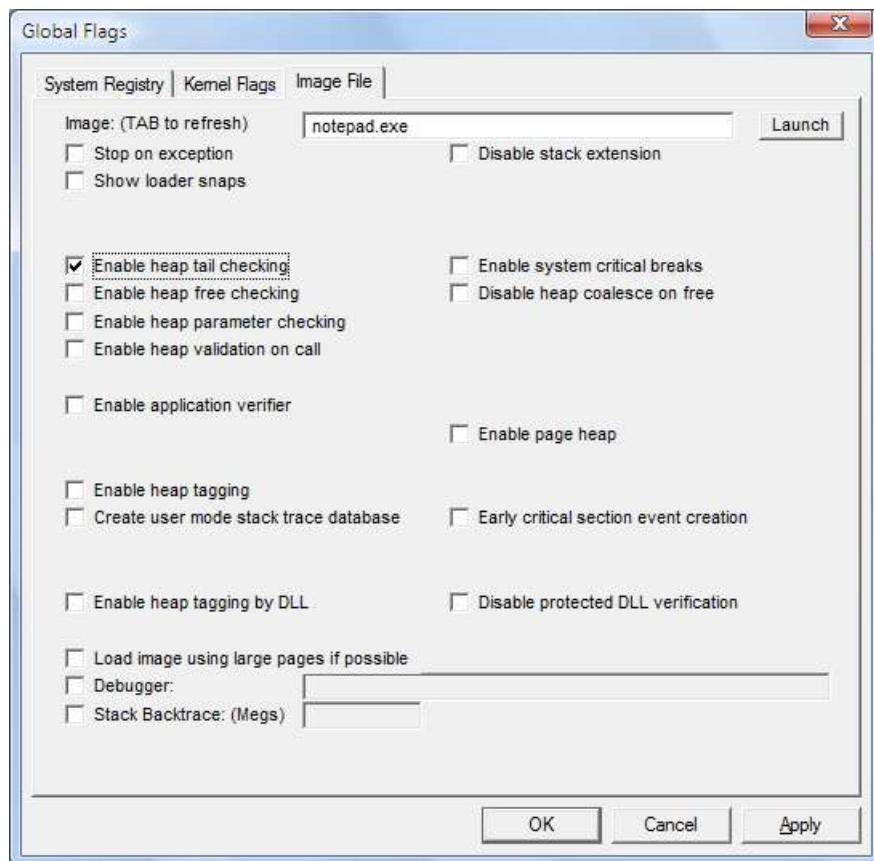

5/26/2017 • 1 min to read • [Edit Online](#)

Image file settings affect instances of the specified program that start after the command completes. They are saved in the registry and remain effective until you change them.

To set and clear the image file registry flags

1. Click the **Image File** tab.

The following screen shot shows the **Image File** tab in Windows Vista.

2. In the **Image** box, type the name of an executable file or DLL, including the file name extension, and then press the TAB key.

This activates the check boxes on the **Image File** tab.

3. Set or clear a flag by selecting or clearing the check box associated with the flag.
4. When you have selected or cleared all of the flags you want, click **Apply**.

[Send comments about this topic to Microsoft](#)

Configuring Silent Process Exit Monitoring

5/26/2017 • 1 min to read • [Edit Online](#)

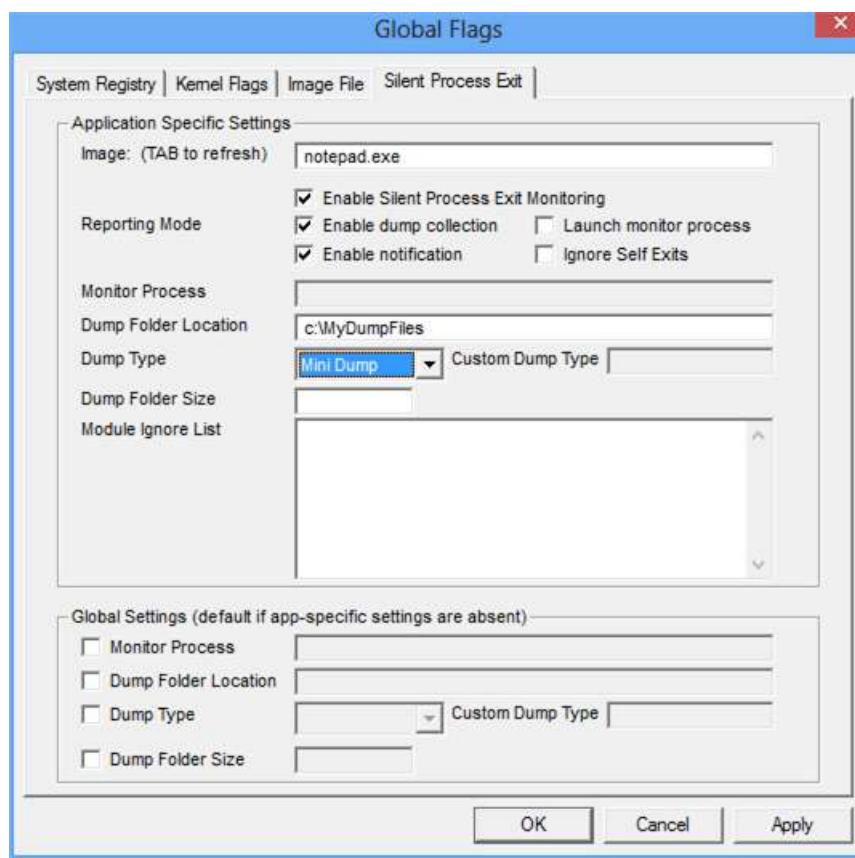

Beginning in Windows 7, you can use the **Silent Process Exit** tab to enable and configure monitoring of silent exit for a process.

Settings that you specify in the **Silent Process Exit** tab are saved in the registry and remain effective until you change them.

To enable and configure silent process exit monitoring

1. Click the **Silent Process Exit** tab.

The following screen shot shows the **Silent Process Exit** tab in Windows 8.

2. In the **Image** box, type the name of an executable file, including the file name extension, and then press the TAB key.

This activates the check boxes on the **Silent Process Exit** tab.

3. Specify your preferences by selecting or clearing check boxes and by entering values in text boxes.
4. When you specified all of your preferences, click **Apply**.

Launching a Program with Flags

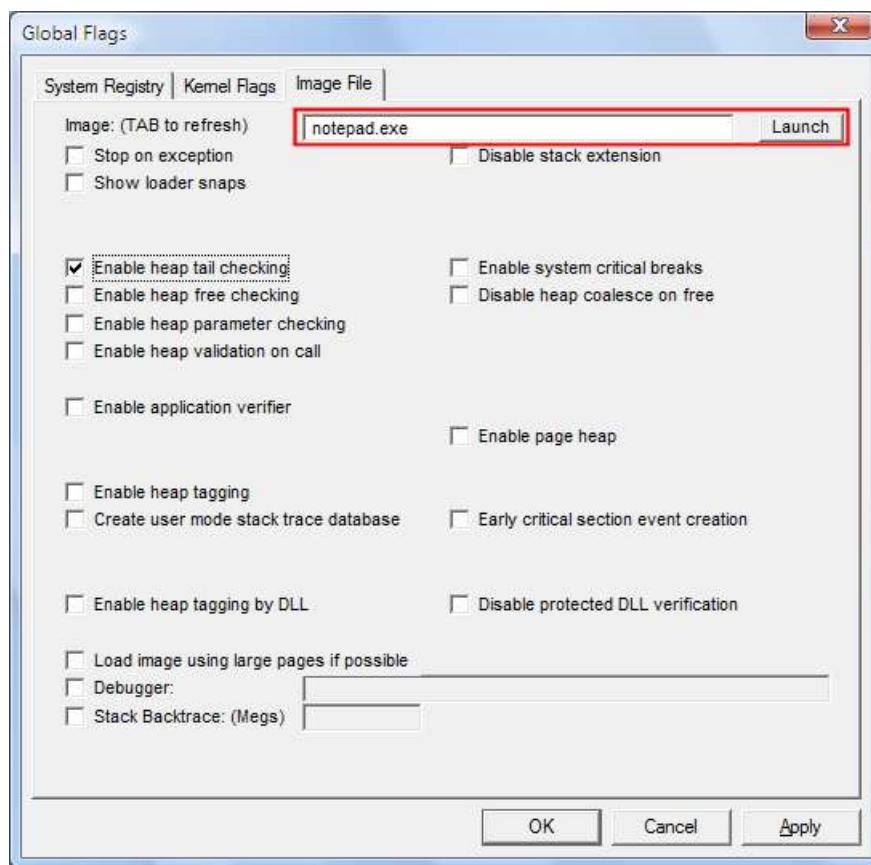

5/26/2017 • 1 min to read • [Edit Online](#)

This feature runs a program once with the specified flags. These settings affect only the instance of the program launched. They are not saved in the registry.

To launch a program with flags

1. Click the **Image File** tab.
 2. In the **Image** box, type the name of an executable file or DLL, including the file name extension, and any commands for the program, and then press the TAB key.
- This activates the **Launch** button and the check boxes on the **Image File** tab.
3. Set or clear a flag by selecting or clearing the check box associated with the flag.
 4. Click the **Launch** button.

The following screen shot shows the **Launch** button on the **Image File** tab in Windows Vista.

Note Flags set in the registry do not affect the instance of the program that is launched. Flags set in the dialog box are used for the launched instance even when they are not image file flags.

[Send comments about this topic to Microsoft](#)

Running a Program in a Debugger

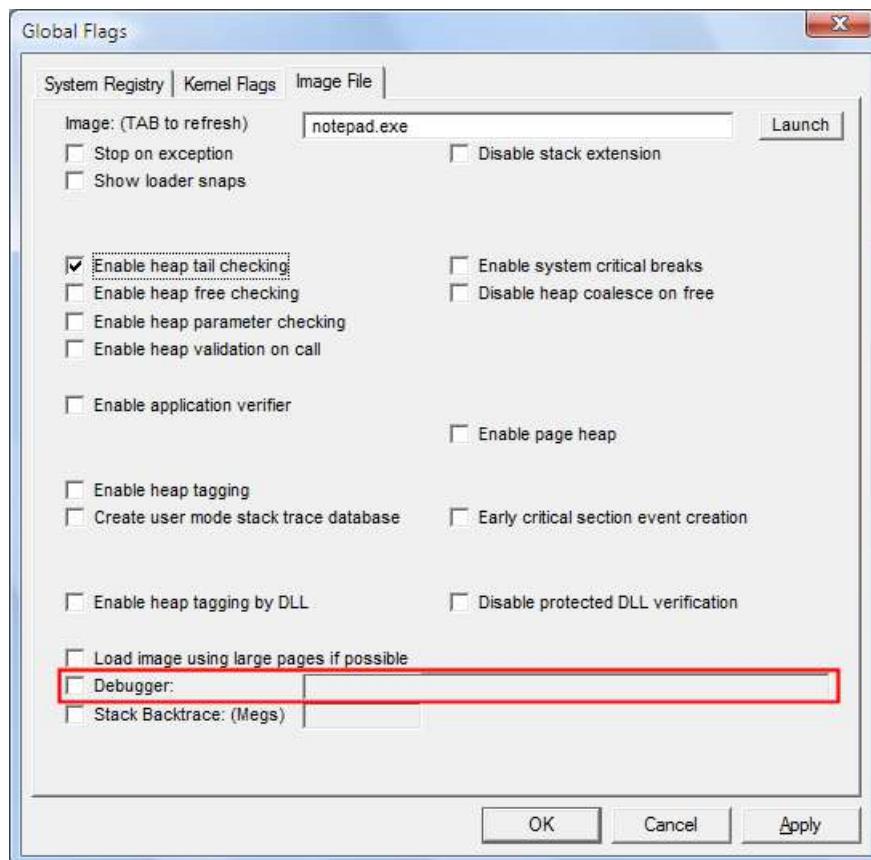

5/26/2017 • 1 min to read • [Edit Online](#)

This feature configures the program so that it always runs in a debugger with the specified options. This setting is saved in the registry. It affects all new instances of the program and remains effective until you change it.

To run a program in a debugger

1. Click the **Image File** tab.
2. In the **Image** box, type the name of an executable file or DLL, including the file name extension, and then press the TAB key.
This activates the check boxes on the **Image File** tab.
3. Click the **Debugger** check box to select it.

The following screen shot shows the **Debugger** check box on the **Image File** tab in Windows Vista.

4. In the **Debugger** box, type the command to run the debugger, including the path (optional) and name of the debugger and parameters. For example, **ntsd -d -g -G** or **c:\debuggers\cdb.exe -g -G**.
5. Click **Apply**.

[Send comments about this topic to Microsoft](#)

Configuring Special Pool

5/26/2017 • 1 min to read • [Edit Online](#)

The Gflags *Special Pool* feature directs Windows to request memory allocations from a reserved memory pool when the memory is allocated with a specified pool tag or is within a specified size range.

For detailed information about this feature, see [Special Pool](#).

In Windows Vista and later versions of Windows, you can configure the Special Pool feature as a system-wide registry setting or as a kernel flags setting that does not require a reboot. In earlier versions of Windows, Special Pool is available only as a registry setting.

In Windows Vista and later versions of Windows, you can also use the command line to request special pool by pool tag. For information, see [GFlags Commands](#).

This section includes the following topics.

[Requesting Special Pool by Pool Tag](#)

[Requesting Special Pool by Allocation Size](#)

[Canceling Requests for Special Pool](#)

[Detecting Overruns and Underruns](#)

Note Use *Driver Verifier* to request special pool for allocations by a particular driver. For more information, see the "Special Pool" topic in the "Driver Verifier" section of the Windows Driver Kit (WDK).

[Send comments about this topic to Microsoft](#)

Requesting Special Pool by Pool Tag

5/26/2017 • 1 min to read • [Edit Online](#)

You can request special pool for all allocations that use a specified pool tag. Only one pool tag on the system can be associated with kernel special pool requests at one time.

In Windows Vista and later versions of Windows, you can also use the command line to request special pool by pool tag. For information, see [GFlags Commands](#).

To request special pool by pool tag

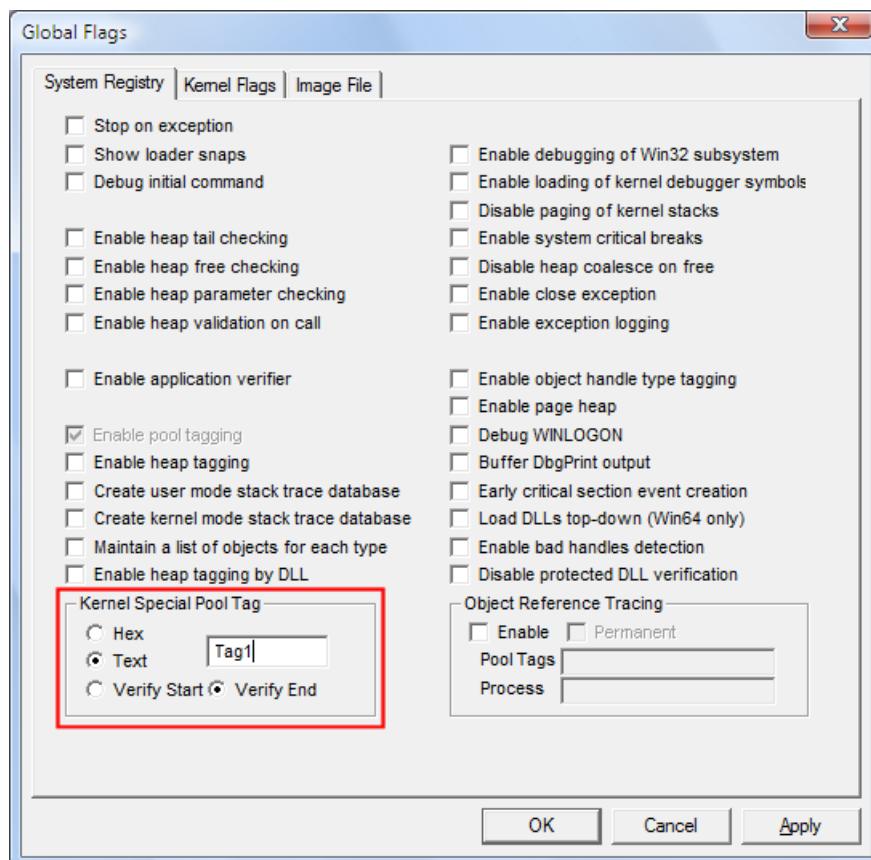

1. Select the **System Registry** tab or the **Kernel Flags** tab.

On Windows Vista and later versions of Windows, this option is available on both tabs. On earlier versions of Windows, it is available only on the **System Registry** tab.

2. In the **Kernel Special Pool Tag** section, click **Text**, and then type a four-character pattern for the tag.

The tag can include the ? (single character) and * (multiple characters) wildcard characters. For example, Fat* or Av?4.

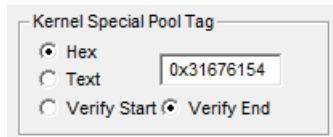

3. The following screen shot shows a tag entered as text on the System Registry tab.

4. Click **Apply**.

When you click **Apply**, GFlags changes the selection from **Text** to **Hex** and displays the ASCII characters as hexadecimal values in reverse (lower endian) order. For example, if you type **Tag1**, GFlags displays the tag as **0x31676154** (1gaT). This is the way that it is stored in the registry and displayed by the debugger and other tools.

The following illustration shows the effect of clicking **Apply**.

Remarks

To use this feature effectively, make sure that your driver or other kernel-mode program uses a unique pool tag. If you suspect that your driver is consuming all of the special pool, consider using multiple pool tags in your code. You can then test your driver several times, assigning special pool to one pool tag in each test.

Also, select a pool tag with a hexadecimal value that is greater than the page size of the system. For kernel mode code, if you enter a pool tag that has a value less than PAGE_SIZE, Gflags requests special pool for all allocations whose size is within the corresponding range and requests special pool for allocations with an equivalent pool tag. For example, if you select a size of **30**, special pool will be used for all allocations between 17 and 32 bytes in size, and for allocations with the pool tag 0x0030.

[Send comments about this topic to Microsoft](#)

Requesting Special Pool by Allocation Size

5/26/2017 • 1 min to read • [Edit Online](#)

You can request special pool for allocations within a specified size range.

In Windows Vista and later versions of Windows, you can also use the command line to request special pool by pool tag. For information, see [GFlags Commands](#).

Note This method is rarely useful for diagnosing driver errors, because it affects all kernel pool requests of the specified size, regardless of which driver or kernel module requested the allocation.

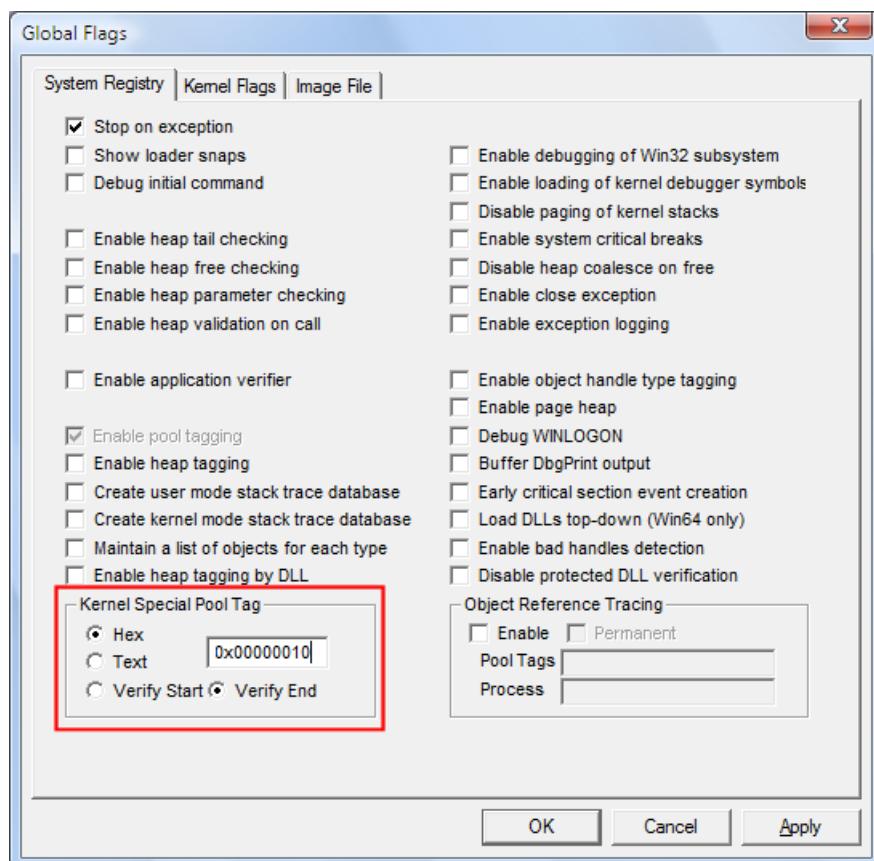

To request special pool by allocation size

1. Select the **System Registry** tab or the **Kernel Flags** tab.

On Windows Vista and later versions of Windows, this option is available on both tabs. On earlier versions of Windows, it is available only on the **System Registry** tab.

2. In the **Kernel Special Pool Tag** section, click **Hex**, and then type a number in hexadecimal format that represents a range of sizes. All allocations within this size range will be allocated from special pool. This number must be less than PAGE_SIZE.
3. Click **Apply**.

The following screen shot shows an allocation size entered as a hexadecimal value.

Send comments about this topic to Microsoft

Canceling Requests for Special Pool

5/26/2017 • 1 min to read • [Edit Online](#)

You can use GFlags to cancel a request for allocation from the special pool if the request was made by using GFlags. You cannot use GFlags to cancel a request for special pool that was made by using Driver Verifier.

In Windows Vista and later versions of Windows, you can also use the command line to cancel special pool requests. For information, see [GFlags Commands](#).

To cancel requests for special pool

1. Select the System Registry tab or the Kernel Flags tab.

On Windows Vista and later versions of Windows, this option is available on both tabs. On earlier versions of Windows, it is available only on the **System Registry** tab.

2. Delete the text or hexadecimal value from the **Kernel Special Pool Tag** box.
3. Click **Apply**.

[Send comments about this topic to Microsoft](#)

Detecting Overruns and Underruns

5/26/2017 • 1 min to read • [Edit Online](#)

You can use the **Verify Start** or **Verify End** option in GFlags to align allocations from the special pool so that they are best suited to detect overruns (accessing memory past the end of the allocation) or underruns (accessing memory that precedes the beginning of the allocation).

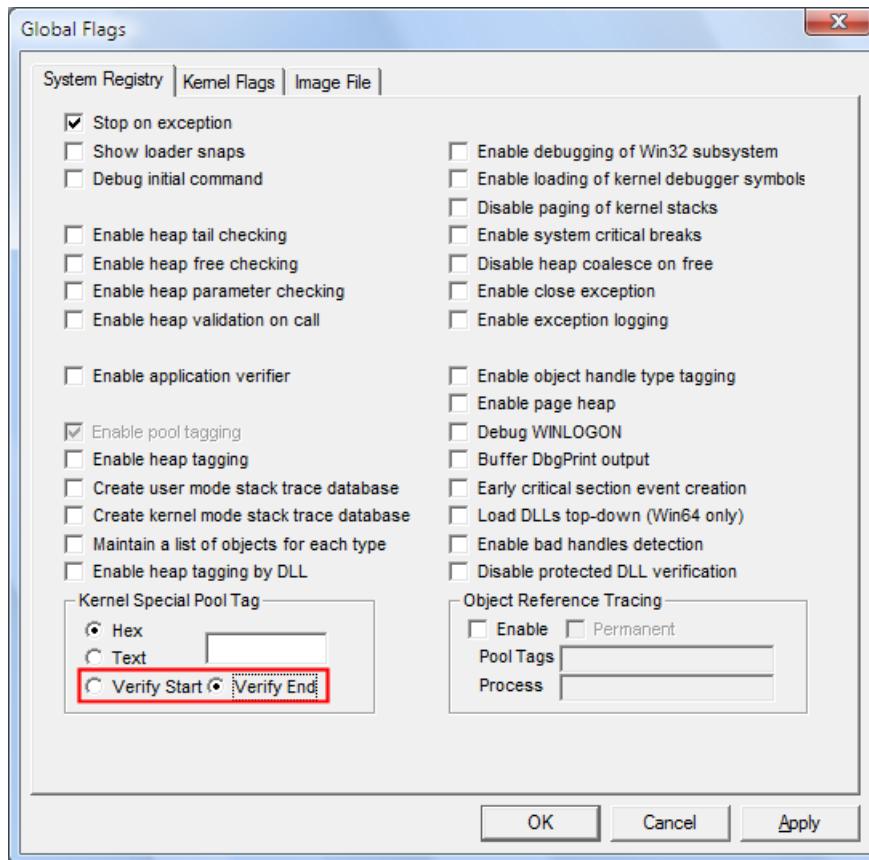

- **Verify Start** enables underrun detection on allocations from the special pool. This causes a bug check when a program tries to access memory preceding its special pool memory allocation.
- **Verify End** enables overrun detection on allocations from the special pool. This causes a bug check when a program tries to access memory beyond its special pool memory allocation. Because overruns are much more common, **Verify End** is the default.

In Windows Vista and later versions of Windows, this option is available on the **System Registry** and **Kernel Flags** tabs. In earlier versions of Windows, it is available only on the **System Registry** tab.

To specify special pool alignment

1. Click the **System Registry** tab.
2. Click **Verify Start** or **Verify End**.
3. Click **Apply**.

The following screen shot shows the Verify Start and Verify End settings on the System **Registry** tab.

Comments

The **Verify Start** and **Verify End** alignment settings apply to all allocations from the special pool, including special pool allocation requests set in Driver Verifier. If you set the alignment without specifying a pool tag or allocation

size, then the settings apply only to requests set in Driver Verifier.

[Send comments about this topic to Microsoft](#)

Configuring Object Reference Tracing

5/26/2017 • 1 min to read • [Edit Online](#)

You can use Gflags to enable, disable, and configure the Object Reference Tracing feature of Windows. Object Reference Tracing records sequential stack traces whenever an object reference counter is incremented or decremented. The traces can help you to detect object reference errors, including double-dereferencing, failure to reference, and failure to dereference objects. This feature is supported only in Windows Vista and later versions of Windows. For detailed information about this feature, see [Object Reference Tracing](#).

To enable Object Reference Tracing

1. In the Gflags dialog box, select the **System Registry** tab or the **Kernel Flags** tab.
2. In the Object Reference Tracing section, select **Enable**.

You must limit the trace to objects with specified pool tags, to objects created by a specified process, or both.

3. To limit the trace to objects with a particular pool tag, type the pool tag name. To list multiple pool tags, use semicolons (;) to separate the pool tags. When you list multiple pool tags, the trace includes objects with any of the specified pool tags. Pool tags are case sensitive.

For example, Fred;Tag1.

4. To limit the trace to objects that are created by a particular process, type the image name of the process. You can specify only one image file name.

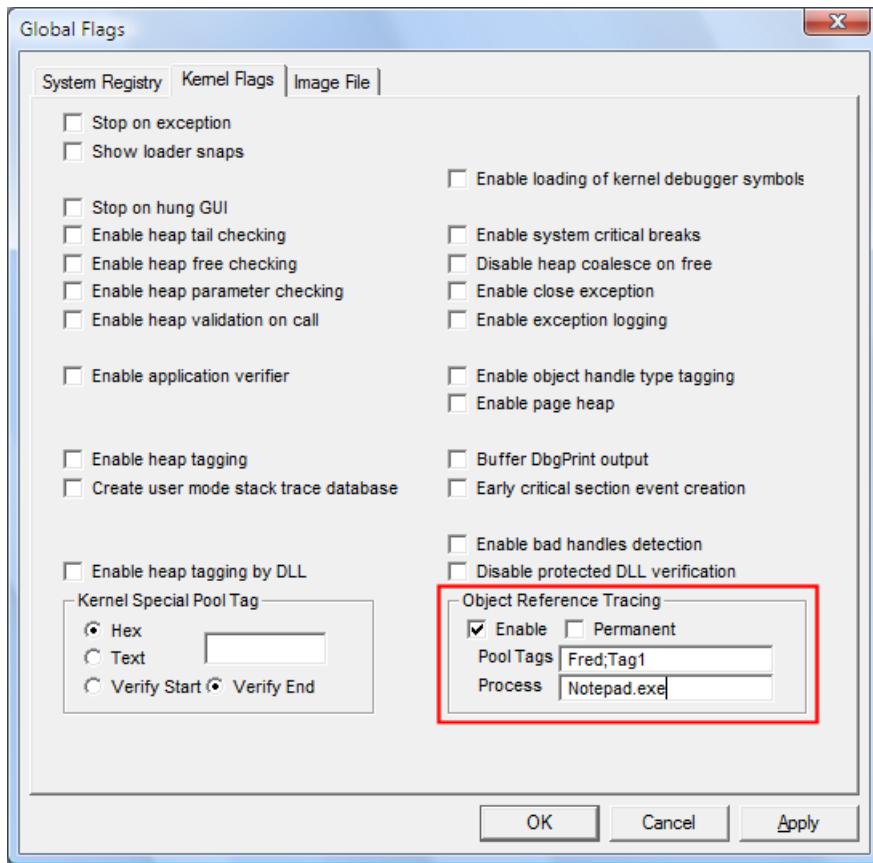

When you specify both pool tags and a process, the trace includes objects that are created by the process that have any of the specified pool tags.

5. To retain the trace after the trace object is destroyed, select **Permanent**.

When you select **Permanent**, the trace is retained until you disable object reference tracing, or shut down or restart Windows.

6. Click **Apply** or **OK**.

The following screen shot shows Object Reference Tracing enabled on the **Kernel Flags** tab.

This trace will include only objects that were created by the notepad.exe process that have the pool tag **Fred** or **Tag1**. Because this is a run time (kernel flags) setting, the trace starts immediately. If it were a registry setting, you would have to restart Windows to start the trace.

To disable Object Reference Tracing

1. In the Gflags dialog box, select the **System Registry** tab or the **Kernel Flags** tab. Object Reference Tracing will appear on the latter tab only in Windows Vista and later versions of Windows.
2. In the Object Reference Tracing section, clear the **Enable** check box.

[Send comments about this topic to Microsoft](#)

Global Flag Reference

5/26/2017 • 1 min to read • [Edit Online](#)

This reference describes the flags that GFlags sets.

Note The symbolic name of each flag is provided for reference only. Because symbolic names change, they are not a reliable identifier of a global flag.

The global flags include:

[Buffer DbgPrint Output](#)

[Create kernel mode stack trace database](#)

[Create user mode stack trace database](#)

[Debug initial command](#)

[Debug WinLogon](#)

[Disable heap coalesce on free](#)

[Disable paging of kernel stacks](#)

[Disable protected DLL verification](#)

[Disable stack extension](#)

[Early critical section event creation](#)

[Enable application verifier](#)

[Enable bad handles detection](#)

[Enable close exception](#)

[Enable debugging of Win32 subsystem](#)

[Enable exception logging](#)

[Enable heap free checking](#)

[Enable heap tagging](#)

[Enable heap tagging by DLL](#)

[Enable heap tail checking](#)

[Enable heap validation on call](#)

[Enable loading of kernel debugger symbols](#)

[Enable object handle type tagging](#)

[Enable page heap](#)

[Enable pool tagging](#)

[Enable system critical breaks](#)

[Load image using large pages if possible](#)

Maintain a list of objects for each type

[Object Reference Tracing](#)

Show loader snaps

Special Pool

Stop on exception

Stop on hung GUI

Stop on unhandled user-mode exception

[Send comments about this topic to Microsoft](#)

Buffer DbgPrint Output

5/26/2017 • 1 min to read • [Edit Online](#)

The **Buffer DbgPrint Output** flag suppresses debugger output from **DbgPrint**, **DbgPrintEx**, **KdPrint**, and **KdPrintEx** calls.

Abbreviation	ddp
Hexadecimal value	0x08000000
Symbolic Name	FLG_DISABLE_DBGPRINT
Destination	System-wide registry entry, kernel flag

Comments

When debugger output is suppressed, it does not automatically appear in the kernel debugger. However, the message is always sent to the DbgPrint buffer, where it can be accessed by using the **!dbgprint** debugger extension.

For information about the functions that communicate with the debugger, see [Sending Output to the Debugger](#).

[Send comments about this topic to Microsoft](#)

Create kernel mode stack trace database

5/26/2017 • 1 min to read • [Edit Online](#)

The **Create kernel mode stack trace database** flag creates a run-time stack trace database of kernel operations, such as resource objects and object management operations, and works only when using the checked build of Windows.

Abbreviation	kst
Hexadecimal value	0x2000
Symbolic Name	FLG_KERNEL_STACK_TRACE_DB
Destination	System-wide registry entry

Comments

GFlags displays this flag as a kernel flag setting, but it is not effective at run time, because the kernel is already started.

[Send comments about this topic to Microsoft](#)

Create user mode stack trace database

5/26/2017 • 1 min to read • [Edit Online](#)

The **Create user mode stack trace database** flag creates a run-time stack trace database in the address space of a particular process (image file mode) or all processes (system-wide).

Abbreviation	ust
Hexadecimal value	0x1000
Symbolic Name	FLG_USER_STACK_TRACE_DB
Destination	System-wide registry entry, kernel flag, image file registry entry

[Send comments about this topic to Microsoft](#)

Debug initial command

5/26/2017 • 1 min to read • [Edit Online](#)

The **Debug initial command** flag debugs the Client Server Run-time Subsystem (CSRSS) and the WinLogon process.

Abbreviation	dic
Hexadecimal value	0x4
Symbolic Name	FLG_DEBUG_INITIAL_COMMAND
Destination	System-wide registry entry, kernel flag

Comments

NTSD debugs the processes (using the command **ntsd -d**), but control is redirected to the kernel debugger.

For details on NTSD, see [Debugging Using CDB and NTSD](#).

See Also

[Enable debugging of Win32 subsystem](#)

[Send comments about this topic to Microsoft](#)

Debug WinLogon

5/26/2017 • 1 min to read • [Edit Online](#)

The **Debug WinLogon** flag debugs the WinLogon service.

Abbreviation	dwl
Hexadecimal value	0x04000000
Symbolic Name	FLG_DEBUG_INITIAL_COMMAND_EX
Destination	System-wide registry entry

Comments

NTSD debugs Winlogon (by using the command **ntsd -d -g -x**), but control is redirected to the kernel debugger.

For details on NTSD, see [Debugging Using CDB and NTSD](#).

See Also

[Debug initial command](#), [Enable debugging of Win32 subsystem](#)

Disable heap coalesce on free

5/26/2017 • 1 min to read • [Edit Online](#)

The **Disable heap coalesce on free** flag leaves adjacent blocks of heap memory separate when they are freed.

Abbreviation	dhc
Hexadecimal value	0x00200000
Symbolic Name	FLG_HEAP_DISABLE_COALESCING
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

By default, Windows combines ("coalesces") newly-freed adjacent blocks into a single block. Combining the blocks takes time, but reduces fragmentation that might force the heap to allocate additional memory when it cannot find contiguous memory.

This flag is used for maintaining compatibility with old applications.

[Send comments about this topic to Microsoft](#)

Disable paging of kernel stacks

5/26/2017 • 1 min to read • [Edit Online](#)

The **Disable paging of kernel stacks** flag prevents paging of the kernel-mode stacks of inactive threads.

Abbreviation	dps
Hexadecimal value	0x80000
Symbolic Name	FLG_DISABLE_PAGE_KERNEL_STACKS
Destination	System-wide registry entry

Comments

Generally, the kernel-mode stack cannot be paged; it is guaranteed to be resident in memory. However, Windows occasionally pages the kernel stacks of inactive threads. This flag prevents these occurrences.

The kernel debugger can provide information about a thread only when its stack is in physical memory. This flag is particularly important when debugging deadlocks and in other cases when every thread must be tracked.

[Send comments about this topic to Microsoft](#)

Disable protected DLL verification

5/26/2017 • 1 min to read • [Edit Online](#)

The **Disable protected DLL verification** flag appears in GFlags, but it has no effect on Windows.

Abbreviation	dpd
Hexadecimal value	0x80000000
Symbolic Name	FLG_DISABLE_PROTDLLS
Destination	System-wide registry entry, kernel flag, image file registry entry

[Send comments about this topic to Microsoft](#)

Disable stack extension

5/26/2017 • 1 min to read • [Edit Online](#)

The **Disable stack extension** flag prevents the kernel from extending the stacks of the threads in the process beyond the initial committed memory.

Abbreviation	dse
Hexadecimal value	0x10000
Symbolic Name	FLG_DISABLE_STACK_EXTENSION
Destination	Image file registry entry

Comments

This feature is used to simulate low memory conditions (where stack extensions fail) and to test the strategic system processes that are expected to run well even with low memory.

[Send comments about this topic to Microsoft](#)

Early critical section event creation

5/26/2017 • 1 min to read • [Edit Online](#)

The **Early critical section event creation** flag creates event handles when a critical section is initialized, rather than waiting until the event is needed.

Abbreviation	cse
Hexadecimal value	0x10000000
Symbolic Name	FLG_CRITSEC_EVENT_CREATION
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

When Windows cannot create an event, it generates the exception during initialization and the calls to enter and leave the critical section do not fail.

Because this flag uses a significant amount of nonpaged pool memory, use it only on very reliable systems that have sufficient memory.

[Send comments about this topic to Microsoft](#)

Enable application verifier

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable application verifier** flag enables system features that are used for user-mode application testing, such as page heap verification, lock checks, and handle checks.

Abbreviation	vrf
Hexadecimal value	0x100
Symbolic Name	FLG_APPLICATION_VERIFIER
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

This flag enables only the most basic detection features. To test user-mode applications reliably, use Application Verifier (appverif.exe). For more information, see [Application Verifier](#).

[Send comments about this topic to Microsoft](#)

Enable bad handles detection

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable bad handles detection** flag raises a user-mode exception (STATUS_INVALID_HANDLE) whenever a user-mode process passes an invalid handle to the Object Manager.

Abbreviation	bhd
Hexadecimal value	0x40000000
Symbolic Name	FLG_ENABLE_HANDLE_EXCEPTIONS
Destination	System-wide registry entry, kernel flag

[Send comments about this topic to Microsoft](#)

Enable close exception

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable close exception** flag raises a user-mode exception whenever an invalid handle is passed to the **CloseHandle** interface or related interfaces, such as **SetEvent**, that take handles as arguments.

Abbreviation	ece
Hexadecimal value	0x00400000
Symbolic Name	FLG_ENABLE_CLOSE_EXCEPTIONS
Destination	System-wide registry entry, kernel flag

Note This flag is still supported, but the [Enable bad handles detection](#) flag (bhd), which performs a more comprehensive check of handle use, is preferred.

[Send comments about this topic to Microsoft](#)

Enable debugging of Win32 subsystem

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable debugging of Win32 subsystem** flag debugs the Client Server Run-time Subsystem (csrss.exe) in the NTSD debugger.

Abbreviation	d32
Hexadecimal value	0x20000
Symbolic Name	FLG_ENABLE_CSRDEBUG
Destination	System-wide registry entry

Comments

NTSD debugs the process by using the command **ntsd -d -p -1**.

This flag is effective only when the [Debug initial command](#) flag (dic) or the [Debug WinLogon](#) flag (dwl) is also set.

For details on NTSD, see [Debugging Using CDB and NTSD](#).

[Send comments about this topic to Microsoft](#)

Enable exception logging

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable exception logging** flag creates a log of exception records in the kernel run-time library. You can access the log from a kernel debugger.

Abbreviation	eel
Hexadecimal value	0x00800000
Symbolic Name	FLG_ENABLE_EXCEPTION_LOGGING
Destination	System-wide registry entry, kernel flag

[Send comments about this topic to Microsoft](#)

Enable heap free checking

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable heap free checking** flag validates each heap allocation when it is freed.

Abbreviation	hfc
Hexadecimal value	0x20
Symbolic Name	FLG_HEAP_ENABLE_FREE_CHECK
Destination	System-wide registry entry, kernel flag, image file registry entry

See Also

[Enable heap tail checking](#), [Enable heap parameter checking](#)

Enable heap parameter checking

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable heap parameter checking** flag verifies selected aspects of the heap whenever a heap function is called.

Abbreviation	hpc
Hexadecimal value	0x40
Symbolic Name	FLG_HEAP_VALIDATE_PARAMETERS
Destination	System-wide registry entry, kernel flag, image file registry entry

See Also

[Enable heap validation on call](#)

[Send comments about this topic to Microsoft](#)

Enable heap tagging

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable heap tagging** flag assigns unique tags to heap allocations.

Abbreviation	htg
Hexadecimal value	0x800
Symbolic Name	FLG_HEAP_ENABLE_TAGGING
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

You can display the tag by using the **[!heap](#)** debugger extension with the **-t** parameter.

See Also

[Enable heap tagging by DLL](#)

[Send comments about this topic to Microsoft](#)

Enable heap tagging by DLL

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable heap tagging by DLL** flag assigns a unique tag to heap allocations created by the same DLL.

Abbreviation	htd
Hexadecimal value	0x8000
Symbolic Name	FLG_HEAP_ENABLE_TAG_BY_DLL
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

You can display the tag by using the **[!heap](#)** debugger extension with the **-t** parameter.

See Also

[Enable heap tagging](#)

[Send comments about this topic to Microsoft](#)

Enable heap tail checking

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable heap tail checking** flag checks for buffer overruns when the heap is freed.

Abbreviation	htc
Hexadecimal value	0x10
Symbolic Name	FLG_HEAP_ENABLE_TAIL_CHECK
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

This flag adds a short pattern to the end of each allocation. The Windows heap manager detects the pattern when the block is freed and, if the block was modified, the heap manager breaks into the debugger.

See Also

[Enable heap free checking](#), [Enable heap parameter checking](#)

[Send comments about this topic to Microsoft](#)

Enable heap validation on call

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable heap validation on call** flag validates the entire heap each time a heap function is called.

Abbreviation	hvc
Hexadecimal value	0x80
Symbolic Name	FLG_HEAP_VALIDATE_ALL
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

To avoid the high overhead associated with this flag, use the **HeapValidate** function instead of setting this flag, especially at critical junctures, such as when the heap is destroyed. However, this flag is useful for detecting random corruption in a pool.

See Also

[Enable heap parameter checking](#)

[Send comments about this topic to Microsoft](#)

Enable loading of kernel debugger symbols

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable loading of kernel debugger symbols** flag loads kernel symbols into the kernel memory space the next time Windows starts.

Abbreviation	ksl
Hexadecimal value	0x40000
Symbolic Name	FLG_ENABLE_KDEBUG_SYMBOL_LOAD
Destination	System-wide registry entry, kernel flag

Comments

The kernel symbols are used in kernel profiling and by advanced kernel debugging tools.

[Send comments about this topic to Microsoft](#)

Enable object handle type tagging

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable object handle type tagging** flag appears in GFlags, but it has no effect on Windows.

Abbreviation	eot
Hexadecimal value	0x01000000
Symbolic Name	FLG_ENABLE_HANDLE_TYPE_TAGGING
Destination	System-wide registry entry, kernel flag

[Send comments about this topic to Microsoft](#)

Enable page heap

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable page heap** flag turns on page heap verification, which monitors dynamic heap memory operations, including allocate and free operations, and causes a debugger break when the verifier detects a heap error.

Abbreviation	hpa
Hexadecimal value	0x02000000
Symbolic Name	FLG_HEAP_PAGE_ALLOCS
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

This option enables full page heap verification when set for image files and standard page heap verification when set in the system registry or as a kernel flag.

- *Full page heap verification* (for **/i**) places a zone of reserved virtual memory at the end of each allocation.
- *Standard page heap verification* (for **/r** or **/k**) places random patterns at the end of an allocation and examines the patterns when a heap block is freed.

Setting this flag for an image file is the same as typing **gflags /p /enable ImageFile /full** for the image file at the command line.

[Send comments about this topic to Microsoft](#)

Enable pool tagging

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable pool tagging** flag collects data and calculates statistics about pool memory allocations sorted by pool tag value.

Abbreviation	ptg
Hexadecimal value	0x400
Symbolic Name	FLG_POOL_ENABLE_TAGGING
Destination	System-wide registry entry

Comments

This flag is permanently set in Windows Server 2003 and later versions of Windows. On these systems, the **Enable pool tagging** check box in the Global Flags dialog box is dimmed and commands to enable or disable pool tagging fail.

Use **ExAllocatePoolWithTag** or **ExAllocatePoolWithTagQuota** to set the tag value. When no tag value is specified (**ExAllocatePool**, **ExAllocatePoolWithTagQuota**), Windows creates a tag with the default value of "None." Because data for all allocations with a "None" tag is combined, you cannot distinguish the data for a specific allocation. For information about these routines, see the Windows Driver Kit (WDK).

In Windows XP and earlier systems, this flag also directs Windows to attach a pool tag even when the pool memory is allocated by using **ExAllocatePoolWithTagQuota**. Otherwise, the tag bytes are used to store the quota values. In Windows Server 2003, tag values and quota values are stored in separate fields that are attached to every pool memory allocation.

Note To display the data that Windows collects about a tagged allocation, use PoolMon, a tool that is included in the Windows Driver Kit. The description of the **Enable Pool Tagging** flag in the Windows XP Support Tools documentation is incomplete. This flag directs Windows to collect and process data by tag value.

[Send comments about this topic to Microsoft](#)

Enable silent process exit monitoring

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable silent process exit monitoring** flag enables silent exit monitoring for a process.

Hexadecimal value	0x200
Symbolic Name	FLG_MONITOR_SILENT_PROCESS_EXIT
Destination	Image file registry entry

Comments

For more information about monitoring a process for silent exit, see [Monitoring Silent Process Exit](#).

[Send comments about this topic to Microsoft](#)

Enable system critical breaks

5/26/2017 • 1 min to read • [Edit Online](#)

The **Enable system critical breaks** flag forces a system break into the debugger.

Abbreviation	scb
Hexadecimal value	0x100000
Symbolic Name	FLG_ENABLE_SYSTEM_CRIT_BREAKS
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

When set for a process (image file), this flag forces a system break into the debugger whenever the specified process stops abnormally. This flag is effective only when the process calls the **RtlSetProcessBreakOnExit** and **RtlSetThreadBreakOnExit** interfaces.

When set system-wide (registry or kernel flag), this flag forces a system break into the debugger whenever processes that have called the **RtlSetProcessBreakOnExit** and **RtlSetThreadBreakOnExit** interfaces stop abnormally.

[Send comments about this topic to Microsoft](#)

Load image using large pages if possible

5/26/2017 • 1 min to read • [Edit Online](#)

The **Load image using large pages if possible** setting directs the system to use large pages (4 MB) rather than the standard small pages (4 KB) when mapping binaries into the process address space.

This setting is most helpful for large executable files, because it significantly reduces the number of page table entries in physical memory.

Abbreviation	lpg
Hexadecimal value	(none)
Symbolic Name	
Destination	Image file registry entry

Comments

This setting is not technically a global flag, because its value is stored in a separate registry entry, not as a value of the GlobalFlag registry entry. As a result, you cannot set it by using a hexadecimal value, and when you select this setting for an image file, it appears in the **Other settings** field of the display.

[Send comments about this topic to Microsoft](#)

Maintain a list of objects for each type

5/26/2017 • 1 min to read • [Edit Online](#)

The **Maintain a list of objects for each type** flag collects and maintains a list of active objects by object type, for example, event, mutex, and semaphore.

Abbreviation	otl
Hexadecimal value	0x4000
Symbolic Name	FLG_MAINTAIN_OBJECT_TYPELIST
Destination	System-wide registry entry

Comments

To display the object list, use Open Handles (oh.exe), a tool included in the Windows 2000 Resource Kit, and now available for download from the [Microsoft Windows 2000 Resource Kit](#) Web site. Because Open Handles automatically sets the OTL flag, but does not clear it, use **GFlags -otl** to clear the flag.

Note The linked lists created when you set this flag use eight bytes of overhead for each object. Remember to clear this flag when your analysis is complete.

[Send comments about this topic to Microsoft](#)

Object Reference Tracing

5/26/2017 • 2 min to read • [Edit Online](#)

The **Object Reference Tracing** feature records sequential stack traces each time that an object reference counter is incremented or decremented. The traces can help you to detect object reference errors, including double-dereferencing, failure to reference, and failure to dereference objects. This feature is supported only in Windows Vista and later versions of Windows.

For information about configuring the Object Reference Tracing feature in the **Global Flags** dialog box, see [Configuring Object Reference Tracing](#). For information about configuring the Object Reference Tracing feature at the command prompt, see [GFlags Commands](#). For an example, see [Example 15: Using Object Reference Tracing](#).

Object reference traces are most useful when you suspect that a particular object is not being referenced or dereferenced properly, typically because increased pool usage indicates that an object is leaking, or a process or session cannot be ended, even though its handle count is zero. Unlike traces that are recorded in logs for later review, object reference traces are designed to be used in real time, while the process is running and the object is being referenced and dereferenced. You view an object reference trace in the debugger by using the **!objtrace debugger extension**. Because this extension requires a specified object address, you must know in advance which object is the likely source of the error.

The following rules apply to Object Reference Tracing:

- You can run only one object reference trace at a time.
- Because a kernel-wide trace is not practical, you must limit the trace to objects that are created with specified pool tags, or to objects that are created by a specified process (indicated by an image file name), or both.
- You can specify only one image file for each trace. If you specify an image file, the trace is limited to objects that are created by the processes that the image represents. Objects that are referenced by the process, but are created by a different process, are not traced.
- You can specify a maximum of 16 pool tags for each trace. Objects with any of the specified pool tags are traced.
- If you specify both an image file and one or more pool tags, the trace is limited to objects that are created by the process and have any of the specified pool tags.
- Object Reference Tracing cannot trace processes that are already running when a trace is started. The trace includes only the objects of processes that start after the trace begins.
- Objects marked for tracing are traced until the object is destroyed or tracing is disabled. By default, the traces for an object are maintained only until the object is destroyed, but you can specify a "permanent" trace (**/p**) where the trace is retained until tracing is disabled.
- You can store the Object Reference Tracing configuration as a registry setting or a kernel flag (run-time) setting. If you have both registry and kernel flag settings, the run-time settings take precedence, but are lost when you shut down or restart the computer.

[Send comments about this topic to Microsoft](#)

Show loader snaps

5/26/2017 • 1 min to read • [Edit Online](#)

The **Show loader snaps** flag captures detailed information about the loading and unloading of executable images and their supporting library modules and displays the data in the kernel debugger console.

Abbreviation	sls
Hexadecimal value	0x2
Symbolic Name	FLG_SHOW_LDR_SNAPS
Destination	System-wide registry entry, kernel flag, image file registry entry

Comments

For system-wide (registry or kernel flag), this flag displays information about driver loading and unloading operations.

For per-process (image file), this flag displays information about loading and unloading of DLLs.

[Send comments about this topic to Microsoft](#)

Special Pool

5/26/2017 • 4 min to read • [Edit Online](#)

The **Special Pool** feature configures Windows to request memory allocations from a reserved memory pool when the memory is allocated with a specified pool tag or is within a specified size range.

Abbreviation	spp
Hexadecimal value	(None)
Symbolic Name	(None)
Destination	System-wide registry entry (Windows Vista and later) System-wide registry entry, kernel flag

Selecting a Pool Tag

When requesting special pool for a particular pool tag, make sure that your driver or other kernel-mode program uses a unique pool tag.

Also, when creating a pool tag (such as by using **ExAllocatePoolWithTag**), consider entering the tag characters in reverse order. For example, if the tag is **Fred**, consider entering it as **derF** (0x64657246). Pool tags are stored in the registry and displayed in the debugger and other tools in reverse (lower endian) order. If you enter them in reverse order, they are displayed in forward order (0x46726564)

If you suspect that your driver is consuming all of the special pool, consider using multiple pool tags in your code. You can then test your driver several times, assigning special pool to one pool tag in each test.

Also, select a pool tag with a hexadecimal value that is greater than the page size of the system. For kernel mode code, if you enter a pool tag that has a value less than PAGE_SIZE, Gflags requests special pool for all allocations whose size is within the corresponding range and requests special pool for allocations with an equivalent pool tag. For example, if you select a size of **30**, special pool will be used for all allocations between 17 and 32 bytes in size, and for allocations with the pool tag 0x0030.

Selecting an Allocation Size

Use the following guidelines to select an allocation size for the Special Pool feature.

On a computer with an x86 processor, PAGE_SIZE is 0x1000 and the allocation size ranges are 8 bytes in length. To configure the Special Pool feature for all allocations with sizes in this range, enter a number equal to the maximum of this range plus 8. (This number is always a multiple of 8.) The following table illustrates these values:

SIZE RANGE	ENTER THIS NUMBER
1 to 8 bytes	10 (decimal 16)

SIZE RANGE	ENTER THIS NUMBER
9 to 16 bytes	18 (decimal 24)
17 to 24 bytes	20 (decimal 32)
...	...
0xFE9 to 0xFF0 bytes	FF8 (decimal 4088)

On a computer with an AMD x86-64 processor, PAGE_SIZE is 0x1000 and the allocation size ranges are 16 bytes in length. To configure the Special Pool feature for all allocations with sizes in this range, enter a number equal to the maximum of this range plus 16. (This number is always a multiple of 16.) The following table illustrates these values:

SIZE RANGE	ENTER THIS NUMBER
1 to 16 bytes	20 (decimal 32)
17 to 32 bytes	30 (decimal 48)
33 to 48 bytes	40 (decimal 64)
...	...
0xFD1 to 0xFE0 bytes	FF0 (decimal 4080)

On a computer with any processor, you can use an asterisk (`*`) or 0x2A (decimal 42) to configure the Special Pool feature for all memory allocations on the system.

Comments

For information about configuring the Special Pool feature in the Global Flags Dialog Box, see [Configuring Special Pool](#). For information about configuring the Special Pool feature at the command line, see [GFlags Commands](#). For an example, see [Example 14: Configuring Special Pool](#).

The Special Pool feature of Gflags directs Windows to request memory allocations from a reserved memory pool when the memory is allocated with a specified pool tag or is within a specified size range. To request special pool for all allocations by a particular driver, use Driver Verifier. For more information, see the "Special Pool" topic in the "Driver Verifier" section of the Windows Driver Kit (WDK).

The special pool features of Gflags and Driver Verifier help you to detect and identify the source of errors in kernel pool use, such as writing beyond the allocated memory space, or referring to memory that has already been freed.

Not all special pool requests are fulfilled. Each allocation from the special pool uses one page of nonpageable physical memory and two pages of virtual address space. If the special pool is exhausted, memory is allocated from the standard pool until the special pool becomes available again. When a special pool request is filled from the standard pool, the requesting function returns a success status. It does not return an error, because the

allocation has succeeded, even though it was not filled from special pool.

The size of the special pool increases with the amount of physical memory on the system; ideally this should be at least 1 Gigabyte (GB). On x86 machines, because virtual (in addition to physical) space is consumed, do not use the **/3GB** boot option when using special pool. It is also a good idea to increase the pagefile minimum/maximum quantities by a factor of two or three.

You can also configure the Special Pool feature to align memory allocation to detect references to memory preceding the allocation ("underruns") or references to memory beyond the allocation ("overruns"). This feature is available only in the Global Flags dialog box on all versions of Windows. For details, see [Detecting Overruns and Underruns](#).

On Windows Vista and later versions of Windows, you can configure the Special Pool feature as a registry setting that requires a reboot, but remains effective until you change it, or as a kernel flag setting that does not require a reboot, but is effective only until you reboot or shut down Windows. In earlier versions of Windows, Special Pool is only available as a registry setting.

On Windows Vista and later versions of Windows, you can configure the Special Pool feature either by using the Global Flags dialog box or at the command line. In earlier version of Windows, this feature is available only in the Global Flags dialog box.

[Example 13: Listing Image Files with Global Flags](#)

[Example 14: Configuring Special Pool](#)

[Example 15: Using Object Reference Tracing](#)

The examples in the second section apply to features available only in Windows Vista and later versions of Windows.

[Send comments about this topic to Microsoft](#)

Example 1: Displaying Global Flags

5/26/2017 • 1 min to read • [Edit Online](#)

The commands demonstrated in this example display the system-wide flags set in the registry, the system flags set for the session (kernel mode), and the flags set for an image file.

The following GFlags command displays the current value of the system-wide flags set in the registry. It uses the **/r** parameter to specify the system-wide registry entry.

```
gflags /r
```

In response, GFlags displays a single hexadecimal value representing the sum of all flags set and a list of the flags set.

```
Current Boot Registry Settings are: 40001400
  ptg - Enable pool tagging
  ust - Create user mode stack trace database
  bhd - Enable bad handles detection
```

In this example, the results show that there are three tags set, with a combined value of 0x40001400.

- [Enable pool tagging](#) (ptg) = 0x400
- [Create user mode stack trace database](#) (ust) = 0x1000
- [Enable bad handles detection](#) (bhd) = 0x40000000

The following command displays the flags set for the current session. It uses the **/k** parameter to indicate kernel mode.

```
gflags /k
```

The following command displays flags set in the registry for the image file notepad.exe. It uses the **/i** parameter to indicate image file mode and specifies the image file.

```
gflags /i notepad.exe
```

Remember that the flag value displayed might not be the current, effective flag value. Changes to the system-wide flags are not effective until you restart Windows. Changes to image file flag settings are not effective until you restart the program.

[Send comments about this topic to Microsoft](#)

Example 2: Setting a Flag by Using a Flag Abbreviation

5/26/2017 • 1 min to read • [Edit Online](#)

The following command sets the [Show loader snaps](#) flag for the notepad.exe image file. **Show Loader Snaps** takes snapshots of the load process, capturing in detail the loading and unloading of executable images and their supporting library modules.

The command uses the **/i** parameter to indicate image file mode and specifies the name of the image file notepad.exe. To identify the flag, the command uses **sls**, the abbreviation for **Show Loader Snaps**, and it precedes the abbreviation with a plus sign (+) to indicate that the flag is set. Without the plus sign, the command has no effect.

```
gflags /i notepad.exe +sls
```

In response, GFlags displays the flags set for notepad.exe. The display indicates that the command is successful. The **Show Loader Snaps** feature is enabled for all new sessions of the Notepad program.

```
Current Registry Settings for notepad.exe executable are: 00000002
  sls - Show Loader Snaps
```

[Send comments about this topic to Microsoft](#)

Example 3: Setting a Flag by Using Its Hexadecimal Value

5/26/2017 • 1 min to read • [Edit Online](#)

The following command sets the system-wide [Enable page heap](#) flag. **Enable Page Heap** adds a guard page and other tracking features to each heap allocation.

The command uses the **/r** parameter to indicate system-wide registry mode. To identify the flag, the command uses **2000000**, which represents 0x2000000, the hexadecimal value for [Enable page heap](#).

Although the command sets a flag, it omits the plus (+) sign. When using hexadecimal values, the sign is optional and add (+) is the default.

```
gflags /r 2000000
```

In response, GFlags displays the system-wide flags set in the registry. The display indicates that the command is successful. The [Enable page heap](#) feature will be enabled for all processes when Windows restarts.

```
Current Boot Registry Settings are: 02000000
    hpa - Enable page heap
```

[Send comments about this topic to Microsoft](#)

Example 4: Setting Multiple Flags

5/26/2017 • 1 min to read • [Edit Online](#)

The following command sets these three flags for the current session:

- [Enable heap free checking](#) (hfc, 0x20)
- [Enable heap parameter checking](#) (hpc, 0x40)
- [Enable heap validation on call](#) (hvc, 0x80)

This command uses the **/k** parameter to specify kernel mode (session only). It sets the value for kernel mode to **E0** (0xE0), the sum of the hexadecimal values of the selected flags (0x20 + 0x40 + 0x80).

```
gflags /k e0
```

In response, GFlags displays the revised value of flags set for the session. The display indicates that the command is successful and that the three flags specified in the command are set.

```
Current Running Kernel Settings are: 000000e0
  hfc - Enable heap free checking
  hpc - Enable heap parameter checking
  hvc - Enable heap validation on call
```

You can use several different GFlags commands to set flags. Each of the following commands has the same effect as the command used in this example and the methods can be used interchangeably:

```
gflags /k +20 +40 +80
gflags /k +E0
gflags /k +hfc +hpc +hvc
```

Kernel (run time) flags are effective immediately and remain effective until Windows shuts down.

[Send comments about this topic to Microsoft](#)

Example 5: Clearing a Flag

5/26/2017 • 1 min to read • [Edit Online](#)

The following command clears the system-wide [Enable page heap](#) flag set in the registry. The command uses the **/r** parameter to indicate the system-wide registry mode and **hpa**, the abbreviation for the **Enable page heap** flag. The minus sign (-) indicates that the flag is to be cleared.

```
gflags /r -hpa
```

In response, GFlags displays the current value of the system-wide registry entry. The display indicates that the command is successful and that there are no longer any flags set.

```
Current Boot Registry Settings are: 00000000
```

Note that the following command, which uses the hexadecimal value of the **Enable Page Heap** flag, has the same effect as the command used in this example. These commands can be used interchangeably:

```
gflags /r -02000000
```

[Send comments about this topic to Microsoft](#)

Example 6: Clearing All Flags

5/26/2017 • 1 min to read • [Edit Online](#)

This example demonstrates two different ways to clear all flags set in the registry and for the session:

- Subtract the current flag value.
- Subtract high values.

Note The methods demonstrated by this example clear flags only. They do not reset the maximum stack trace size or kernel special pool tag to the default values.

Subtract the Current Flag Value

The following command clears all flags set in the system-wide flag entry in the registry by subtracting the current value of the entry. In this example, the current value is 0xE0. The command uses the **/r** parameter to indicate the system-wide registry mode and the E0 value with a minus sign (-) to subtract E0 from the flag value.

```
gflags /r -E0
```

In response, GFlags displays the revised value of system-wide flag registry entry. A value of zero indicates that the command is successful and that there are no longer any system-wide flags set in the registry.

```
Current Boot Registry Settings are: 00000000
```

Note that the following commands have the same effect as the command used in this example and can be used interchangeably:

```
gflags /r -20 -40 -80  
gflags /r -hfc -hpc -hvc
```

Subtract High Values

The following command clears all system-wide flags by subtracting high values (0xFFFFFFFF) from the system-wide flag setting.

```
gflags /r -xffffffff
```

In response, GFlags displays the revised value of the system-wide flag entry. A value of zero indicates that the command is successful and that there are no longer any system-wide flags set in the registry.

```
Current Boot Registry Settings are: 00000000
```

Tip Type this command into Notepad, then save the file as clearflag.bat. Thereafter, to clear all flags, just type **ClearFlag**.

Finally, the following example demonstrates that the intuitive method of clearing all flags does not work.

The following command appears to set the value of the system-wide flag entry to 0. However, it actually adds zero to the system-wide flag value. In this example, the current value of the system-wide flag entry is 0xE0.

```
gflags /r 0
```

In response, GFlags displays the system-wide flag value after the command completes:

```
Current Boot Registry Settings are: 000000e0
  hfc - Enable heap free checking
  hpc - Enable heap parameter checking
  hvc - Enable heap validation on call
```

The command has no effect because it adds the value 0 to system-wide flag entry.

[Send comments about this topic to Microsoft](#)

Example 7: Clearing All Flags for an Image File

5/26/2017 • 1 min to read • [Edit Online](#)

The following command clears all flags and image debugger options for an image file. The command adds high-values (0xFFFFFFFF) to the current flag value. GFlags responds by deleting the **GlobalFlag** registry entry for the image file, thereby deleting all of the values it stores.

This command does not affect flags set in the system-wide **GlobalFlag** registry entry or flags set for the session (kernel mode).

```
gflags /i notepad.exe ffffffff
```

In response, GFlags displays a message indicating that there are no flags set for the image file:

```
No Registry Settings for notepad.exe executable
```

[Send comments about this topic to Microsoft](#)

Example 8: Enlarging the User-Mode Stack Trace Database

5/31/2017 • 1 min to read • [Edit Online](#)

The following GFlags command increases the maximum size of the user-mode stack trace database for myapp.exe, a fictitious program, from 8 MB to 24 MB.

The command uses the **/i** parameter to specify the image file. It uses the **/tracedb** parameter to set the maximum stack trace database size and the value 24 to indicate the size in megabytes. The command uses decimal units. (Hexadecimal units are not valid.)

```
gflags /i MyApp.exe /tracedb 24
```

As the following error message indicates, this command fails because the [Create user mode stack trace database](#) (+ust) flag is not set for the MyApp image file. You cannot set the size of a trace database until you create one.

```
Failed to set the trace database size for `MyApp.exe'
```

The following commands fix the error. The first command creates a trace database for myapp.exe and the second command sets the maximum size of the trace database to 24 MB. These commands cannot be combined into a single command. The following display shows the commands and the success message from GFlags.

```
gflags /i MyApp.exe +ust
Current Registry Settings for MyApp.exe executable are: 00001000
    ust - Create user mode stack trace database

gflags /i MyApp.exe /tracedb 24
Trace database size for `MyApp.exe' set to 24 Mb.
```

GFlags can change the size of the user-mode stack trace database, but it does not display it. To display the trace database size, use registry APIs, Regedit, or Reg (reg.exe), a tool included in Windows XP and Windows Server 2003, to check the value of the **StackTraceDatabaseSizeInMB** registry entry (HKLM\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\ImageFileName\StackTraceDatabaseSizeInMB).

(A version of Reg is included in Windows XP, but that version does not permit the **/v** and **/s** switches in the same command.)

The following command uses Reg to query the value of **StackTraceDatabaseSizeInMB**:

```
reg query "HKLM\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\MyApp.exe" /v
StackTraceDatabaseSizeInMB
```

In response, Reg displays the value of **StackTraceDatabaseSizeInMB**, which confirms that the new value, 24 (0x18), was set. This value becomes effective when you restart myapp.exe.

```
! REG.EXE VERSION 3.0
```

```
HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\MyApp.exe
  StackTraceDatabaseSizeInMB  REG_DWORD      0x18
```

Tip Type the **reg query** command into Notepad, then save the file as tracedb.bat. Thereafter, to display the value of **StackTraceDatabaseSizeInMB**, just type **TraceDb**.

[Send comments about this topic to Microsoft](#)

Example 9: Detecting a Pool Memory Leak

5/26/2017 • 2 min to read • [Edit Online](#)

The following example uses GFlags to set the system-wide [Enable pool tagging](#) flag in the registry. Then, it uses PoolMon (poolmon.exe), a tool in the Windows Driver Kit, to display the size of the memory pools.

PoolMon monitors the bytes in the paged and nonpaged memory pools and sorts them by pool tag. By running PoolMon periodically, you can identify pools that expand continuously over time. This pattern often indicates a memory leak.

Note Pool tagging is permanently enabled in Windows Server 2003 and later versions of Windows. On these systems, the **Enable pool tagging** check box on the **Global Flags** dialog box is dimmed, and commands to enable or disable pool tagging fail. If pool tagging is not enabled, PoolMon fails and displays the following message: "Query pooltags Failed c0000002."

To detect a pool memory leak

1. To enable pool tagging for all processes in versions of Windows earlier than Windows Server 2003, set the system-wide [Enable pool tagging](#) flag in the registry. The following command line uses the flag abbreviation method, but you can identify the flag by its hexadecimal value or use the **Global Flags** dialog box:

```
gflags /r +ptg
```

2. Restart the computer to make the registry change effective.
3. Run PoolMon periodically by using the following command. In this command, the **/b** parameter sorts the pools in descending size order.

```
poolmon /b
```

In response, PoolMon displays allocations from the memory pools in descending size order, including the number of allocate operations and free operations, and the amount of memory remaining in the pool (in the **Bytes** column).

Memory:	16224K	Avail:	4564K	PageFlts:	31	InRam	Krnl:	684K	P:	680K
Commit:	24140K	Limit:	24952K	Peak:	24932K	Pool N:	744K	P:	2180K	
Tag	Type	Allocs		Frees		Diff	Bytes		Per Alloc	
CM	Paged	1283	(0)	1002	(0)	281	1377312	(0)	4901	
Strg	Paged	10385	(10)	6658	(4)	3727	317952	(512)	85	
Fat	Paged	6662	(8)	4971	(6)	1691	174560	(128)	103	
MmSt	Paged	614	(0)	441	(0)	173	83456	(0)	482	

If the value in the **Bytes** column for an allocation expands continuously for no obvious reason, there might be a memory leak in that pool.

4. Clear the **Enable pool tagging** flag.

The following command line uses the flag abbreviation method, but you can identify the flag by its hexadecimal value or use the **Global Flags** dialog box:

```
gflags /r -ptg
```

5. Restart Windows to make the registry change effective.

Note Use the append symbol (**>>**) to redirect the PoolMon output to a log file. Later, you can examine the log file for pool size trends. For example:

```
poolmon.exe /b >> poolmon.log
```

[Send comments about this topic to Microsoft](#)

Example 10: Detecting a Heap Memory Leak in a Process

5/26/2017 • 1 min to read • [Edit Online](#)

This example uses GFlags and User Mode Dump Heap (UMDH, umdh.exe), a tool included in Microsoft Debugging Tools for Windows.

To detect a leak in heap memory in notepad.exe

1. Set the [Create user mode stack trace database \(ust\)](#) flag for the notepad.exe image file.

The following command uses GFlags to set the **Create user mode stack trace database** flag. It uses the **/i** parameter to identify the image file and the **ust** abbreviation for the flag.

```
gflags /i Notepad.exe +ust
```

As a result of this command, a user-mode stack trace is created for all new instances of the Notepad process.

2. Set the symbol file path.

The following command creates an environment variable that stores the path to the directory of symbol files:

```
set _NT_SYMBOL_PATH=C:\Windows\symbols
```

3. Start Notepad.

4. Find the process identifier (PID) of the Notepad process.

You can find the PID of any running process from Task Manager or Tasklist (tasklist.exe), a tool included in Windows XP Professional and Windows Server 2003 operating systems. In this example, the Notepad PID is 1228.

5. Run UMDH.

The following command runs UMDH (umdh.exe). It uses the **-p:** parameter to specify the PID that, in this example, is 1228. It uses the **/f:** parameter to specify the name and location of the output file for the heap dump, notepad.dmp.

```
umdh -p:1228 -f:notepad.dmp
```

In response, UMDH writes a complete dump of all active heaps to the notepad.dmp file.

[Send comments about this topic to Microsoft](#)

Example 11: Enabling Page Heap Verification

5/26/2017 • 1 min to read • [Edit Online](#)

The following commands enable full and standard page heap verification for myapp.exe, a fictitious program.

The first command enables *standard* page heap verification for myapp.exe. It uses the **/p** parameter to enable page heap for a process. By default, **/p** enables standard page heap.

```
gflags /p /enable myapp.exe
```

The following commands enable *full* page heap verification for the myapp.exe program. Although these commands create different settings in the registry, they are all functionally equivalent to selecting the **Enable page heap** check box for the myapp.exe image file in the **Global Flags** dialog box. These methods can be used interchangeably.

```
gflags /p /enable myapp.exe /full
gflags /i myapp.exe +hpa
gflags /i myapp.exe +02000000
```

The following commands disable full or standard page heap verification for the myapp.exe program, regardless of the command or dialog box method used to enable page heap verification.

```
gflags /p /disable myapp.exe
gflags /i myapp.exe -hpa
gflags /i myapp.exe -02000000
```

Note When using the **/debug** or **/kdebug** parameters, use the **/p /disable** parameters to turn off the page heap verification (not the **/i -hpa** parameters). The **/p /disable** parameters disable page heap verification and delete registry entries that the debugger reads.

[Send comments about this topic to Microsoft](#)

Example 12: Using Page Heap Verification to Find a Bug

5/26/2017 • 5 min to read • [Edit Online](#)

The following series of commands demonstrates how to use the page heap verification features of GFlags and the NTSD debugger to detect an error in heap memory use. In this example, the programmer suspects that a fictitious application, pheap-buggy.exe, has a heap error, and proceeds through a series of tests to identify the error.

For details on NTSD, see [Debugging Using CDB and NTSD](#).

Step 1: Enable standard page heap verification

The following command enables standard page heap verification for pheap-buggy.exe:

```
gflags /p /enable pheap-buggy.exe
```

Step 2: Verify that page heap is enabled

The following command lists the image files for which page heap verification is enabled:

```
gflags /p
```

In response, GFlags displays the following list of programs. In this display, **traces** indicates standard page heap verification, and **full traces** indicates full page heap verification. In this case, pheap-buggy.exe is listed with **traces**, indicating that standard page heap verification is enabled, as intended.

```
pheap-buggy.exe: page heap enabled with flags (traces )
```

Step 3: Run the debugger

The following command runs the **CorruptAfterEnd** function of pheap-buggy.exe in NTSD with the **-g** (ignore initial breakpoint) and **-x** (set second-chance break on access violation exceptions) parameters:

```
ntsd -g -x pheap-buggy /CorruptAfterEnd
```

When the application fails, NTSD generates the following display, which indicates that it detected an error in pheap-buggy.exe:

```
=====
VERIFIER STOP 00000008: pid 0xAA0: corrupted suffix pattern

00C81000 : Heap handle
00D81EB0 : Heap block
00000100 : Block size
#      00000000 :

=====
Break instruction exception - code 80000003 (first chance)
eax=00000000 ebx=00d81eb0 ecx=77f7e257 edx=0006fa18 esi=00000008 edi=00c81000
eip=77f7e098 esp=0006fc48 ebp=0006fc5c iopl=0          nv up ei pl zr na po nc
cs=001b ss=0023 ds=0023 es=0023 fs=0038 gs=0000          efl=00000246
ntdll!DbgBreakPoint:
77f7e098 cc          int     3
```

The header information includes the address of the heap with the corrupted block (00C81000 : Heap handle), the address of the corrupted block (00D81EB0 : Heap block), and the size of the allocation (00000100 : Block size).

The "corrupted suffix pattern" message indicates that the application violated the data integrity pattern that GFlags inserted after the end of the pheap-buggy.exe heap allocation.

Step 4: Display the call stack

In the next step, use the addresses that NTSD reported to locate the function that caused the error. The next two commands turn on line number dumping in the debugger and display the call stack with line numbers.

```
C:\>.lines
Line number information will be loaded
C:\>kb
ChildEBP RetAddr  Args to Child
WARNING: Stack unwind information not available. Following frames may be wrong.
0006fc5c 77f9e6dd 00000008 77f9e3e8 00c81000 ntdll!DbgBreakPoint

0006fdc0 77fc0dc2 00c80000 01001002 00d81eb0 ntdll!RtlpNtEnumerateSubKey+0x67ba
0006fe78 77fdbd87b 00c80000 01001002 00d81eb0 ntdll!RtlSizeHeap+0x16a8
0006ff24 010013a4 00c80000 01001002 00d81eb0 ntdll!RtlFreeHeap+0x69
0006ff3c 01001450 00000000 00000001 0006ff0 pheap-buggy!TestCorruptAfterEnd+0x2b
[d:\nttest\base\tests\kernel\rtl\pageheap\pheap-buggy.cxx @ 185]
0006ff4c 0100157f 00000002 00c65a68 00c631d8 pheap-buggy!main+0xa9
[d:\nttest\base\tests\kernel\rtl\pageheap\pheap-buggy.cxx @ 69]
0006ffc0 77de43fe 00000000 00000001 7ffdf000 pheap-buggy!mainCRTStartup+0xe3 [crtexe.c @ 349]
0006ffff 00000000 0100149c 00000000 78746341 kernel32!DosPathToSessionPathA+0x204
```

As a result, the debugger displays the call stack for pheap-buggy.exe with line numbers. The call stack display shows that the error occurred when the **TestCorruptAfterEnd** function in pheap-buggy.exe tried to free an allocation at 0x00c80000 by calling **HeapFree**, a redirect to **RtlFreeHeap**.

The most likely cause of this error is that the program wrote past the end of the buffer that it allocated in this function.

Step 5: Enable full page heap verification

Unlike standard page heap verification, full page heap verification can catch the misuse of this heap buffer as soon as it occurs. The following command enables full page heap verification for pheap-buggy.exe:

```
gflags /p /enable pheap-buggy.exe /full
```

Step 6: Verify that full page heap is enabled

The following command lists the programs for which page heap verification is enabled:

```
gflags /p
```

In response, GFlags displays the following list of programs. In this display, **traces** indicates standard page heap verification, and **full traces** indicates full page heap verification. In this case, pheap-buggy.exe is listed with **full traces**, indicating that full page heap verification is enabled, as intended.

```
pheap-buggy.exe: page heap enabled with flags (full traces )
```

Step 7: Run the debugger again

The following command runs the **CorruptAfterEnd** function of pheap-buggy.exe in the NTSD debugger with the **-g** (ignore initial breakpoint) and **-x** (set second-chance break on access violation exceptions) parameters:

```
ntsd -g -x pheap-buggy /CorruptAfterEnd
```

When the application fails, NTSD generates the following display, which indicates that it detected an error in pheap-buggy.exe:

```
Page heap: process 0x5BC created heap @ 00880000 (00980000, flags 0x3)
ModLoad: 77db0000 77e8c000  kernel32.dll
ModLoad: 78000000 78046000  MSVCRT.dll
Page heap: process 0x5BC created heap @ 00B60000 (00C60000, flags 0x3)

01001398 889801010000 mov [eax+0x101],bl ds:0023:00c87001=??
```

With full page heap verification enabled, the debugger breaks at an access violation. To find the precise location of the access violation, turn on line number dumping and display the call stack trace.

The numbered call stack trace appears as follows: The line displaying the problem appears in bold text.

```
ChildEBP RetAddr  Args to Child
0006ff3c 01001450 00000000 00000001 0006ffc0 pheap-buggy!TestCorruptAfterEnd+0x1f
[d:\nttest\base\tests\kernel\rtl\pageheap\pheap-buggy.cxx @ 184]
0006ff4c 0100157f 00000002 00c16fd0 00b70eb0 pheap-buggy!main+0xa9
[d:\nttest\base\tests\kernel\rtl\pageheap\pheap-buggy.cxx @ 69]
0006ffc0 77de43fe 00000000 00000001 7ffdf000 pheap-buggy!mainCRTStartup+0xe3 [crtexe.c @ 349]
WARNING: Stack unwind information not available. Following frames may be wrong.
0006ffff 00000000 0100149c 00000000 78746341 kernel32!DosPathToSessionPathA+0x204
```

The stack trace shows that the problem occurs in line 184 of pheap-buggy.exe. Because full page heap verification is enabled, the call stack starts in the program code, not in a system DLL. As a result, the violation was caught where it happened, instead of when the heap block was freed.

Step 8: Locate the error in the code

A quick inspection reveals the cause of the problem: The program tries to write to the 257th byte (0x101) of a 256-byte (0x100) buffer, a common off-by-one error.

```
*((PCHAR)Block + 0x100) = 0;
```

[Send comments about this topic to Microsoft](#)

Example 13: Listing Image Files with Global Flags

5/26/2017 • 1 min to read • [Edit Online](#)

GFlags displays the flags set for a particular image file, but it does not display all image files that have flags set.

Windows stores flags for an image file that the **GlobalFlag** registry entry in a registry subkey named for the image file in the following registry path, **HKEY_LOCAL_MACHINE\ SOFTWARE\ Microsoft\ Windows NT\ CurrentVersion\ Image File Execution Options\ImageFileName\GlobalFlag**.

To determine which image files have flags set, use Reg (reg.exe), a tool included in Windows Server 2003.

The following Reg **Query** command searches for the **GlobalFlag** registry entry in the specified registry path. The **-v** parameter specifies the **GlobalFlag** registry entry. The **/s** parameter makes the search recursive.

```
reg query "HKLM\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options" /v GlobalFlag /s
```

In response, Reg displays all instances of the **GlobalFlag** registry entry in the path and the value of the entry.

```
HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\notepad.exe
GlobalFlag      REG_SZ      0x00001000

HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\photohse.EXE
GlobalFlag      REG_SZ      0x00200000

HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\printhse.EXE
GlobalFlag      REG_SZ      0x00200000
```

Tip Type the **Reg** command into Notepad, then save the file as imageflags.bat. Thereafter, to find image files for which flags have been set, just type **ImageFlags**.

Example 14: Configuring Special Pool

5/26/2017 • 5 min to read • [Edit Online](#)

Beginning in Windows Vista, you can configure the [Special Pool](#) feature as a kernel flag setting or as a registry setting. If you configure it as a kernel flag (run time) setting, you do not need to restart the computer to make the change effective. In earlier versions of Windows, Special Pool is available only as a registry setting.

Also, beginning in Windows Vista, you can set and configure the Special Pool feature from the command line. In earlier versions of Windows, you can set and configure the Special Pool feature only in the Global Flags dialog box.

Request Special Pool by pool tag without rebooting

The following command requests special pool for all allocations with the **Tag1** pool tag. This setting becomes effective immediately, but it is lost if you shut down or restart Windows.

This command uses the **/k** parameter to specify a kernel flag (run time) setting and the **+spp** abbreviation to set a special pool request.

```
gflags /k +spp Tag1
```

Gflags responds by printing:

```
Special Pool set to 0x31676154
PoolTagOverruns set to 0x1
Current Running Kernel Settings are: 00000000
```

Notice that the special pool allocation request is not a kernel flag setting and is not reflected in the kernel settings value.

Also, a special pool allocation request does not change the value of the overrun (0x1) or underrun (0x0) setting for special pool. To change from overruns, the default, to underruns, use the Gflags Dialog Box. For information, see [Detecting Overruns and Underruns](#).

You cannot display the pool tag at the command line. To verify that the pool tag is a kernel setting, use the Gflags Dialog Box.

Request Special Pool by pool tag in the registry

The following command requests special pool for all allocations with the **Tag1** pool tag. Because this setting is stored in the registry, you must restart the computer to make it effective, but it remains effective until you change it.

This command uses the **/r** parameter to specify a registry setting and the **+spp** abbreviation to set a special pool request.

```
gflags /r +spp Tag1
```

Gflags responds by printing:

```
Special Pool set to 0x31676154
PoolTagOverruns set to 0x1
Current Boot Registry Settings are: 00000000
```

Notice that the special pool allocation request is not a registry flag setting and is not reflected in the registry settings value.

Also, a special pool allocation request does not change the value of the overrun (0x1) or underrun (0x0) setting for special pool. To change from overruns, the default, to underruns, use the Gflags Dialog Box. For information, see [Detecting Overruns and Underruns](#).

To verify that the value has been added to the registry, use Reg or Regedit to display the value of the **PoolTag** entry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management** key.

For example:

```
c:>reg query "HKLM\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management" -v PoolTag
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management
PoolTag      REG_DWORD      0x31676154
```

Request Special Pool by size without rebooting

The following command requests special pool for allocations of 1 to 8 bytes on an x86 computer with a PAGE_SIZE of 0x1000 and allocation granularity of 8 bytes.

This command uses the **/k** parameter to specify a kernel flag (run time) setting and the **+spp** abbreviation to set a special pool request. The size value is preceded by **0x** to indicate that it is a size and not a pool tag.

The value, **0x10**, is calculated by adding the allocation granularity (8 bytes) to the largest size in the range (8 bytes) for a total of 16 bytes (**0x10**). For help in determining the correct value to enter, see "Selecting an Allocation Size" in [Special Pool](#).

```
gflags /k +spp 0x10
```

Gflags responds by printing:

```
Special Pool set to 0x10
PoolTagOverruns set to 0x1
Current Running Kernel Settings are: 00000000
```

Again, the special pool allocation request is not a kernel flag setting and is not reflected in the kernel settings value.

Also, a special pool allocation request does not change the value of the overrun (0x1) or underrun (0x0) setting for special pool. To change from overruns, the default, to underruns, use the Gflags Dialog Box. For information, see [Detecting Overruns and Underruns](#).

Request Special Pool by size in the registry

The following command requests special pool for allocations of 1024 to 1040 bytes on an x64 computer with a PAGE_SIZE of 0x1000 and allocation granularity of 16 bytes.

This command uses the **/r** parameter to specify a system-wide registry setting and the **+spp** abbreviation to set a special pool request. The size value is preceded by **0x** to indicate that it is a size and not a pool tag.

The value, **0x420**, is calculated by adding the allocation granularity (16 bytes) to the largest size in the range (1040 bytes) for a total of 1056 bytes (**0x420**). For help in determining the correct value to enter, see "Selecting an Allocation Size" in [Special Pool](#).

```
gflags /r +spp 0x420
```

Gflags responds by printing:

```
Special Pool set to 0x420
PoolTagOverruns set to 0x1
Current Boot Registry Settings are: 00000000
```

Again, the special pool allocation request is not a registry flag setting and is not reflected in the registry settings value.

Also, a special pool allocation request does not change the value of the overrun (0x1) or underrun (0x0) setting for special pool. To change from overruns, the default, to underruns, use the Gflags Dialog Box. For information, see [Detecting Overruns and Underruns](#).

To verify that the value has been added to the registry, use Reg or Regedit to display the value of the **PoolTag** entry in the **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management** key.

For example:

```
c:>reg query "HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management" -v PoolTag
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Memory Management
    PoolTag      REG_DWORD      0x420
```

Cancel a Special Pool Request

The following command cancels a request for Special Pool as a kernel flag (run time) setting. The command is the same for a request by pool tag or by size.

```
gflags /k -spp
```

The following command cancels a request for Special Pool as a registry setting. The command is the same for a request by pool tag or by size.

```
gflags /r -spp
```

When the command is successful, Gflags responds by printing:

```
Special Pool value has been deleted.
```

[Send comments about this topic to Microsoft](#)

Example 15: Using Object Reference Tracing

5/26/2017 • 5 min to read • [Edit Online](#)

Object Reference Tracing is a Windows feature that records a sequential stack trace when an object is referenced or dereferenced. It is designed to detect errors in object handling that can lead to crashes or memory leaks. Some of these errors are difficult to detect because they do not appear consistently. For detailed information, see [Object Reference Tracing](#).

You can configure Object Reference Tracing by using the **Global Flags** dialog box or at a command prompt. The following examples use the command prompt. For information about using the **Global Flags** dialog box to configure Object Reference Tracing, see [Configuring Object Reference Tracing](#).

You can use Gflags to enable, disable, and configure Object Reference Tracing. The process is as follows:

- **Use Gflags to enable Object Reference Tracing** in the registry or as a kernel flag (run time) setting. If you add the setting to the registry, you must restart the computer to start tracing. If you enable the run time version of the settings, the trace starts immediately, but the trace settings revert to those in the registry key when you shut down or restart the computer.
- **Start the process that creates the suspect object.** The trace includes only objects created by processes that are started after the trace begins. If the process starts during or soon after restarting, add the trace settings to the registry, and then restart the system.
- **Use the !obtrace debugger extension** to view the trace. By default, the trace is maintained until the object is destroyed, but you can use the **/p** parameter to maintain the trace until tracing is disabled.
- **Use Gflags to disable Object Reference Tracing.** in the registry or as a kernel flag (run time) setting. If you delete the setting from the registry, you must restart the computer to end tracing. If you disable the run time version of the settings, the trace ends immediately, but the trace settings revert to those in the registry when you shut down or restart the computer.

These examples show how to use Gflags to enable and disable object reference tracing. \

Enable Run-time Tracing

The following command enables Object Reference Tracing at the command prompt. The command uses the **/ko** parameter to enable Object Reference Tracing as a kernel flag (run time) setting. The command uses the **/t** parameter to specify the pool tags **Tag1** and **Fred**. As a result, all objects that are created with **Tag1** or **Fred** are traced.

```
gflags /ko /t Tag1;Fred
```

Because the command changes the kernel flag (run-time) settings, object reference tracing starts immediately. The trace will include all objects with the pool tags **Tag1** or **Fred** that are created by processes that start after the command is submitted.

Gflags responds by printing the following message:

```
Running Kernel Settings :  
Object Ref Tracing Enabled  
Temporary Traces  
Pool Tags: Tag1;Fred  
Process Name: All Processes
```

This message indicates that Object Reference Tracing is enabled. "Temporary Traces" indicates that all records of the trace are deleted when the object is destroyed. To make the trace "permanent," use the **/p** parameter, which directs Windows to retain the trace data until Object Reference Tracing is disabled, or the computer is shut down or restarted.

Enable Tracing in the Registry

The following command adds an Object Reference Tracing configuration to the registry. The trace that you configure begins when you restart the computer.

The command uses the **/ro** parameter to enable Object Reference Tracing as a registry setting. The command uses the **/i** to specify the process for notepad.exe and the **/t** parameter to specify the pool tags **Tag1** and **Fred**. As a result, all objects that are created by the Notepad process with the **Tag1** or **Fred** pool tags are traced. The command also uses the **/p** parameter, which retains the trace data until the tracing is disabled.

```
gflags /ro /t Tag1;Fred /i Notepad.exe /p
```

When you submit the command, Gflags stores the information in the registry. However, because registry settings are not effective until you restart the computer, this object reference tracing is configured, but is not yet started.

Gflags responds by printing the following message:

```
Boot Registry Settings :  
Object Ref Tracing Enabled  
    Permanent Traces  
    Pool Tags: Tag1;Fred  
    Process Name: Notepad.exe
```

The message indicates that Object Reference Tracing is enabled in the registry. "Permanent Traces" indicates that the trace data will be retained until you shut down or restart the computer. The message also lists the pool tags and image file names that will be traced.

Display the Object Reference Tracing Configuration

You can display the Object Reference Tracing configuration that is currently effective or is stored in the registry to be used when the computer is restarted.

In this example, there is one Object Reference Tracing configuration stored in the registry and a different one configured for run time. The run-time trace begins immediately (and overrides any registry settings). However, if you restart the system, the run-time settings are lost, and the Object Reference Tracing session registry settings become effective.

The following command displays the run time Object Reference Tracing configuration. It uses the **/ko** parameter with no other parameters.

```
gflags /ko
```

```
Running Kernel Settings :  
Object Ref Tracing Enabled  
    Temporary Traces  
    Pool Tags: Tag1;Fred  
    Process Name: All Processes
```

If Object Reference Tracing is enabled, as it is in this example, the settings that are displayed describe a trace that is in progress.

The following command displays the Object Reference Tracing configuration data stored in the registry. It uses the **/ro** parameter with no other parameters.

```
gflags /ro
```

In response, Gflags displays the data stored in the registry:

```
Boot Registry Settings :  
Object Ref Tracing Enabled  
    Permanent Traces  
    Pool Tags: Tag1;Fred  
    Process Name: Notepad.exe
```

If you have restarted the computer since you added the Object Reference Tracing configuration to the registry, the settings that are displayed in response to a gflags /ro command describe the trace that is in progress. However, if you have not yet restarted, or you have restarted, but then started a run-time object reference trace (**/ko**), the settings that are stored in the registry are not currently effective, but they will become effective again when you reboot the system.

Disable Object Reference Tracing

When you disable run-time (kernel flag) Object Reference Tracing settings, the trace stops immediately. When you disable Object Reference Tracing settings in the registry, the trace stops when you restart the computer.

The following command disables run-time Object Reference Tracing. It uses the **/d** parameter to disable all settings. You cannot disable settings selectively.

```
gflags /ko -d
```

When the command succeeds, Gflags responds with the following message:

```
Running Kernel Settings :  
Object Ref Tracing Disabled
```

The following command disables run-time Object Reference Tracing.

The following command disables Object Reference Tracing settings in the registry. It uses the **/d** parameter to disable all settings. You cannot disable settings selectively. This command is effective when you restart the computer.

```
gflags /ro -d
```

When the command succeeds, Gflags responds with the following message:

```
Boot Registry Settings :  
Object Ref Tracing Disabled
```

Kill Tool

5/31/2017 • 1 min to read • [Edit Online](#)

The Kill tool, kill.exe, terminates one or more processes and all of their threads. This tool works only on processes running on the local computer.

Where to get Kill Tool

Kill.exe is included in [Debugging Tools for Windows](#).

Kill Tool command-line options

```
kill [/f] { PID | Pattern* }
```

Parameters

/f

Forces the termination of the process without prompting the user for confirmation. This option is required to terminate a protected process, such as a system service.

PID

Specifies the process identifier (PID) of the task to be terminated.

To find the PID for a task, use TaskList in Microsoft Windows XP and later or [TList](#) in Windows 2000.

*Pattern**

Specifies all or part of the name of a task or window. The Kill tool terminates all processes whose process names or window names match the pattern. The asterisk is required.

Before using a pattern that might match many process or window names unintentionally, use the **tlist pattern** command to test the pattern. See [TList](#) for details.

Examples

The following command terminates processes whose names begin with "myapp."

```
kill myapp*
```

The following command terminates the process whose process ID (PID) is 2520:

```
kill 2520
```

The following command terminates processes whose names begin with "my*." It does not prompt for confirmation. This command succeeds even when this process is a system service:

```
kill /f my*
```

Logger and LogViewer

5/26/2017 • 1 min to read • [Edit Online](#)

The *Logger* and *LogViewer* tools provide an alternative to standard user-mode debugging. *Logger* can monitor the actions of a user-mode target application and record all of its API calls. The resulting information can be displayed in the debugger, saved as a text file, or displayed in a powerful interactive format by the *LogViewer* tool..

Where to get Logger and LogViewer

Logger and *LogViewer* are included in [Debugging Tools for Windows](#).

In this section

[Logger](#)

[LogViewer](#)

[The Logger Manifest](#)

Logger

5/26/2017 • 1 min to read • [Edit Online](#)

The Logger tool can be activated through two different vehicles. One way is to use the stand-alone Logger.exe program. The other is to start CDB or WinDbg, and use the Logexts.dll debugger extensions. Both of these methods will produce the same type of log output. However, the best vehicle to use on any NT-based operating system is CDB or WinDbg with the Logexts.dll extension commands.

The Logger vehicle works as well, but using the debugger gives you the full power of the debugger along with the power of Logger.

This section includes:

[Using the Debugger and Logexts.dll](#)

[Using Logger.exe](#)

[Logger Restrictions and Limitations](#)

[Send comments about this topic to Microsoft](#)

Using the Debugger and Logexts.dll

5/26/2017 • 3 min to read • [Edit Online](#)

One way to activate Logger is to start CDB or WinDbg and attach to a user-mode target application as usual. Then, use the **[!logexts.logi](#)** or **[!logexts.loge](#)** extension command.

This will insert code at the current breakpoint that will jump off to a routine that loads and initializes Logexts.dll in the target application process. This is referred to as "injecting Logger into the target application."

There will actually be two instances of Logexts.dll running, since this module is both a debugger extension DLL and the program that is injected into the target application. The debugger and target instances of Logexts.dll communicate through a shared section of memory that includes the output file handles, current category mask, and a pointer to the log output buffer.

Attaching to the Target Application

For information about attaching the debugger to the target application, see [Debugging a User-Mode Process Using WinDbg](#) or [Debugging a User-Mode Process Using CDB](#).

Using the Logger Extension Commands

For the full syntax of each extension, see its reference page.

[!logexts.logi](#)

Injects Logger into the target application. This initializes logging, but does not enable it.

[!logexts.loge](#)

Enables logging. If **[!logexts.logi](#)** has not been used, this extension will initialize and then enable logging.

[!logexts.logd](#)

Disables logging. This will cause all API hooks to be removed in an effort to allow the program to run freely. COM hooks are not removed because they cannot be re-enabled at will.

[!logexts.logo](#)

Displays or modifies output options. Three types of output are possible: messages sent directly to the debugger, a text file, or an .lgv file. The .lgv file contains much more information than the other two; it can be read with [LogViewer](#).

If you disable the text file output, a .txt file of size zero will still be created. This may overwrite a previously-saved text file in the same location.

[!logexts.logc](#)

Displays available API categories, controls which categories will be logged and which will not, and displays the APIs that are contained in any category.

If a category is disabled, the hooks for all APIs in that category will be removed so that there is no longer any performance overhead. COM hooks are not removed because they cannot be re-enabled at will.

Enabling only certain categories can be useful when you are only interested in a particular type of interaction that the program is having with Windows -- for example, file operations. This reduces the log file size and also reduces the effect that Logger has on the execution speed of the process.

[!logexts.logb](#)

Displays or flushes the current output buffer. As a performance consideration, log output is flushed to disk only when the output buffer is full. By default, the buffer is 2144 bytes.

Since the buffer memory is managed by the target application, the automatic writing of the buffer to the log files on the disk will not occur if there is an access violation or some other non-recoverable error in the target application. In such cases, you should use this command to manually flush the buffer to the disk, or else the most recently-logged APIs may not appear in the log files.

[!logexts.logm](#)

Displays or creates a module inclusion/exclusion list. It is often desirable to only log those API calls that are made from a certain module or set of modules. To facilitate that, Logger allows you to specify a module inclusion list or, alternatively, a module exclusion list. For instance, you would use an inclusion list if you only wanted to log calls from one or two modules. If you wanted to log calls made from all modules except a short list of modules, you would use an exclusion list. The modules Logexts.dll and Kernel32.dll are always excluded, since Logger is not permitted to log itself.

[Send comments about this topic to Microsoft](#)

Using Logger.exe

5/26/2017 • 4 min to read • [Edit Online](#)

One way to activate Logger is to run the stand-alone Logger.exe program. This is essentially a very small debugger that can only take a single target. To run it, include the name of the target application on the command line:

```
logger Target
```

When this is activated, it will load the specified application, and insert code into the target application that will jump off to a routine that loads and initializes Logexts.dll in the target application process. This is referred to as "injecting Logger into the target application."

The Logger.exe utility and the Logexts.dll module are the two components of this Logger vehicle. They communicate through a shared section of memory that includes the output file handles, current category mask, and a pointer to the log output buffer.

A window entitled **Logger (debugger)** will appear. This window will display the progress of Logger.

Change Settings Dialog Box

After the initialization finishes and the initial display is complete, the **Change Settings** dialog box will appear. This allows you to configure the Logger settings. The various settings are described here:

API Settings

This list displays the available API categories. The highlighted categories will be logged; the non-highlighted categories will not. The first time you run Logger, all categories will be highlighted. However, on subsequent runs, Logger will keep track of which categories are selected for a given target application.

If a category is disabled, the hooks for all APIs in that category will be removed so that there is no longer any performance overhead. COM hooks are not removed because they cannot be re-enabled at will.

Enabling only certain categories can be useful when you are only interested in a particular type of interaction that the program is having with Windows -- for example, file operations. This reduces the log file size and also reduces the effect that Logger has on the execution speed of the process.

Logging

This section contains **Enable** and **Disable** radio buttons. Disabling logging will cause all API hooks to be removed in an effort to allow the program to run freely. COM hooks are not removed because they cannot be re-enabled at will.

Inclusion / Exclusion List

This section controls the module inclusion/exclusion list. It is often desirable to log only those function calls that are made from a certain module or set of modules. To facilitate that, Logger allows you to specify a module inclusion list or, alternatively, a module exclusion list. For instance, you would use an inclusion list if you only wanted to log calls from one or two module. If you wanted to log calls made from all modules except a short list of modules, you would use an exclusion list. The modules Logexts.dll and Kernel32.dll are always excluded, since Logger is not permitted to log itself.

Flush the Buffer

This button will flush the current output buffer. As a performance consideration, log output is flushed to disk only when the output buffer is full. By default, the buffer is 2144 bytes.

Since the buffer memory is managed by the target application, the automatic writing of the buffer to the log files

on the disk will not occur if there is an access violation or some other non-recoverable error in the target application. In such cases, you should try to activate the target application's window and hit F12 to get this dialog box back, and then press **Flush the Buffer**. If this is not done, the most recently-logged functions might not appear in the log files.

Go

This causes the target application to begin executing.

Running the Target Application

Once you have chosen the settings, click **Go**. The dialog box will close and the target application will begin to run.

If you make the target application's window active and press F12, it will break into Logger. This will cause the target application to freeze and the **Change Settings** dialog box to reappear. You can alter the settings if you wish, and then press **Go** to continue execution.

You can let the target application run for as long as you wish. If it terminates normally or due to an error, the logging will stop and cannot be restarted.

When you wish to exit, select **File | Exit** and click **Yes**. If the target application is still running, it will be terminated.

Limitations of Logger.exe

When you are running Logger through the Logger.exe tool, it will create only one output file -- an .lgv file. No text file will be written. However, a .txt file of size zero will be created; this could overwrite a text log written by the debugger previously.

The output file will always be placed in LogExts subdirectory of the desktop; this location cannot be changed.

These limitations will not apply if you are running Logger through the debugger and Logexts.dll.

[Send comments about this topic to Microsoft](#)

Logger Restrictions and Limitations

5/26/2017 • 1 min to read • [Edit Online](#)

Logger increases stack consumption for a process because it introduces an additional "wrapping" function before the actual function call.

This can expose bugs in applications that are usually related to uninitialized variables. Since Logger alters stack usage, a local variable declared in a function call might take a different initial value than it does without the presence of Logger. If the program uses this variable without initializing it, the program might crash or otherwise behave differently than if Logger was not present.

Unfortunately, there is no easy way around such problems. The only workaround is to try disabling categories of functions in an attempt to isolate the area that is causing the problem.

[Send comments about this topic to Microsoft](#)

LogViewer

5/26/2017 • 1 min to read • [Edit Online](#)

The LogViewer utility can manipulate an .lgv file, which is a compressed log file produced by the Logger tool. To load a file, simply launch Logviewer.exe through Windows Explorer or from a Command Prompt window. It will take a moment to parse the manifest files. Once this is complete, you can invoke **File | Open** and select the desired .lgv file.

Once LogViewer has opened an .lgv file, it will display a list of all functions in the order they were logged. LogViewer supports powerful commands to filter out functions that you are not interested in. It can also save a filtered version of the log file as a text file.

This section includes:

[Reading the LogViewer Display](#)

[Filtering the LogViewer Function List](#)

[Exporting LogViewer Files to Text](#)

[Send comments about this topic to Microsoft](#)

Reading the LogViewer Display

5/26/2017 • 1 min to read • [Edit Online](#)

LogViewer displays a list of all functions in the order they were logged.

Each row of the display contains several columns. The significance of each column is as follows.

COLUMN	MEANING
+/-	If this column contains a "+" (plus sign), it indicates that the function takes one or more parameters. To see the parameters and their values, either double-click the row or hit the right arrow key when the row is outlined in red. To hide it again, double click it again or hit the left arrow key when the row is outlined in red. There is also a "d#" value in this column. This indicates the "depth" of the function call (in other words, how deep the call is nested in other logged function calls).
#	The sequential row number of the function call. This is useful when you have filters applied and are interested to know how far apart two function calls are.
Thrd	The thread number on which the function call was made. This number is not a thread ID, but is rather an assigned number based on the order that threads were created in the process.
Caller	The instruction address that made the function call. This is derived from the return address for the call. It is actually the return address minus 5 bytes (the typical size of a call dword ptr instruction).
Module	The module that contains the calling instruction.
API Function	The name of the function. The name of the module that contains the function is omitted for brevity.
Return Value	The value returned by the function, if it is not a void function.

Double-clicking on a row in the viewer will expand the row to reveal the parameters to the function and their values "going in" to the function. If they are designated as OUT parameters, their value "coming out" is shown on the right.

You can also use the ENTER key or the right and left arrow keys to expand and collapse rows.

Function calls that returned failure status codes are shaded in pink.

[Send comments about this topic to Microsoft](#)

Filtering the LogViewer Function List

5/26/2017 • 1 min to read • [Edit Online](#)

Logger usually captures some function calls that are not needed for your analysis. These can be filtered out by Logger when it creates the log file. However, this process is not reversible, so it is usually preferable to allow all functions to be logged, and then filter the display in LogViewer.

There are several ways to filter out function calls in LogViewer:

- In the main viewing area, selected a function by clicking on it or using the cursor keys. (When a function is selected, LogViewer outlines it in red.) Then, press the **DELETE** key, or right-click and select **Hide**. This will hide all instances of that function call from view.
- Select **View | APIs Display**. A dialog box will appear that has three areas. On the right is an alphabetical listing of all functions, and on the left are categorical groupings. You can enable or disable the display of any function by checking or clearing the box to the left of its name.
- Select **View | Modules Display**. A dialog box will appear that allows you to select calling modules; only those functions that were called from these modules will be displayed.
- Select **View | First Level Calls Only**. This will display only calls that have "d0" in the left column. It is often desirable to hide function calls that are made by other logged functions. (For example, it is usually not interesting to know that **ShellExecuteEx** makes thirty different registry calls during its course of execution.)

[Send comments about this topic to Microsoft](#)

Exporting LogViewer Files to Text

5/26/2017 • 1 min to read • [Edit Online](#)

A powerful way to manipulate log files is to export them to text. This allows you to find specific parameter values by using the Find facility of any text editor. Although it is possible for a text file to be generated by Logger directly, you will have more flexibility if you use LogViewer to filter the function calls or add aliasing, and then export this information into a text file.

To create a text file from an .lgv file, open the file in LogViewer, and then select **File | Export to Text**. In the dialog box, choose a file name and location.

There are several options at the bottom of the dialog box:

Export Diff Information

This option will alias all pointers, handle values, and other values that change from execution to execution. Instead of outputting the actual value of a pointer (for example, "0x00123FA2"), LogViewer will output "Pointer." Similarly, handles will be aliased as "HeapHandle1" or some other value that will not register as a *diff* when the two files are compared using a differencing tool.

Include Non-Visible Rows

This option disables whatever filters are currently applied to the view while exporting.

Create a Separate File For Each Thread

This option splits up the text file by thread, making it easier to follow a thread of execution. This is useful if you intend to "diff" two instances of execution.

Export Range

This option specifies the range of rows to export.

The Logger Manifest

5/26/2017 • 1 min to read • [Edit Online](#)

This section includes:

[Overview of the Logging Manifest](#)

[Manifest File Placement](#)

[Manifest File Format](#)

[Send comments about this topic to Microsoft](#)

Overview of the Logging Manifest

5/26/2017 • 1 min to read • [Edit Online](#)

The logging manifest is the group of "header" files that define the functions and COM interfaces that are intercepted and logged. These are not true C++ header files -- they are in a slightly different format that explicitly declares the information needed by Logger.

For example, the manifest format facilitates the following features:

- Designation of OUT parameters. These are parameters that should be logged both on their way into a function and also on their way out.
- Definition of flag masks. This feature allows LogViewer to break a DWORD flag into its constituent bit labels for easier reading.
- Definition of failure cases. This feature allows LogViewer to shade the rows of functions that have returned a failure status code or another error code. Also, if the function sets the "LastError" value for the thread, LogViewer can store away the error code and expand it to its corresponding human-readable error message.
- Designation of parameters that can be aliased for log differencing. This feature gives LogViewer the option of assigning a constant string to a value that changes from execution to execution like pointers and handles when it exports the data to a file. You can then use a differencing tool to compare two execution logs for discrepancies. If pointers and handle values were not aliased, they would produce uninteresting discrepancies when the two files are compared.

[Send comments about this topic to Microsoft](#)

Manifest File Placement

5/26/2017 • 1 min to read • [Edit Online](#)

The primary manifest file must be named Main.h.

When Logger is running, Main.h must be located in the Manifest subdirectory of the directory containing Logexts.dll.

LogViewer is more flexible than Logger. It will search for Main.h in the following directories in this order:

1. The Manifest directory subordinate to the directory containing Logviewer.exe
2. The WinExt\Manifest directory subordinate to the directory containing logviewer.exe
3. The %WinDir%\System32\Manifest directory
4. The %WinDir%\System\Manifest directory

All additional manifest files must reside in the same directory as Main.h.

[Send comments about this topic to Microsoft](#)

Manifest File Format

5/26/2017 • 7 min to read • [Edit Online](#)

The file format for the manifest files borrows as much from C++ and IDL as possible. As a result, it is fairly easy to take a normal C++ SDK header file and modify it to be a manifest file. The parser fully supports C and C++ style comments to help you organize and document the file.

If you are attempting to add a manifest file or make alterations to an existing file, the best way to do it is to just experiment. When you issue a **!logexts.logi** or **!logexts.loge** command in the debugger, Logger will attempt to parse the manifest files. If it encounters a problem, it will produce an error message which might indicate the mistake.

A manifest file is made up of the following basic elements: module labels, category labels, function declarations, COM interface definitions, and type definitions. Other types of elements exist as well, but these are the most important.

Module Labels

A module label simply declares what DLL exports the functions that are declared thereafter. For example, if your manifest file is for logging a group of functions from Comctl32.dll, you would include the following module label before declaring any function prototypes:

```
module COMCTL32.DLL:
```

A module label must appear before any function declarations in a manifest file. A manifest file can contain any number of module labels.

Category Labels

Similar to a module label, a category label identifies which "category" all subsequent functions and/or COM interfaces belong to. For example, if you are creating a Comctl32.dll manifest file, you can use the following as your category label:

```
category CommonControls:
```

A manifest file can contain any number of category labels.

Function Declarations

A function declaration is what actually prompts Logger to log something. It is nearly identical to a function prototype found in a C/C++ header file. There are a few notable additions to the format, which can be best illustrated by the following example:

```
HANDLE [gle] FindFirstFileA(  
    LPCSTR lpFileName,  
    [out] LPWIN32_FIND_DATAA lpFindFileData);
```

The function **FindFirstFileA** takes two parameters. The first is *lpFileName*, which is a full path (usually with wildcards) defining where to search for a file or files. The second is a pointer to a WIN32_FIND_DATAA structure that will be used to contain the search results. The returned HANDLE is used for future calls to **FindNextFileA**. If **FindFirstFileA** returns INVALID_HANDLE_VALUE, then the function call failed and an error code can be procured by calling the **GetLastError** function.

The HANDLE type is declared as follows:

```
value DWORD HANDLE
{
#define NULL          0 [fail]
#define INVALID_HANDLE_VALUE -1 [fail]
};
```

If the value returned by this function is 0 or -1 (0xFFFFFFFF), Logger will assume that the function failed, because such values have a [fail] modifier in the value declaration. (See the Value Types section later in this section.) Since there is a [gle] modifier right before the function name, Logger recognizes that this function uses **GetLastError** to return error codes, so it captures the error code and logs it to the log file.

The [out] modifier on the *lpFindFileData* parameter informs Logger that the data structure is filled in by the function and should be logged when the function returns.

COM Interface Definitions

A COM interface is basically a vector of functions that can be called by a COM object's client. The manifest format borrows heavily from the Interface Definition Language (IDL) used in COM to define interfaces.

Consider the following example:

```
interface IDispatch : IUnknown
{
    HRESULT GetTypeInfoCount( UINT pctinfo  );

    HRESULT GetTypeInfo(
        UINT iTInfo,
        LCID lcid,
        LPVOID ppTInfo );

    HRESULT GetIDsOfNames(
        REFIID riid,
        LPOLECHAR* rgszNames,
        UINT cNames,
        LCID lcid,
        [out] DISPID* rgDispId );

    HRESULT Invoke(
        DISPID dispIdMember,
        REFIID riid,
        LCID lcid,
        WORD wFlags,
        DISPPARAMS* pDispParams,
        VARIANT* pVarResult,
        EXCEPINFO* pExcepInfo,
        UINT* puArgErr );
};
```

This declares an interface called **IDispatch** that is derived from **IUnknown**. It contains four member functions, which are declared in specific order within the interface's braces. Logger will intercept and log these member functions by replacing the function pointers in the interface's vtable (the actual binary vector of function pointers used at run time) with its own. See the COM_INTERFACE_PTR Types section later in this section for more details on how Logger captures interfaces as they are handed out.

Type Definitions

Defining data types is the most important (and most tedious) part of manifest file development. The manifest language allows you to define human-readable labels for numeric values that are passed in or returned from a function.

For example, Winerror.h defines a type called "WinError" that is a list of error values returned by most Microsoft Win32 functions and their corresponding human-readable labels. This allows Logger and LogViewer to replace uninformative error codes with meaningful text.

You can also label individual bits within a bit mask to allow Logger and LogViewer to break a DWORD bit mask into its components.

There are 13 basic types supported by the manifest. They are listed in the following table.

TYPE	LENGTH	DISPLAY EXAMPLE
Pointer	4 bytes	0x001AF320
VOID	0 bytes	
BYTE	1 byte	0x32
WORD	2 bytes	0xA23
DWORD	4 bytes	-234323
BOOL	1 byte	TRUE
LPSTR	Length byte plus any number of characters	"Quick brown fox"
LPWSTR	Length byte plus any number of Unicode characters	"Jumped over the lazy dog"
GUID	16 bytes	{0CF774D0-F077-11D1-B1BC-00C04F86C324}
COM_INTERFACE_PTR	4 bytes	0x0203404A
value	Dependent on base type	ERROR_TOO_MANY_OPEN_FILES
mask	Dependent on base type	WS_MAXIMIZED WS_ALWAYSONTOP
struct	Dependent on size of encapsulated types	+ IPoint nLeft 34 nRight 54 nTop 100 nBottom 300

Type definitions in manifest files work like C/C++ `typedefs`. For example, the following statement defines PLONG as a pointer to a LONG:

```
typedef LONG *PULONG;
```

Most basic typedefs have already been declared in Main.h. You should only have to add typedefs that are specific to your component. Structure definitions have the same format as C/C++ struct types.

There are four special types: value, mask, GUID, and COM_INTERFACE_PTR.

Value Types

A value is a basic type that is broken out into human-readable labels. Most function documentation only refers to the **#define** value of a particular constant used in a function. For example, most programmers are unaware of what the actual value is for all the codes returned by **GetLastError**, making it unhelpful to see a cryptic numerical value in LogViewer. The manifest value overcomes this by allowing value declarations like as in the following example:

```
value LONG ChangeNotifyFlags
{
#define SHCNF_IDLIST      0x0000      // LPITEMIDLIST
#define SHCNF_PATHA        0x0001      // path name
#define SHCNF_PRINTERA    0x0002      // printer friendly name
#define SHCNF_DWORD        0x0003      // DWORD
#define SHCNF_PATHW        0x0005      // path name
#define SHCNF_PRINTERW    0x0006      // printer friendly name
};
```

This declares a new type called "ChangeNotifyFlags" derived from LONG. If this is used as a function parameter, the human-readable aliases will be displayed instead of the raw numbers.

Mask Types

Similar to value types, a mask type is a basic type (usually a DWORD) that is broken out into human-readable labels for each of the bits that have meaning. Take the following example:

```
mask DWORD DirectDrawOptSurfaceDescCapsFlags
{
#define DDOSDCAPS_OPTCOMPRESSED          0x00000001
#define DDOSDCAPS_OPTREORDERED          0x00000002
#define DDOSDCAPS_MONOLITHICMIPMAP    0x00000004
};
```

This declares a new type derived from DWORD that, if used as a function parameter, will have the individual values broken out for the user in LogViewer. So, if the value is 0x00000005, LogViewer will display:

```
DDOSDCAPS_OPTCOMPRESSED | DDOSDCAPS_MONOLITHICMIPMAP
```

GUID Types

GUIDs are 16-byte globally-unique identifiers that are used extensively in COM. They are declared in two ways:

```
struct __declspec(uuid("00020400-0000-0000-C000-00000000046")) IDispatch;
```

or

```
class __declspec(uuid("11219420-1768-11D1-95BE-00609797EA4F")) ShellLinkObject;
```

The first method is used to declare an interface identifier (IID). When displayed by LogViewer, "IID_" is appended to the beginning of the display name. The second method is used to declare a class identifier (CLSID). LogViewer appends "CLSID_" to the beginning of the display name.

If a GUID type is a parameter to a function, LogViewer will compare the value against all declared IIDs and CLSIDs. If a match is found, it will display the IID friendly name. If not, it will display the 32-hexadecimal-character value in standard GUID notation.

COM_INTERFACE_PTR Types

The COM_INTERFACE_PTR type is the base type of a COM interface pointer. When you declare a COM interface, you are actually defining a new type that is derived from COM_INTERFACE_PTR. As such, a pointer to such a type can be a parameter to a function. If a COM_INTERFACE_PTR basic type is declared as an OUT parameter to a function and there is a separate parameter that has an [iid] label, Logger will compare the passed in IID against all declared GUIDs. If there is a match and a COM interface was declared that has the same name as the IID, Logger will hook all the functions in that interface and log them.

Here is an example:

```
STDAPI CoCreateInstance(
    REFCLSID rclsid,      //Class identifier (CLSID) of the object
    LPUNKNOWN pUnkOuter,  //Pointer to controlling IUnknown
    CLSCTX dwClsContext, //Context for running executable code
    [iid] REFIID riid,    //Reference to the identifier of the interface
    [out] COM_INTERFACE_PTR * ppv
        //Address of output variable that receives
        //the interface pointer requested in riid
);
```

In this example, *riid* has an [iid] modifier. This indicates to Logger that the pointer returned in *ppv* is a COM interface pointer for the interface identified by *riid*.

It is also possible to declare a function as follows:

```
DDRESULT DirectDrawCreateClipper( DWORD dwFlags, [out] LPDIRECTDRAWCLIPPER *lpDDClipper, IUnknown *pUnkOuter
);
```

In this example, LPDIRECTDRAWCLIPPER is defined as a pointer to the **IDirectDrawClipper** interface. Since Logger can identify which interface type is being returned in the *lpDDClipper* parameter, there is no need for an [iid] modifier on any of the other parameters.

PLMDebug

5/31/2017 • 3 min to read • [Edit Online](#)

PLMDebug.exe is a tool that enables you to use the Windows debugger to debug Windows app, which run under Process Lifecycle Management (PLM). With PLMDebug, you can take manual control of suspending, resuming, and terminating a Windows app.

Tip With Windows 10, version 1607 or later, you can use the UWP commands, such as `.createpackageapp` to debug UWP apps. For more information see [Debugging a UWP app using WinDbg](#).

Where to get PLMDebug

PLMDebug.exe is included in [Debugging Tools for Windows](#).

```
plmdebug /query [Package]
plmdebug /enableDebug Package [DebuggerCommandLine]
plmdebug /terminate Package
plmdebug /forceTerminate Package
plmdebug /cleanTerminate Package
plmdebug /suspend Package
plmdebug /resume Package
plmdebug /disableDebug Package
plmdebug /enumerateBgTasks Package
plmdebug /activateBgTaskTaskId
```

Parameters

Package

The full name of a package or the ID of a running process.

DebuggerCommandLine

A command line to open a debugger. The command line must include the full path to the debugger. If the path has blank spaces, it must be enclosed in quotes. The command line can also include arguments. Here are some examples:

```
"C:\Program Files (x86)\Windows Kits\8.0\Debuggers\x64\WinDbg.exe"
```

```
"\"C:\Program Files\Debugging Tools for Windows (x64)\WinDbg.exe\" -server npipe:pipe=test"
```

/query [Package]

Displays the running state for an installed package. If *Package* is not specified, this command displays the running states for all installed packages.

/enableDebug Package [DebuggerCommandLine]

Increments the debug reference count for a package. The package is exempt from PLM policy if it has a non-zero debug reference count. Each call to **/enableDebug** must be paired with a call to **/disableDebug**. If you specify *DebuggerCommandLine*, the debugger will attach when any app from the package is launched.

/terminate Package

Terminates a package.

/forceTerminate Package

Forces termination of a package.

/cleanTerminate Package

Suspends and then terminates a package.

/suspend *Package*

Suspends a package.

/resume *Package*

Resumes a package.

/disableDebug *Package*

Decrements the debug reference count for a package.

/enumerateBgTasks *Package*

Enumerate background task ids for a package.

/activateBgTask *TaskId*

Activates a background task. Note that not all background tasks can be activated using PLMDbg.

Remarks

You must call **plmdebug /enableDebug** before you call any of the suspend, resume, or terminate functions.

The PLMDbg tool calls the methods of the [IPackageDebugSettings interface](#). This interface enables you to take manual control of the process lifecycle management for your apps. Through this interface (and as a result, through this tool), you can suspend, resume, and terminate your Windows app. Note that the methods of the [IPackageDebugSettings interface](#) apply to an entire package. Suspend, resume, and terminate affect all currently running apps in the package.

Examples

Example 1

Attach a debugger when your app is launched

Suppose you have an app named MyApp that is in a package named MyApp_1.0.0.0_x64_tnq5r49etfg3c. Verify that your package is installed by displaying the full names and running states all installed packages. In a Command Prompt window, enter the following command.

plmdebug /query

```
Package full name: 1daa103b-74e1-426d-8193-b6bc7ed66fed_1.0.0.0_x86_tnq5r49etfg3c
Package state: Terminated

Package full name: 41fb5f27-7b60-4f5e-8459-803673131dd9_1.0.0.0_x86_tnq5r49etfg3c
Package state: Suspended
...
Package full name: MyApp_1.0.0.0_x64_tnq5r49etfg3c
Package state: Terminated
...
```

Increment the debug reference count for your package, and specify that you want WinDbg to attach when your app is launched.

plmdebug /enableDebug *MyApp_1.0.0.0_x64_tnq5r49etfg3c* "C:\Program Files (x86)\Windows Kits\8.0\Debuggers\x64\WinDbg.exe"

When you launch your app, WinDbg will attach and break in.

When you have finished debugging, detach the debugger. Then decrement the debug reference count for your package.

```
plmdebug /disableDebug MyApp_1.0.0.0_x64_tnq5r49etfg3c
```

Example 2

Attach a debugger to an app that is already running

Suppose you want to attach WinDbg to MyApp, which is already running. In WinDbg, on the **File** menu, choose **Attach to a Process**. Note the process ID for MyApp. Let's say the process ID is 4816.

Increment the debug reference count for the package that contains MyApp.

```
plmdebug /enableDebug 4816
```

In WinDbg, in the **Attach to Process** dialog box, select process 4816, and click **OK**. WinDbg will attach to MyApp.

When you have finished debugging MyApp, detach the debugger. Then decrement the debug reference count for the package.

```
plmdebug /disableDebug 4816
```

Example 3

Manually suspend and resume your app

Suppose you want to manually suspend and resume your app. First, increment the debug reference count for the package that contains your app.

```
plmdebug /enableDebug MyApp_1.0.0.0_x64_tnq5r49etfg3c
```

Suspend the package. Your app's suspend handler is called, which can be helpful for debugging.

```
plmdebug /suspend MyApp_1.0.0.0_x64_tnq5r49etfg3c
```

When you have finished debugging, resume the package.

```
plmdebug /resume MyApp_1.0.0.0_x64_tnq5r49etfg3c
```

Finally, decrement the debug reference count for the package.

```
plmdebug /disableDebug MyApp_1.0.0.0_x64_tnq5r49etfg3c
```

Remote Tool

5/26/2017 • 1 min to read • [Edit Online](#)

The Remote tool, Remote.exe, is a command-line tool that lets you run and control any console program from a remote computer.

Where to get the Remote tool

Remote.exe is included in [Debugging Tools for Windows](#).

Remote tool components

The Remote tool includes the following components:

- A server application that starts a console program and opens a named pipe for client connections.
- A client application that establishes a connection to a server. Commands typed on the client computer are sent to the console application on the server, and the remote client displays the output from the server's console window.
- A query feature that lists the remote sessions running on a server computer.

With the Remote tool, you can start multiple server sessions on a single computer where multiple clients can connect to each session. The sessions are limited only by the computer's resources.

This is an older tool that has been eclipsed by more sophisticated tools, primarily Remote Desktop. However, because it is simple and uses very few resources, it is still widely used, typically for remote debugging.

The Remote tool requires that commands be submitted on both the local and remote computers. As such, to use this tool on a computer without a local user, you must develop an alternate way to submit the commands and to restart the computer, if necessary.

The Remote tool can compromise security on your computer, because it does not authenticate users or use Microsoft Windows permissions. By default, any remote computer that can connect and provide the session name can use the named pipe that this tool creates, although you can use Remote tool options to include and exclude particular users and groups.

This section includes:

[Remote Tool Concepts](#)

[Remote Tool Commands](#)

[Remote Tool Examples](#)

Related topics

[Tools Included in Debugging Tools for Windows](#)

[Send comments about this topic to Microsoft](#)

Remote Tool Concepts

5/26/2017 • 1 min to read • [Edit Online](#)

The following concepts are used in the Remote tool.

Client and Server

The Remote tool uses a client-server paradigm that avoids the words *local* and *remote*, which are relative terms that can be confusing when there are multiple users and multiple computers.

Commands that you type at the client and server computers appear in the Command Prompt windows of both computers.

The Server

The *server* is the computer on which the console program runs. The *Remote Server* is the instance of the Remote tool running on the server. The server establishes and names the remote session (named pipe), issues the command to start the console program, and determines who is permitted to connect to the session.

The Client

The *client* is a remote computer that sends commands to the console program. The *Remote Client* is the instance of the Remote tool running on the client computer. The client connects to the remote session that the server established and uses the remote session (named pipe) that the server created to send commands to the console program that runs on the server.

The Remote tool supports multiple clients in each remote session. Each client is running one Remote Client. All of the clients can send commands to the console program running on the server, and all of the clients can see the commands sent and output displayed.

Visible Session

When remote sessions are *visible*, they appear in the list of remote sessions on the computer. To display the list, use the [Remote Server query command \(/q\)](#).

By default, only debugger sessions are visible, that is, sessions in which the value of the *Command* parameter include the words **kd**, **dbg**, **remoteds**, **ntsd**, or **cdb**; otherwise, the session is not visible. The *Command* parameter is part of the Remote tool command on the server.

To make a session visible, add the **/v** parameter to the [Remote Server](#) command. To make a debugger session invisible, add the **/-v** parameter to the command.

For help with the Remote Server query command, see [Remote Server Query Command](#).

[Send comments about this topic to Microsoft](#)

Remote Tool Commands

5/26/2017 • 1 min to read • [Edit Online](#)

The Remote tool has a separate command syntax for the client and server sides of a session. Commands to start a server session must be entered first because they establish the communications pipe to which the client connects.

The Remote tool also has a query command and a separate set of commands that you use to communicate with the Remote tool (instead of the console program) during a remote session.

These commands are described in the following topics:

[Remote Server Syntax](#)

[Remote Client Syntax](#)

[Remote Server Query Command](#)

[Remote Session Commands](#)

[Send comments about this topic to Microsoft](#)

Remote Server Syntax

5/31/2017 • 2 min to read • [Edit Online](#)

To start the server side of the Remote tool, use the following syntax at the command line.

```
remote /s Command SessionName [/f Color] [/b] [/u User [/u User...]] [/ud User [/ud User...]] [/v | /-v]
```

Parameters

/s

Starts a server session.

Command

Specifies the command that starts the console-based program. The command can include parameters. If the command includes spaces, enclose it in quotation marks.

SessionName

Assigns a name to the remote session. If the name includes spaces, enclose it in quotation marks. This parameter is not case-sensitive.

/f

Specifies the color of the text in the server command window.

/b

Specifies the background color of the server command window.

Color

Specifies a color. Valid values are black, blue, green, cyan, red, purple, yellow, white, lblack, lblue, lgreen, lred, lpurple, lyellow, and lwhite.

/u

Specifies users or groups that are permitted to connect to the remote session; by default, everyone is permitted. When you use this parameter, everyone is denied permission, except for the users and groups specified by the *User* subparameter.

/ud

Specifies users or groups that are denied permission to connect to the remote session; by default, no one is denied permission.

User

Specifies the name of a user or group in *[domain | computer]\{user | group}* format. When specifying users or groups on the local computer, omit the computer name.

/v

Makes a session visible. For more information, see [Visible Session](#).

By default, only debugger sessions are visible, that is, sessions in which the value of the *Command* parameter include the words **kd**, **dbg**, **remoted**, **ntsd**, or **cdb**; otherwise, the session is not visible.

-v

Makes a remote debugger session invisible. For more information, see [Visible Session](#).

Comments

The *Command* and *SessionName* parameters must appear in the order shown on the syntax line.

To end a remote session, type **@k**. For more information, see [Remote Session Commands](#).

The Remote tool will not create a session that the current user does not have permission to join.

When starting more than one remote session on a single computer, open a new command window for each session. Also, use a different session name for each session. Because the session names are used to label the named pipes, they must be unique on the computer.

Sample Usage

```
remote /s "i386kd -v" TestSession
remote /s "cmd" "My Remote Session" /f white /b black /u Server01\Administrators
remote /s "ntsd -d -g -x" DebugIt /-v
remote /q Server01
```

[Send comments about this topic to Microsoft](#)

Remote Client Syntax

5/31/2017 • 1 min to read • [Edit Online](#)

To start the client side of the Remote tool, use the following syntax at the command line.

```
remote /c Server SessionName [/L Lines] [/f] [/b] [/k ColorFile]
```

Parameters

/c

Connects the client to a remote session.

Server

Specifies the computer name of the server that established the session.

SessionName

Specifies the name of the remote session. This parameter is not case-sensitive.

/L Lines

Specifies the number of lines from the console display that are sent to the client computer. The default is 200 lines. *Lines* is a decimal number.

/f

Specifies the color of the text in the server command window.

/b

Specifies the background color of the server command window.

Color

Specifies a color. Valid values are black, blue, green, cyan, red, purple, yellow, white, lblack, lblue, lgreen, lred, lpurple, lyellow, and lwhite.

/k ColorFile

Indicates the path (optional) and name of a formatted text file that specifies the colors for displaying the output on the client computer.

The color file associates keywords in the output with text colors. When the keywords appear in a line of output, the Remote tool applies the associated text color to that line. For the format of the file, see "Remarks".

/q Computer

Displays the remote sessions available on the specified computer. Only visible sessions appear in the list. (See **/v** in [Remote Server Syntax](#).)

Comments

The *Server* and *SessionName* parameters must appear in the order shown on the syntax line.

To disconnect from a remote session, type **@q**. For more information, see [Remote Session Commands](#).

Keyword Color File. The format of the keyword color file is as follows. The keyword interpreter is not case sensitive.

The keyword or phrase appears on a line by itself. The colors associated with that keyword appear by themselves on the following line, as shown in the syntax:

```
Keyword
TextColor[, BackgroundColor]
```

For example, the following file directs Remote to display lines that include the word "error" in black text on a light red background; to display lines that include the word "warning" in light blue (on the default background), and lines that include the phrase "Windows Vista" in light green on the default background.

```
ERROR
black, lred
WARNING
lblue
Windows Vista
lgreen
```

Sample Usage

```
remote /c Server01 TestSession
remote /c Domain1\ComputerA0 "cmd" "My Remote Session"
remote /c Server01 TestSession /L 50 /f black /b white /k c:\remote_file.txt
remote /q Server01
```

[Send comments about this topic to Microsoft](#)

Remote Server Query Command

5/31/2017 • 1 min to read • [Edit Online](#)

To display a list of available sessions on a local or Remote Server, use the following syntax.

```
remote /q Computer
```

Parameters

/q

Query. Displays the visible remote sessions on the specified computer.

Computer

Specifies the name of the computer. This parameter is required (even on the local computer).

Comments

The query display includes only server sessions; it does not display client connections to remote sessions.

The query display includes only visible sessions. There is no command to display invisible sessions.

The query display includes all visible sessions, including those that restrict users (**/u** and **/ud**). The user might not have permission to connect to all of the sessions in the list.

When there are no remote sessions running on the server, the Remote tool displays the following message:

```
No Remote servers running on \\Computer
```

However, when the only remote sessions running on the computer are invisible remote sessions, the Remote tool displays the following message:

```
No visible sessions on server \\Computer
```

[Send comments about this topic to Microsoft](#)

Remote Session Commands

5/26/2017 • 1 min to read • [Edit Online](#)

Use the following commands to communicate with the Remote tool during a console session.

@H

Displays the session commands on server and client computers. Works on server and client computers.

@M Message

Displays the specified message on all server and client computers in the session. Works on server and client computers.

@P Message

Generates a pop-up window on the server computer with the specified message. On client computers, the message appears in the command window. Works on server and client computers.

@Q

Quit. Disconnects a client computer from the session. Works only on a client computer.

@K

Disconnects all clients and ends the remote session. Works only on a server computer.

Comments

For samples, see "Using the Session Commands" in [Remote Tool Examples](#).

In response to the session commands, the Remote tool displays a label with the day and time that the command was executed. The time for all events is displayed in the time zone of the server computer.

[Send comments about this topic to Microsoft](#)

Remote Tool Examples

5/26/2017 • 6 min to read • [Edit Online](#)

The examples in this section demonstrate the use of the Remote tool and show sample input and output.

Basic Server Command

The following command starts a remote session on the computer.

The command uses the **/s** parameter to indicate a server-side command. It uses the command, **cmd**, to start the Windows command shell (Cmd.exe), and names the session **test1**.

```
remote /s cmd test1
```

In response, the Remote tool starts the session and displays the command that clients would use to connect to the session.

```
*****  
*****      REMOTE      *****  
*****      SERVER      *****  
*****  
To Connect: Remote /C SERVER06 "test1"  
  
Microsoft Windows XP [Version 5.1.2600]  
(C) Copyright 1985-2001 Microsoft Corp.
```

Basic Client Command

The following command connects to a remote session on the Server01 computer. The command uses the **/c** parameter to indicate a client-side command. It specifies the name of the server computer, **Server01**, and the name of the session on that computer, **test1**.

```
remote /c server01 test1
```

In response, the Remote tool displays a message reporting that the client computer is connected to the session on the server computer. The message displays the name of the server computer and local user (**Server04 user1**).

```
*****  
*****      REMOTE      *****  
*****      CLIENT      *****  
*****  
Connected...  
  
Microsoft Windows XP [Version 5.1.2600]  
(C) Copyright 1985-2001 Microsoft Corp.  
  
C:\Program Files\Debugging Tools for Windows>  
**Remote: Connected to SERVER04 user1 [Tue 9:39 AM]
```

After the client connects to the server, the commands typed at the command prompt on the client and server computers appear on both displays..

For example, if you type **dir** at the command prompt of the client computer, the directory display appears in the Command Prompt window on both the client and server computers.

Using Server Options

The following server-side command starts a remote session with the NTSD debugger.

The command uses the **/s** parameter to indicate a server-side command. The next parameter, "**ntsd -d -v**", is the console command that starts the debugger, along with the debugger options. Because the console command includes spaces, it is enclosed in quotation marks. The command includes a name for the session, **debugit**.

The command uses the **/u** parameter to permit only administrators of the computer and a particular user, User03 in Domain01, to connect to the session. It uses the **/f** and **/b** options to specify black text (foreground) on a white background.

Finally, the command uses the **/-v** parameter to make the session invisible to user queries. Debugger sessions are visible by default.

```
remote /s "ntsd -d -v" DebugIt /u Administrators /u Domain01\User03  
/f black /b white /-v
```

In response, the Remote tool creates a session named DebugIt and starts NTSD with the specified parameters. The message indicates that only the specified users have permission to connect. It also changes the command window to the specified colors.

```
*****  
*****      REMOTE      *****  
*****      SERVER      *****  
*****  
  
Protected Server! Only the following users or groups can connect:  
Administrators  
Domain01\User03  
To Connect: Remote /C SERVER06 "debugit"  
  
Microsoft Windows XP [Version 5.1.2600]  
(C) Copyright 1985-2001 Microsoft Corp.
```

Using Client Options

The following command connects to the remote session with the NTSD debugger that was started in the previous example.

The command uses the **/c** parameter to indicate a client-side command. It specifies the name of the server computer, **server06**, and the name of the remote session, **debugit**.

The command also includes the **/k** parameter to specify the location of a keyword color file.

```
remote /c server06 debugit /k c:\remote_client.txt
```

The color file includes the following text:

```
Registry  
white, blue  
Token  
red, white
```

This text instructs the Remote tool to display lines of output with the word "registry" (not case sensitive) in white text on a blue background and to display lines of output with the word "token" in red text on a white background.

In response, the Remote tool connects the client to the server session and displays the following message.

```
*****  
***** REMOTE *****  
***** CLIENT *****  
*****  
Connected...  
  
Microsoft Windows XP [Version 5.1.2600]  
(C) Copyright 1985-2001 Microsoft Corp.
```

The client can now send commands to the NTSD debugger on the server computer. The output from the command appears on both the client and server computers.

Lines of output with the word "registry" are displayed on the client computer in white text on a blue background, and lines of output with the word "kernel" in red text on a white background.

Querying a Session

The Remote tool includes a query parameter (**/q**) that displays a list of remote sessions on a particular computer. The display includes only visible sessions (debugger sessions started without the **/v** parameter and non-debugger sessions started with the **/v** parameter).

You can query for sessions from the server or client computers. You must specify the computer name, even when querying for sessions on the local computer.

The following command queries for sessions on the local computer, **Server04**.

```
remote /q Server04
```

In response, the Remote tool reports that there are no remote sessions running on the local computer.

```
Querying server \\Server04  
No Remote servers running on \\Server04
```

In contrast, in response to a query about sessions on a different computer, **Server06**, the Remote tool lists the sessions running on that computer.

```
Querying server \\Server06  
  
Visible sessions on server Server06:  
  
ntsd [Remote /C SERVER06 "debug"] visible  
cmd [Remote /C SERVER06 "test"] visible
```

The display lists the visible sessions, the console programs running on those sessions (NTSD and the Command Prompt window), and the command that connects to the session. The session name appears in the command syntax in quotation marks.

The display does not show the permissions established for these sessions, if any. Therefore, the display might include sessions that you do not have permission to join.

Using the Session Commands

You can use the remote session commands at any time during a remote session.

The following command sends a message to all computers connected to the session.

```
@M I think I found the problem.
```

As a result, the message appears in the Command Prompt windows of all computers in the session. The message includes the computer name and the day and time of the message.

```
@m I think I found the problem.      [SERVER01]      Wed 11:53 AM]
```

When the message is sent from the server computer, "Local" appears in the label instead of the computer name.

```
@m I think I found the problem.      [Local]      Wed 11:52 AM]
```

The following command generates a pop-up message that appears on the server computer. On all client computers in the session, it writes a message to the Command Prompt window.

```
@P Did you see that?
```

On client computers, the pop-up message appears in the command window.

```
From SERVER02 [Wed 11:58 AM]
```

```
Did you see that?
```

The time that appears in the message label is always the time on the server computer, even if the client computer that sent the message is in a different time zone.

Ending a Remote Session

The following examples demonstrate how to use the remote session commands to disconnect a client computer from a session and to end a remote session. Only the server computer that started the remote session can end it.

To disconnect a client computer from a remote session, on the client computer, type **@q**.

In response, the following message appears on the client computer that disconnected.

```
*** SESSION OVER ***
```

On all other computers in the session, the Remote tool posts a message with the name of the computer and user who disconnected, and the day and time of the disconnect.

```
**Remote: Disconnected from SERVER04 User01 [Wed 12:01 PM]
```

To end a remote session, on the server computer, type **@k**. This command automatically disconnects the clients, and then ends the session.

title: TList description: TList (Task List Viewer), Tlist.exe, displays the processes running on the local computer along with useful information about each process. ms.assetid: 4cba525f-12f0-45c9-8dee-c3e0ab9fd944 keywords: ["TList", "Task List Viewer", "Task List Viewer, See "TList"""] ms.author: windowsdriverdev ms.date: 05/23/2017 ms.topic: article ms.prod: windows-hardware

ms.technology: windows-devices

TList

TList (Task List Viewer), Tlist.exe, is a command-line tool that displays the processes running on the local computer along with useful information about each process.

TList displays:

- All processes running on the computer, along with their process IDs (PIDs).
- A tree showing which processes created each process.
- Details of the process, including its virtual memory use and the command that started the process.
- Threads running in each process, including their thread IDs, entry points, last reported error, and thread state.
- The modules running in each process, including the version number, attributes, and virtual address of the module.

You can use TList to search for a process by name or PID, or to find all processes that have loaded a specified module.

In Windows XP and later versions of Windows, TList was replaced by TaskList (Tasklist.exe), which is described in Help and Support for those systems. TList is included in Debugging Tools for Windows to support users who do not have access to TaskList.

This section includes:

TList Commands

[TList Examples](#)

[Send comments about this topic to Microsoft](#)

TList Commands

5/31/2017 • 2 min to read • [Edit Online](#)

The syntax of the TList command is as follows:

```
tlist [/p ProcessName | PID | Pattern | /t | /c | /e | /k | /m [Module] | /s | /v
```

Parameters

tlist

Without additional parameters, TList displays all running processes, their process identifiers (PIPs), and the title of the window in which they are running, if any.

/p ProcessName

Displays the process identifier (PID) of the specified process.

ProcessName is the name of the process (with or without file name extension), not a pattern.

If the value of *ProcessName* does not match any running process, TList displays -1. If it matches more than one process name, TList displays only the PID of the first matching process.

PID

Displays detailed information about the process specified by the PID. For information about the display, see the "Remarks" section below. To find a process ID, type **tlist** without additional parameter.

Pattern

Displays detailed information about all processes whose names or window titles match the specified pattern.

Pattern can be a complete name or a regular expression.

/t

Displays a task tree in which each process appears as a child of the process that created it.

/c

Displays the command line that started each process.

/e

Displays the session identifier for each process.

/k

Displays the COM components active in each process.

/m Module

Lists tasks in which the specified DLL or executable module is loaded. Module can be a complete module name or a module name pattern.

/s

Displays the services that are active in each process.

/v

Displays details of running processes including the process ID, session ID, window title, command line, and the services running in the process.

Comments

In its detailed display of a process (**tlist PID** or **tlist Pattern**), TList displays the following information.

- Process ID, executable name, friendly name of the program.
- Current working directory (CWD).
- The command line that started the process (CmdLine).
- Current virtual address space values.
- Number of threads.
- A list of threads running in the process. For each thread, TList displays the thread ID (TID), the function that the thread is running, the address of the entry point, the address of the last reported error (if any), and the thread state.
- A list of the modules loaded for the process. For each module, TList displays the version number, attributes, virtual address of the module, and the module name.

When using the **/e** parameter, valid session identifiers appear in the process list only under the following conditions. Otherwise, the session identifier is zero (0).

- On Windows 2000 and Windows Server 2003, at least one user must be connected to a session other than the console session.
- On Windows XP, Fast User Switching must be enabled and more than one user must be connected to the non-console session.
- On Windows Vista, where all processes are associated with two Terminal Services sessions by default, at least one user must be connected to the non-console session.

[Send comments about this topic to Microsoft](#)

TList Examples

5/26/2017 • 3 min to read • [Edit Online](#)

The following examples demonstrate how to use TList.

Simplest TList Command (tlist)

Typing **tlist** without additional parameters displays a list of running processes, their process IDs (PIDs), and the title of the window in which they are running, if any.

```
c:\>tlist

 0 System Process
 4 System
308 smss.exe
356 csrss.exe
380 winlogon.exe      NetDDE Agent
424 services.exe
436 lsass.exe
604 svchost.exe
776 svchost.exe
852 spoolsv.exe
1000 clisvcl.exe
1036 InoRpc.exe
1064 InoRT.exe
1076 InoTask.exe
1244 WTTSvc.exe
1492 Sysparse_com.exe OleMainThreadWndName
1980 explorer.exe     Program Manager
1764 launch32.exe    SMS Client User Application Launcher
1832 msmsgs.exe      MSBLNetConn
2076 ctfmon.exe
2128 ISATRAY.EXE     IsaTray
4068 tlist.exe
```

Find a process ID (-p)

The following command uses the **-p** parameter and process name to find the process ID of the Explorer.exe (Explorer) process.

In response, TList displays the process ID of the Explorer process, 328.

```
c:\>tlist -p explorer
328
```

Find process details using PID

The following command uses the process ID of the process in which Explorer is running to find detailed information about the Explorer process.

```
c:\>tlist 328
```

In response, TList displays details of the Explorer process including the following elements:

- Process ID, executable name, program friendly name.
- Current working directory (CWD).

- The command line that started the process (CmdLine).
- Current virtual address space values.
- Number of threads.
- A list of threads running in the process. For each thread, TList displays the thread ID (TID), the function that the thread is running, the address of the entry point, the address of the last reported error (if any), and the thread state.
- A list of the modules loaded for the process. For each module, TList displays the version number, attributes, virtual address of the module, and the module name.

The following is an excerpt of the output resulting from this command.

```
328 explorer.exe      Program Manager
  CWD:      C:\Documents and Settings\user01\
  CmdLine: C:\WINDOWS\Explorer.EXE
  VirtualSize:  90120 KB  PeakVirtualSize:  104844 KB
  WorkingSetSize: 19676 KB  PeakWorkingSetSize: 35716 KB
  NumberOfThreads: 17
    332 Win32StartAddr:0x010160cc LastErr:0x00000008 State:Waiting
    1232 Win32StartAddr:0x70a7def2 LastErr:0x00000000 State:Waiting
    1400 Win32StartAddr:0x77f883de LastErr:0x00000000 State:Waiting
    1452 Win32StartAddr:0x77f91e38 LastErr:0x00000000 State:Waiting
    1484 Win32StartAddr:0x70a7def2 LastErr:0x00000006 State:Waiting
    1904 Win32StartAddr:0x74b02ed6 LastErr:0x00000000 State:Ready
    1948 Win32StartAddr:0x72d22ecc LastErr:0x00000000 State:Waiting
    .... (thread data deleted here)

  6.0.2800.1106 shp 0x01000000 Explorer.EXE
  5.1.2600.1217 shp 0x77F50000 ntdll.dll
  5.1.2600.1106 shp 0x77E60000 kernel32.dll
  7.0.2600.1106 shp 0x77C10000 msrvct.dll
  5.1.2600.1106 shp 0x77DD0000 ADVAPI32.dll
  5.1.2600.1254 shp 0x78000000 RPCRT4.dll
  5.1.2600.1106 shp 0x77C70000 GDI32.dll
  5.1.2600.1255 shp 0x77D40000 USER32.dll
  .... (module data deleted here)
```

Find multiple processes (Pattern)

The following command searches for processes by a regular expression that represents the process name or window name of one or more processes. In this example, the command searches for a process whose process name or window name begins with "ino."

```
c:\>tlist ino*
```

In response, TList displays process details for Inorpc.exe, Inort.exe, and Inotask.exe. For a description of the output, see the "Find process details using PID" subsection above.

Display a process tree (/t)

The following command displays a tree that represents the processes running on the computer. Processes appear as the children of the process that created them.

```
c:\>tlist /t
```

The resulting process tree follows. This tree shows, among other things, that the System (4) process created the Smss.exe process, which created Csrss.exe, Winlogon.exe, Lsass.exe and Rundll32.exe. Also, Winlogon.exe created

Services.exe, which created all of the service-related processes.

```
System Process (0)
System (4)
smss.exe (404)
csrss.exe (452)
winlogon.exe (476) NetDDE Agent
services.exe (520)
svchost.exe (700)
svchost.exe (724)
svchost.exe (864)
svchost.exe (888)
spoolsv.exe (996)
scardsvr.exe (1040)
alg.exe (1172)
atievxx.exe (1200) ATI video bios poller
InoRpc.exe (1248)
InoRT.exe (1264)
InoTask.exe (1308)
mdm.exe (1392)
dllhost.exe (2780)
lsass.exe (532)
rundll32.exe (500)
explorer.exe (328) Program Manager
WLANMON.exe (1728) TI Wireless LAN Monitor
ISATRAY.EXE (1712) IsaTray
cmmn32.exe (456)
WINWORD.EXE (844) Tlist.doc - Microsoft Word
dexplore.exe (2096) Platform SDK - CreateThread
```

Find process by module (/m)

The following command finds all of the processes running on the computer that load a particular DLL.

```
c:\>tlist /m
```

In response, TList displays process details for Inorpc.exe, Inort.exe, and Inotask.exe. For a description of the output, see the "Find process details using PID" subsection above.

[Send comments about this topic to Microsoft](#)

UMDH

5/31/2017 • 1 min to read • [Edit Online](#)

The User-Mode Dump Heap (UMDH) tool, Umdh.exe, analyzes the Microsoft Windows heap memory allocations for a given process. UMDH has the following modes.

- **Analyze a running process** ("Mode 1"). UMDH captures and analyzes the heap memory allocations for a process. For each allocation, UMDH displays the size of the allocation, the size of the overhead, the pointer to the allocation and the allocation stack. If a process has more than one active memory heap, UMDH captures all heaps. This analysis can be displayed in realtime or saved in a log file.
- **Analyze UMDH log files** ("Mode 2"). UMDH analyzes the log files it has previously created. UMDH can compare two logs created for the same process at different times, and display the calls in which the allocation size increased the most. This technique can be used to find memory leaks.

This section includes:

[Preparing to Use UMDH](#)

[UMDH Commands](#)

[Interpreting a UMDH Log](#)

[Interpreting a Log Comparison](#)

[Send comments about this topic to Microsoft](#)

Preparing to Use UMDH

5/31/2017 • 3 min to read • [Edit Online](#)

You must complete the configuration tasks described in this section before using User-Mode Dump Heap (UMDH) to capture the heap allocations for a process. If the computer is not configured correctly, UMDH will not generate any results or the results will be incomplete or incorrect.

Create the user-mode stack trace database

Before using UMDH to capture the heap allocations for a process, you must configure Windows to capture stack traces.

To enable stack trace capturing for a process, use [GFlags](#) to set the **Create user mode stack trace database** flag for the process. This can be done by either of the following methods:

- In the GFlags graphical interface, choose the **Image File** tab. Type the process name, including the file name extension (for example, Notepad.exe). Press the **TAB** key, select **Create user mode stack trace database**, and then click **Apply**.
- Or, equivalently, use the following GFlags command line, where *ImageName* is the process name (including the file name extension):

```
gflags /i ImageName +ust
```

By default, the amount of stack trace data that Windows gathers is limited to 32 MB on an x86 processor, and 64 MB on an x64 processor. If you must increase the size of this database, choose the **Image File** tab in the GFlags graphical interface, type the process name, press the **TAB** key, check the **Stack Backtrace (Megs)** check box, type a value (in MB) in the associated text box, and then click **Apply**.

Note Increase this database only when necessary, because it may deplete limited Windows resources. When you no longer need the larger size, return this setting to its original value.

These settings affects all new instances of the program. It does not affect currently running instances of the program.

Access the Necessary Symbols

Before using UMDH, you must have access to the proper symbols for your application. UMDH uses the symbol path specified by the environment variable `_NT_SYMBOL_PATH`. Set this variable equal to a path containing the symbols for your application.

If you also include a path to Windows symbols, the analysis may be more complete. The syntax for this symbol path is the same as that used by the debugger; for details, see [Symbol Path](#).

For example, if the symbols for your application are located at `C:\MyApp\Symbols`, and you have installed the Windows symbol files to `\myshare\winsymbols`, you would use the following command to set your symbol path:

```
set _NT_SYMBOL_PATH=c:\myapp\symbols;\myshare\winsymbols
```

As another example, if the symbols for your application are located at `C:\MyApp\Symbols`, and you want to use the public Microsoft symbol store for your Windows symbols, using `C:\MyCache` as your downstream store, you would use the following command to set your symbol path:

```
set _NT_SYMBOL_PATH=c:\myapp\symbols;srv*c:\mycache*https://msdl.microsoft.com/download/symbols
```

Important Suppose you have two computers: a *logging computer* where you create a UMDH log and an *analysis computer* where you analyze the UMDH log. The symbol path on your analysis computer must point to the symbols for the version of Windows that was loaded on the logging computer at the time the log was made. Do not point the symbol path on the analysis computer to a symbol server. If you do, UMDH will retrieve symbols for the version of Windows that is running on the analysis computer, and UMDH will not display meaningful results.

Disable BSTR Caching

Automation (formerly known as OLE Automation) caches the memory used by BSTR strings. This can prevent UMDH from correctly determining the owner of a memory allocation. To avoid this problem, you must disable BSTR caching.

To disable BSTR caching, set the OANOCACHE environment variable equal to one (1). This setting must be made before launching the application whose allocations are to be traced.

Alternatively, you can disable BSTR caching from within the application itself by calling the .NET Framework **SetNoOaCache** function. If you choose this method, you should call this function early, because any BSTR allocations that have already been cached when **SetNoOaCache** is called will remain cached.

If you need to trace the allocations made by a service, you must set OANOCACHE as a system environment variable and then restart Windows for this setting to take effect.

On Windows 2000, in addition to setting OANOCACHE equal to 1, you must also install the hotfix available with [Microsoft Support Article 139071](#). This hotfix is not needed on Windows XP and later versions of Windows.

Find the Process ID

UMDH identifies the process by its process identifier (PID). You can find the PID of any running process by using Task Manager, Tasklist (Windows XP and later operating systems), or [TList](#).

[Send comments about this topic to Microsoft](#)

UMDH Commands

5/26/2017 • 1 min to read • [Edit Online](#)

UMDH has two different modes, each with its own command syntax and parameters:

- **Analyze a Running Process** - Displays all the heap allocation in a process.
- **Analyze UMDH Logs** - Compares the allocation list made at two different times for the same process. Analyzing the differences can help to identify memory leaks.

[Send comments about this topic to Microsoft](#)

Analyze a Running Process

5/31/2017 • 1 min to read • [Edit Online](#)

Use the following commands to record and analyze the heap memory allocations in a running process. This analysis focuses on stack traces.

```
umdh -p:PID [-f:LogFile] [-v[:MsgFile]] | [-g] | [-h]
```

Parameters

-p:PID

Specifies the process to analyze. *PID* is the process ID of the process. This parameter is required.

To find the PID of a running process, use Task Manager, Tasklist (Windows XP and later operating systems), or [TList](#).

-f:LogFile

Saves the log contents in a text file. By default, UMDH writes the log to stdout (command window).

LogFile specifies the path (optional) and name of the file. If you specify an existing file, UMDH overwrites the file.

Note If UMDH was not started in Administrator mode, or attempts to write to "protected" paths, it will be denied access.

-v[:MsgFile]

Verbose mode. Generates detailed informational and error messages. By default, UMDH writes these messages to stderr.

MsgFile specifies the path (optional) and name of a text file. When you use this variable, UMDH writes the verbose messages to the specified file, instead of to stderr. If you specify an existing file, UMDH overwrites the file.

-g

Logs the heap blocks that are not referenced by the process ("garbage collection").

-h

Displays help.

Comments

On Windows 2000, if UMDH is reporting errors finding the stack trace database, and you have enabled the **Create user mode stack trace database** option in [GFlags](#), you might have a symbol file conflict. To resolve it, copy the DBG and PDB symbol files for the application to the same directory, and try again.

Sample Usage

```
umdh -?  
umdh -p:2230  
umdh -p:2230 -f:dump_allocations.txt

Analyze UMDH Logs

5/31/2017 • 1 min to read • [Edit Online](#)

Use the following commands to analyze User-Mode Dump Heap (UMDH) logs that were created by running UMDH with the syntax described in [Analyze a Running Process](#). This analysis focuses on allocations, instead of stack traces.

You can analyze a single log file or compare logs from different runs to detect the changes in the program or driver's memory dump allocations over time.

```
umdh [-d] [-v] [-l] File1 [File2] [-h | ?]
```

Parameters

-d

Displays numeric data in decimal numbers. The default is hexadecimal.

-v

Verbose mode. Includes the traces, as well as summary information. The traces are most helpful when analyzing a single log file.

-l

Includes file names and line numbers in the log. (Please note that the parameter is the lowercased letter "L," not the number one.)

File1 [File2]

Specifies the UMDH log files to analyze.

UMDH creates log files when you run it in the [analyze a running process](#) mode and save the log content in a text file (**-f**).

When you specify one log file, UMDH analyzes the file and displays the function calls in each trace in descending order of bytes allocated.

When you specify two log files, UMDH compares the files and displays in descending order the function calls whose allocations have grown the most between the two trials.

-h | ?

Displays help.

Sample Usage

```
umdh dump.txt
umdh -d -v dump.txt
umdh dump1.txt dump2.txt
```

Remarks

Suppose you have two computers: a *logging computer* where you create a UMDH log and an *analysis computer* where you analyze the UMDH log. The symbol path on your analysis computer must point to the symbols for the version of Windows that was loaded on the logging computer at the time the log was made. Do not point the symbol path on the analysis computer to a symbol server. If you do, UMDH will retrieve symbols for the version of

Windows that is running on the analysis computer, and UMDH will not display meaningful results.

[Send comments about this topic to Microsoft](#)

Interpreting a UMDH Log

5/26/2017 • 1 min to read • [Edit Online](#)

User-Mode Dump Heap (UMDH) log files display the list of heap allocations in the process and the stacks where the allocations were made.

This example shows how to generate a log for a process that has ID 1204. The log is written to the file log1.txt.

```
umdh -p:1204 -f:log1.txt
```

The log file is not readable because the symbols are not resolved. UMDH resolves symbols when you analyze the log. This example shows how to analyze log1.txt and store the result in result.txt.

```
umdh -v log1.txt > result.txt
```

Symbol Files for Analyzing a Log File

Suppose you have two computers: a *logging computer* where you create a UMDH log and an *analysis computer* where you analyze the UMDH log. The symbol path on your analysis computer must point to the symbols for the version of Windows that was loaded on the logging computer at the time the log was made. Do not point the symbol path on the analysis computer to a symbol server. If you do, UMDH will retrieve symbols for the version of Windows that is running on the analysis computer, and UMDH will not display meaningful results.

[Send comments about this topic to Microsoft](#)

Interpreting a Log Comparison

5/26/2017 • 1 min to read • [Edit Online](#)

You can generate multiple User-Mode Dump Heap (UMDH) logs of the same process over time. Then, you can use UMDH to compare the logs and determine which call stack allocations have grown the most between trials.

For example, the following command directs UMDH to compare two UMDH logs, Log1.txt and Log2.txt, and redirects the output to a third file, Compare.txt.

```
umdh -v Log1.txt Log2.txt > Compare.txt
```

The resulting Compare.txt file lists the call stacks recorded in each log and, for each stack, displays the change in heap allocations between the log files.

For example, the following line from the file shows the change in allocation size for the functions in the call stack labeled "Backtrace00053."

In Log1.txt, the calls in the stack accounts for 40,432 (0x9DF0) bytes, but in Log2.txt, the same call stack accounts for 61,712 (0xF110) bytes, a difference of 21,280 (0x5320) bytes.

```
+ 5320 (f110 - 9df0) 3a allocs BackTrace00053
Total increase == 5320
```

Following is the stack for the allocation:

```
ntdll!RtlDebugAllocateHeap+0x000000FD
ntdll!RtlAllocateHeapSlowly+0x0000005A
ntdll!RtlAllocateHeap+0x00000080
MyApp!_heap_alloc_base+0x00000069
MyApp!_heap_alloc_dbg+0x000001A2
MyApp!_nh_malloc_dbg+0x00000023
MyApp!_nh_malloc+0x00000016
MyApp!operator new+0x0000000E
MyApp!LeakyFunc+0x0000001E
MyApp!main+0x0000002C
MyApp!mainCRTStartup+0x000000FC
KERNEL32!BaseProcessStart+0x0000003D
```

An examination of the call stack shows that the **LeakyFunc** function is allocating memory by using the Visual C++ run-time library. If examination of the other log files shows that the allocation grows over time, you might be able to conclude that memory allocated from the heap is not being freed.

Symbol Files for Analyzing a Log File

Suppose you have two computers: a *logging computer* where you create a UMDH log and an *analysis computer* where you analyze the UMDH log. The symbol path on your analysis computer must point to the symbols for the version of Windows that was loaded on the logging computer at the time the log was made. Do not point the symbol path on the analysis computer to a symbol server. If you do, UMDH will retrieve symbols for the version of Windows that is running on the analysis computer, and UMDH will not display meaningful results.

USBView

5/26/2017 • 1 min to read • [Edit Online](#)

USBView (Universal Serial Bus Viewer, Usbview.exe) is a Windows graphical user interface application that enables you to browse all USB controllers and connected USB devices on your computer. USBView works on all versions of Windows.

Where to get USBView

USBView is included in [Debugging Tools for Windows](#).

[USBView](#) is also available in the [Windows driver samples](#) repository on GitHub.

Using USBView

USBView can enumerate USB host controllers, USB hubs, and attached USB devices. It can also query information about the devices from the registry and through USB requests to the devices.

The main USBView window contains two panes. The left pane displays a connection-oriented tree view, enabling you to select any USB device.

The right pane displays the USB data structures that pertain to the selected USB device. These structures include Device, Configuration, Interface, and Endpoint Descriptors, as well as the current device configuration.

Tools Related to Debugging Tools for Windows

5/26/2017 • 1 min to read • [Edit Online](#)

This section describes tools that are related to debugging but are not included in the Debugging Tools for Windows package.

[Application Verifier](#)

Monitor application actions while the application runs, subject the application to a variety of stresses and tests, and generate a report about potential errors in application execution or design. Application Verifier is included in the Windows Software Development Kit (SDK) for Windows 8. You can find information about downloading and installing the Windows SDK for Windows 8 [here](#).

[Windows Error Reporting](#)

You can configure Windows Error Reporting (WER) to write user-mode dump files when exceptions and other errors occur in user-mode code. WER is included in Windows Vista and later versions of Windows.

Application Verifier

5/26/2017 • 1 min to read • [Edit Online](#)

Application Verifier (AppVerifier.exe) is a *dynamic verification* tool for user-mode applications. This tool monitors application actions while the application runs, subjects the application to a variety of stresses and tests, and generates a report about potential errors in application execution or design.

Application Verifier can detect errors in any user-mode applications that are not based on managed code, including user-mode drivers. It finds subtle programming errors that might be difficult to detect during standard application testing or driver testing.

You can use Application Verifier alone or in conjunction with a user-mode debugger. This tool runs on Microsoft Windows XP and later versions of Windows. The current user must be a member of the Administrators group on the computer.

Application Verifier is not included in Debugging Tools for Windows. Application Verifier is included in the Windows Software Development Kit (SDK). You can find information about downloading and installing the Windows SDK [here](#). After you install the Windows SDK, AppVerifier.exe and AppVerifier.chm will be in Windows\System32. To start Application Verifier, open a Command Prompt window and enter **appverif**.

The Application Verifier tool comes with its own documentation. To read the documentation, start Application Verifier, and from the **Help** menu, click **Help**, or press **F1**.

Windows Error Reporting

5/26/2017 • 1 min to read • [Edit Online](#)

Windows Error Reporting (WER) is included in Windows Vista and later versions of Windows. You can configure WER to write user-mode dump files when exceptions and other errors occur in user-mode code. For more information, see [Enabling Postmortem Debugging](#) and [Collecting User-Mode Dumps](#).

WER replaced Dr. Watson, which was included in Windows XP.

[Send comments about this topic to Microsoft](#)

Source Code

5/26/2017 • 1 min to read • [Edit Online](#)

This section contains the following topics.

- [Source Path](#)
- [Using a Source Server](#)
- [Creating Your Own Source Control System](#)
- [SrcSrv](#)

[Send comments about this topic to Microsoft](#)

Source Path

5/31/2017 • 3 min to read • [Edit Online](#)

The *source path* specifies the directories where the C and C++ source files are located.

If you are debugging a user-mode process on the computer where the executable file was built, and if the source files are still in their original location, the debugger can automatically locate the source files.

In most other situations, you have to set the source path or load the individual source files.

When you are performing [remote debugging through the debugger](#), the debugging server uses the source path. If you are using WinDbg as your debugger, each debugging client also has its own *local source path*. All source-related commands access the source files on the local computer. You have to set the proper paths on any client or server that you want to use source commands.

This multiple-path system also enables a debugging client to use source-related commands without actually sharing the source files with other clients or with the server. This system is useful if there are private or confidential source files that one of the users has access to.

You can also load source files at any time, regardless of the source path.

Source Path Syntax

The debugger's source path is a string that consists of multiple directory paths, separated by semicolons.

Relative paths are supported. However, unless you always start the debugger from the same directory, you should add a drive letter or a network share before each path. Network shares are also supported.

Note If you are connected to a corporate network, the most efficient way to access source files is to use a source server. You can use a source server by using the **srv*** string within your source path. For more information about source servers, see [Using a Source Server](#).

Controlling the Source Path

To control the source path and local source path, you can do one of the following:

- Before you start the debugger, use the **_NT_SOURCE_PATH** [environment variable](#) to set the source path. If you try to add an invalid directory through this environment variable, the debugger ignores this directory.
- When you start the debugger, use the **-srcpath**[command-line option](#) to set the source path.
- Use the **.srcpath (Set Source Path)** command to display, set, change, or append to the source path. If you are using a source server, **.srcfix (Use Source Server)** is slightly easier.
- (WinDbg only) Use the **.lsrcpath (Set Local Source Path)** command to display, set, change, or append to the local source path. If you are using a source server, **.lsrcfix (Use Local Source Server)** is slightly easier. You can also use the WinDbg Command-Line with the parameter **-lscrpath**. For more information, see [WinDbg Command-Line Options](#).
- (WinDbg only) Use the **File | Source File Path** command or press **CTRL+P** to display, set, change, or append to the source path or the local source path.

You can also directly open or close a source file by doing one of the following:

- Use the **lsf (Load or Unload Source File)** command to open or close a source file.
- (WinDbg only) Use the **.open (Open Source File)** command to open a source file.

- (WinDbg only) Use the [File | open source file](#) command or press **ctrl+o** to open a source file. you can also use the **open source file (ctrl+o)** button (

Note When you use **File | Open Source File** (or its shortcut menu or button equivalents) to open a source file, the path of that file is automatically appended to the source path.

- (WinDbg only) Use the [File | Recent Files](#) command to open one of the four source files that you most recently opened in WinDbg.
- (WinDbg only) Use the [File | Close Current Window](#) command or click the **Close** button in the corner of the [Source window](#) to close a source file.

For more information about how to use source files, see [Debugging in Source Mode](#).

[Send comments about this topic to Microsoft](#)

Using a Source Server

5/31/2017 • 2 min to read • [Edit Online](#)

A source server enables the debugger to automatically retrieve the source files that match the current target. To use a source server, you must be debugging binaries that have been source indexed at build time and whose source file locations are embedded in the PDB files.

Debugging Tools for Windows includes the source server [SrcSrv](#) (Srcsrv.exe).

Using SrcSrv with a Debugger

[SrcSrv](#) can be used with WinDbg, KD, NTSD, or CDB.

To use [SrcSrv](#) with the debugger, enter the following command to set the source path to `srv*`.

```
.srcfix
```

You can get the same result by entering the following command.

```
.srcpath srv*
```

Setting the source path to `srv*` tells the debugger that it should retrieve source files from locations specified in the target modules' symbol files.

If you want to use [SrcSrv](#) and also include a list of directories in your source path, use semicolons to separate `srv*` from any directories that are in the path.

For example:

```
.srcpath srv*;c:\someSourceCode
```

If the source path is set as shown in the preceding example, the debugger first uses [SrcSrv](#) to retrieve source files from locations specified in the target modules' symbol files. If [SrcSrv](#) is unable to retrieve a source file, the debugger attempts to retrieve it from `c:\someSourceCode`. Regardless of whether `srv*` is the first element in the path or appears later, the debugger always uses [SymSrv](#) before it searches any other directories listed in the path.

You can also use [.srcfix+](#) to append `srv*` to your existing source path, as shown in the following example.

```
3: kd> .srcpath c:\mySource
Source search path is: c:\mySource
3: kd> .srcfix+
Source search path is: c:\mySource;SRV*
```

If a source file is retrieved by the source server, it will remain on your hard drive after the debugging session is over. Source files are stored locally in the `src` subdirectory of the home directory (unlike the symbol server, the source server does not specify a local cache in the `srv*` syntax itself). The home directory defaults to the debugger installation directory; it can be changed by using the [!homedir](#) extension or by setting the `DBGHELP_HOMEDIR` environment variable. If this subdirectory does not already exist, it will be created.

If you use the [.open \(Open Source File\)](#) command to open a new source file through [SrcSrv](#), you must include the `-m` Address parameter.

For information on how to index your sources, or if you plan to create your own source control provider module, see [SrcSrv](#).

Using AgeStore to Reduce the Cache Size

Any source files downloaded by [SrcSrv](#) will remain on your hard drive after the debugging session is over. To control the size of the source cache, the AgeStore tool can be used to delete cached files that are older than a specified date, or to reduce the contents of the cache below a specified size. For details, see [AgeStore](#).

[Send comments about this topic to Microsoft](#)

SrcSrv

5/26/2017 • 1 min to read • [Edit Online](#)

The SrcSrv tool (Srcsrv.dll) enables a client to retrieve the exact version of the source files that were used to build an application. Because the source code for a module can change between versions and over the course of years, it is important to look at the source code as it existed when the version of the module in question was built.

SrcSrv retrieves the appropriate files from source control. To use SrcSrv, the application must have been source-indexed.

This section includes:

[Using SrcSrv](#)

[Source Indexing](#)

[Source Control Systems](#)

[HTTP Sites and UNC Shares](#)

[Send comments about this topic to Microsoft](#)

Using SrcSrv

5/26/2017 • 2 min to read • [Edit Online](#)

To use [SrcSrv](#) with WinDbg, KD, NTSD, or CDB, verify that you have installed a recent version of the Debugging Tools for Windows package (version 6.3 or later). Then, include the text `srv*` in the source path, separated by semicolons from any directories that are also in the source path.

For example:

```
.srcpath srv*c:\someSourceCode
```

If the source path is set as shown in the preceding example, the debugger first uses [SrcSrv](#) to retrieve source files from locations specified in the target modules' symbol files. If SrcSrv is unable to retrieve a source file, the debugger attempts to retrieve it from `c:\someSourceCode`. Regardless of whether `srv*` is the first element in the path or appears later, the debugger always uses SymSrv before it searches any other directories listed in the path.

If a source file is retrieved by [SrcSrv](#), it remains on your hard drive after the debugging session is over. Source files are stored locally in the `src` subdirectory of the home directory (unlike the symbol server, the source server does not specify a local cache in the `srv*` syntax itself). The home directory defaults to the Debugging Tools for Windows installation directory; it can be changed by using the [!homedir](#) extension or by setting the `DBGHELP_HOMEDIR` environment variable. If the `src` subdirectory of the home directory does not already exist, it is created.

Debugging SrcSrv

If you experience any trouble extracting the source files from the debugger, start the debugger with the `-n` command-line parameter to view the actual source extraction commands along with the output of those commands. The `!sym noisy` command does the same thing, but you may have already missed important information from previous extraction attempts. This is because the debugger gives up trying to access source from version control repositories that appear to be unreachable.

Retrieving Source Files

If you use the [.open \(Open Source File\)](#) command to open a new source file through [SrcSrv](#), you must include the `-m` Address parameter.

To facilitate the use of [SrcSrv](#) from tools other than the debuggers listed previously, the DbgHelp API provides access to SrcSrv functionality through the [SymGetSourceFile](#) function. To retrieve the name of the source file to be retrieved, call the [SymEnumSourceFiles](#) or [SymGetLineFromAddr64](#) function. For more details on the DbgHelp API, see the `dbghelp.chm` documentation, which can be found in the `sdk/help` subdirectory of the Debugging Tools for Windows installation directory, or see [Debug Help Library](#) on MSDN.

Using AgeStore to Reduce the Cache Size

Any source files downloaded by [SrcSrv](#) remain on your hard drive after the debugging session is over. To control the size of the source cache, the AgeStore tool can be used to delete cached files that are older than a specified date or to reduce the contents of the cache below a specified size. For details, see [AgeStore](#).

[Send comments about this topic to Microsoft](#)

Source Indexing

5/26/2017 • 1 min to read • [Edit Online](#)

Generally, binaries are source-indexed during the build process after the application has been built. The information needed by SrcSrv is stored in the .pdb files. SrcSrv currently supports the following source control systems:

- Perforce
- Microsoft Visual SourceSafe
- Microsoft Team Foundation Server

You can also create a custom script to index your code for a different source control system. One such module for Subversion is included in this package.

SrcSrv includes five tools that are used in the source indexing process:

[The Srcsrv.ini File](#)

[The Ssindex.cmd Script](#)

[The SrcTool Utility](#)

[The PDBStr Tool](#)

[The VSSDump Tool](#)

These tools are installed with Debugging Tools for Windows in the subdirectory `srcsrv`, and should remain installed in the same path as SrcSrv. The PERL scripts in these tools require PERL 5.6 or later.

[Send comments about this topic to Microsoft](#)

The Srcsrv.ini File

5/26/2017 • 1 min to read • [Edit Online](#)

The Srcsrv.ini file is the master list of all source control servers. Each entry has the following format:

```
MY SERVER=ServerInfo
```

When using Perforce, the *ServerInfo* consists of the full network path to the server, followed by a colon, followed by the port number it uses. For example:

```
MY SERVER=machine.corp.company.com:1666
```

Srcsrv.ini is a required file when you are actually source indexing a build using the modules shipped with this package. This entry creates an alias that is used to describe the server info. The value should be unique for every server that you support.

This file can also be installed on the computer running the debugger. When SrcSrv starts, it looks at Srcsrv.ini for values; these values override the information contained in the .pdb file. This enables users to configure a debugger to use an alternative source control server at debug time. However, if you manage your servers well and do not rename them, there should be no need to include this file with your client debugger installations.

This file also serves other purposes on the client side. For more information, see the sample Srcsrv.ini file installed with SrcSrv tools.

Using a Different Location or File Name

By default, SrcSrv uses as its master configuration file the file named Srcsrv.ini, located in the srcsrv subdirectory of the Debugging Tools for Windows installation directory.

You can specify a different file for configuration by setting the SRCSRV_INI_FILE environment variable equal to the full path and file name of the desired file.

For example, if several people want to share a single configuration file, they could place it on a share accessible to all of their systems, and then set an environment variable like the following:

```
set SRCSRV_INI_FILE=\\ourserver\\ourshare\\bestfile.txt
```

[Send comments about this topic to Microsoft](#)

The Ssindex.cmd Script

5/26/2017 • 1 min to read • [Edit Online](#)

The Ssindex.cmd script builds the list of files checked into source control along with the version information of each file. It stores a subset of this information in the .pdb files generated when you built the application. SSIndex uses one of the following Perl modules to interface with source control:

- p4.pm (Perforce)
- vss.pm (Visual SourceSafe)
- tfs.pm (Team Foundation Servers)
- svn.pm (Subversion)

For more information, run Ssindex.cmd with the **-?** or **-??** (verbose help) option or examine the script.

[Send comments about this topic to Microsoft](#)

The SrcTool Utility

5/26/2017 • 1 min to read • [Edit Online](#)

The SrcTool (Srctool.exe) utility lists all files indexed within the .pdb file. For each file, it lists the full path, source control server, and version number of the file. You can use this information for reference.

You can also use SrcTool to list the raw source file information from the .pdb file. To do this, use the **-s** switch on the command line.

SrcTool has other options as well. Use the **?** switch to see them. Of most interest is that this utility can be used to extract all of the source files from version control. This is done with the **-x** switch.

Note Previous versions of this program created a directory called src below the current directory when extracting files. This is no longer the case. If you want the src directory used, you must create it yourself and run the command from that directory.

[Send comments about this topic to Microsoft](#)

The PDBStr Tool

5/26/2017 • 1 min to read • [Edit Online](#)

The PDBStr (Pdbstr.exe) tool is used by the indexing scripts to insert the version control information into the "srcsrv" alternative stream of the target .pdb file. It can also read any stream from a .pdb file. You can use this information to verify that the indexing scripts are working properly.

For more information, run PDBStr with the **-?** option.

[Send comments about this topic to Microsoft](#)

The VSSDump Tool

5/31/2017 • 4 min to read • [Edit Online](#)

The VSSDump (Vssdump.exe) tool is used by the indexing script for Microsoft Visual SourceSafe. It gathers the list of source files to be indexed. This program is also a valuable command-line utility that you can use to examine which files may be processed by the indexing script.

To prepare for source indexing, edit Srcsrv.ini so that it contains an entry for your version control server. This is an operation that you must do only once. Details are listed in the sample version Srcsrv.ini. You can use an environment variable or switch to the indexing script to denote the location of this file. However, it is best to put it in the same directory as the script because the contents of this file are intended to be global across all projects in your business or development system. This file serves to uniquely identify different version control servers. Note that you can provide a different version of this file to debuggers so that they look at a replicated copy of the version control server, which can be useful if you want to reduce traffic on the server.

To source-index a particular build, make certain that no source files are checked out on the build computer. If any files are checked out and edited, those changes are not reflected in the final source indexed .pdb files. Furthermore, if your build process includes a pre-compilation pass that generates source files from other files, you must check in those generated files to version control as part of the pre-compilation.

Upon completion of the build, set the current working directory to be the root of all source files and generated .pdb files. Then run SSIndex. You must specify what version control system you are using as a parameter. For example:

ssindex.cmd -server=vss

SSIndex accepts parameters that allow you to run the script from anywhere and to specify the location of the source files and .pdb files separately. This is most useful if the source is kept in another location from the output .pdb files. For example:

ssindex.cmd -server=vss -source=c:\source -symbols=c:\outputdir

These directories can also be specified with environment variables. Use the -? or -?? command line options for more information.

Here is an example of the output generated by this script:

```
## C:\ >ssindex.cmd -system=vss -?

SSIndex.cmd [/option=<value> [...] [ModuleOptions] [/Debug]
General SrcSrv settings:
  NAME      SWITCH    ENV. VAR      Default
  -----
 1) srcsrv.ini    Ini      SRCSRV_INI    .\srcsrv.ini
 2) Source root   Source   SRCSRV_SOURCE  .
 3) Symbols root  Symbols  SRCSRV_SYMBOLS .
 4) Control system System  SRCSRV_SYSTEM  <N/A>
 5) Save File (opt.) Save    SRCSRV_SAVE   <N/A>
 6) Load File (opt.) Load   SRCSRV_LOAD   <N/A>
Visual Source Safe specific settings:
  NAME      SWITCH    ENV. VAR      Default
  -----
 A) VSS Server   Server   SSDIR        <N/A>
 B) VSS Client   Client   SSROOT       <Current directory>
 C) VSS Project  Project  SSPROJECT    <N/A>
 D) VSS Label    Label    SSLABEL      <N/A>
Precedence is: Default, environment, cmdline switch. (ie. env overrides default,
switch overrides env).
Using '/debug' will turn on verbose output.
Use "SSIndex.cmd -??" for verbose help information.
## See SrcSrv documentation for more information.
```

You can also use one of the provided wrapper scripts (Vssindex.cmd) to avoid specifying the version control system. The script source-indexes all .pdb files found in the current directory and below with version control information to locate all source files found in the current directory and below. You can specify different locations for these files by using environment variables and command-line switches.

Upon completion of the source indexing, you can test the output by running SrcTool on the .pdb files. This program displays data that indicates whether or not the .pdb file is source indexed. It also displays the specific information for every source file. Lastly, it displays the number of indexed sources and the number of sources that no indexing information was found for. It sets an %ERRORLEVEL% of -1 if the file is not source-indexed. Otherwise, it sets %ERRORLEVEL% to the number of indexed source files.

VSSDump can also be used independently to diagnose issues while source-indexing. The syntax is as follows:

vssdump.exe Options

Options can be any combination of the following options.

-a

Causes all projects to be searched, rather than restricting to the current project. This option may not be used with the **-p** option.

-p *ProjectName*

Causes *VSSDump* to restrict its search to the project specified by *ProjectName*. If this option is not present, the current project is used. This option may not be used with the **-a** option.

-d *RootDirectory*

Causes *VSSDump* to restrict its search to the root directory specified by *RootDirectory*. If this option is not present, the current directory is used.

-l *Label*

Causes *VSSDump* to list only those files with a label that matches that specified by *Label*.

VSSDump-*v* *SharePath*

Specifies that the location of the Virtual SourceSafe database is in *SharePath*. This option overrides the path specified in the SSDIR environment variable.

-r

Causes *VSSDump* to search subdirectories recursively.

-f

Causes *VSSDump* to list directories containing source files without listing the files themselves.

-i

Causes *VSSDump* to ignore the current directory and list the entire project. This option may not be used with **-r**.

-s

Causes *VSSDump* to format output for use with script files.

-c

Causes *VSSDump* to display only the Virtual SourceSafe configuration information.

Source Control Systems

5/26/2017 • 1 min to read • [Edit Online](#)

SrcSrv includes provider modules for Visual SourceSafe (vss.pm), Perforce (p4.pm), Team Foundation Servers (tfn.pm), and Subversion (svn.pm). There is also a Concurrent Versions Systems (CVS) module for use with SrcSrv, but it has not been tested extensively. It is also possible to generate your own modules to support other versions of control systems.

This section includes:

[Using Visual SourceSafe](#)

[Debugging with Visual SourceSafe](#)

[Using CVS](#)

[Using Other Source Control Systems](#)

[Send comments about this topic to Microsoft](#)

Using Visual SourceSafe

5/26/2017 • 3 min to read • [Edit Online](#)

Visual SourceSafe is an x86-based application, and the source indexing scripts and tools associated with it are installed only with the x86 package of Debugging Tools for Windows.

To successfully use Visual SourceSafe with SrcSrv, several defaults must be set in the system, including the Visual SourceSafe default database, the current project, and the working folder. You must also stamp each build project with a label so that Visual SourceSafe can differentiate between versions of a given file. Finally, you must set up any credentials needed to access the Visual SourceSafe database.

Visual SourceSafe Database

The default Visual SourceSafe database can be set with the SSDIR environment variable. If it is not set there, the SrcSrv indexing script can usually determine this from the registry. If it cannot, the script prompts you to set SSDIR. Regardless, this database value must be listed in your [Srcsrv.ini](#) file along with a simple alias to identify the database. More instructions can be found in the comments in Srcsrv.ini. You should add the entry in the variables section of Srcsrv.ini using the following syntax:

```
MYDATABASE=\\server\\VssShare
```

Current Project

Visual SourceSafe uses the concept of a *current project*. The SrcSrv indexing script respects this value and limits processing to those source files that are part of the current project. To display the current project, use the following command:

```
ss.exe project
```

To change the current project, use the following command:

```
ss.exe cp Project
```

where *Project* indicates the current project. For example, to process all projects, set the current project to the root:

```
ss.exe cp $/
```

Working Folder

Visual SourceSafe projects are associated with *working folders*. A working folder is the location on the client computer that corresponds to the root of a project. However it is possible for such a computer to obtain and build source without a working folder being specified, usually when creating projects through the Visual Studio interface or by using the command:

```
ss.exe get -R
```

However, this mode of operation is incompatible with SrcSrv indexing. SrcSrv requires that a working folder be specified. To set the working folder, use the command:

```
ss.exe workfold Project Folder
```

where *Project* indicates the current project and *Folder* indicates the location corresponding to the root of the project.

Labels

Visual SourceSafe cannot determine what version of a file exists within the working directory of a build machine. Consequently, you must use labels to stamp the project with an identifier that is used to extract source files on the debugger client. Thus, before indexing, you must verify that all changes are checked into the database and then apply a label to the project. Labels can be applied using the command:

```
ss.exe label Project
```

where *Project* indicates the current project.

In the following example, the label "VERSION_3" is applied to a project called "\$/sdktools":

```
E:\nt\user>ss.exe label $/sdktools
Label for $/sdktools: VERSION_3
Comment for $/sdktools:
This is a comment.
```

After the label is applied, you can specify this label to the SrcSrv indexing script by setting the environment variable, SSLABEL, or by passing it as a command-line parameter, as in the following example:

```
vssindex.cmd -label=VERSION_3
```

Again, this label is required for SrcSrv indexing to work. Note that if you pass a label that does not exist in the project, it can take a long time for the script to complete and the results are of no use.

Credentials

If your Visual SourceSafe database requires a user and optional password for access, these values must be set through the SSUSER and SSPWD environment variables. This applies not only at the time the build is indexed, but also on the debugger client.

[Send comments about this topic to Microsoft](#)

Debugging with Visual SourceSafe

5/26/2017 • 1 min to read • [Edit Online](#)

In order for source files indexed using Visual SourceSafe to work properly with the debugger, you must configure your system properly.

If the Visual SourceSafe database requires a user and optional password for access, these values must be set using the SSUSER and SSPWD environment variables. Furthermore, the version of SrcSrv that ships with Visual Studio 2005 cannot detect whether Visual SourceSafe is prompting for credentials, which causes the application to stop responding.. Upgrade to the version of SrcSrv that ships with Debugging Tools for Windows to prevent this.

If Visual SourceSafe is not set in the path of your debugging computer, you can get around this by adding an entry to the [Srcsrv.ini](#) file that works with your debugger. When using a standard installation of Visual Studio, this file should be located in

```
%PROGRAMFILES%\Microsoft Visual Studio 8\Common7\IDE\srcsrv.ini
```

In the [trusted commands] section of Srcsrv.ini, add an entry of the form

```
ss.exe="Path"
```

where *Path* is the location of Ss.exe.

[Send comments about this topic to Microsoft](#)

Using CVS

5/26/2017 • 1 min to read • [Edit Online](#)

The CVS module for Source Server was developed using Concurrent Versions System (CVS) 1.11.17 (client). It has not been tested with any other versions of CVS. Furthermore, the current version of the module is a beta version.

CVSROOT

On the computer on which you source index the build, CVSROOT cannot contain password and user information. Use cvs.exe to set your credentialing information.

To prepare the [Srcsrv.ini](#) file for CVS indexing you must enter an alias for your repository that uniquely distinguishes it from any others in your network. This repository must match the value of CVSROOT in your environment. There is no need to set this value in the copy of Srcsrv.ini that you keep with your debugger clients because the alias is defined in the source indexed .pdb file.

Client Computer

The client computer that extracts files during debugging does not need a CVS sandbox or CVSROOT set. It does need CVS binaries in the path, and if the repository is locked, you must set the username and password with Cvs.exe.

Revision Tags

CVS is unable to extract a file by its version number. Instead, it must be done using what is known as a *tag*. When indexing a CVS-based system, you must ensure that all changes are checked into the repository and then apply a tag using the "cvs tag" command. Then, when indexing the file, make certain you use the "label" command-line parameter to specify the tag that you want to associate with the build you are indexing. You can achieve the same result by setting CVS_LABEL in the environment. Other values can be set from the environment or the command line. Use the -?? command-line option with SSIndex to examine your choices and to verify that all was configured correctly:

```
ssindex.cmd -system=cvs -??
```

Using Other Source Control Systems

5/26/2017 • 1 min to read • [Edit Online](#)

Included in this package is Svn.pm. A closer look at this file shows how you can modify one of the existing scripts to support the Subversion Version Control system. Other control systems, even a control system that you create yourself, can be supported by creating your own provider module.

This section includes:

[Creating Your Own Provider Module](#)

[Creating Your Own Source Control System](#)

[Send comments about this topic to Microsoft](#)

Creating Your Own Provider Module

5/26/2017 • 1 min to read • [Edit Online](#)

In general, to create your own provider module, you must implement the following set of interfaces.

\$module::SimpleUsage()

Purpose

Displays simple module usage information to STDOUT.

Parameters

None

Return Value

None

\$module::VerboseUsage()

Purpose

Displays in-depth module usage information to STDOUT.

Parameters

None

Return Value

None

\$objref = \$module::new(@CommandArguments)

Purpose

Initializes an instance of the provider module.

Parameters

@CommandArguments

All @ARGV arguments that are not recognized by ssindex.cmd as being general arguments.

Return Value

A reference that can be used in later operations.

\$objref->GatherFileInformation(\$SourcePath,\$ServerHashReference)

Purpose

Enables the module to gather the required source-indexing information for the directory specified by the *\$SourcePath* parameter. The module should not assume that this entry is called only once for each object instance because SSIndex may call it multiple times for different paths.

Parameters

\$SourcePath

The local directory containing the source to be indexed.

\$ServerHashReference

A reference to a hash containing all of the entries from the specified Srcsrv.ini file.

Return Value

None

(\$VariableHashReference,\$FileEntry) = \$objref->GetFileInfo(\$LocalFile)

Purpose

Provides the necessary information to extract a single, specific file from the source control system.

Parameters

\$LocalFile

A fully qualified file name.

Return Values

\$VariableHashReference

A hash reference of the variables necessary to interpret the returned *\$FileEntry*. Ssindex.cmd caches these variables for every source file used by a single debug file to reduce the amount of information written to the source index stream.

\$FileEntry

The file entry to be written to the source index stream to allow SrcSrv to extract this file from source control. The exact format of this line is specific to the source control system.

\$TextString= \$objref->LongName()

Purpose

Provides a descriptive string to identify the source control system to the end user.

Parameters

None

Return Value

\$TextString

The descriptive name of the source control system.

@StreamVariableLines=\$objref->SourceStreamVariables()

Purpose

Enables the source control system to add source-control-specific variables to the source stream for each debug file. The sample modules use this method for writing the required EXTRACT_CMD and EXTRACT_TARGET variables.

Parameters

None

Return Value

@StreamVariableLines

The list of entries for the source stream variables.

Creating Your Own Source Control System

5/26/2017 • 1 min to read • [Edit Online](#)

This section enables you to understand how to prepare instrumentation scripts so that SrcSrv can be integrated into your build or version control system. The implementation is dependent on the language specification version that ships with SrcSrv.

Many of the specifics of how Srcsrv.dll is called by symbol handler code are discussed. However, this information is not static and will not become so in the future. No one should attempt to write code that calls Srcsrv.dll directly.

This is reserved for DbgHelp or the Visual Studio products. Third-party vendors wanting to integrate such functionality into their products should use the **SymGetSourceFile** function. This function, along with others in the DbgHelp API, is described in the DbgHelp documentation, which can be found in the sdk/help subdirectory of the Debugging Tools for Windows installation directory.

This section includes:

[Language Specification 1](#)

[Language Specification 2](#)

[Send comments about this topic to Microsoft](#)

Language Specification 1

5/26/2017 • 6 min to read • [Edit Online](#)

The first version of SrcSrv works as follows. (This behavior may change in future versions.)

First, the client calls **SrcSrvInit** with the target path to be used as a base for all source file extractions. This path is stored in the special variable TARG.

When DbgHelp loads a module's .pdb file, it extracts the SrcSrv stream from the .pdb file and passes this data block to SrcSrv by calling **SrcSrvLoadModule**.

Then when DbgHelp needs to obtain a source file, it calls **SrcSrvGetFile** to retrieve a specified source file from version control.

SrcSrv reviews all the source file entries in the data block for an entry that matches exactly the requested source specification. This match is found in VAR1.

After SrcSrv finds the entry, it fills in the special variables (VAR1, VAR2, etc.) with the contents of this source file entry. Then the SRCSRVRG variable is resolved using these special variables.

The following shows how the SRCSRVRG variable is resolved using the special variables. We assume that the source path is still:

```
c:\proj\src\file.cpp*TOOLS_PRJ*tools/mytool/src/file.cpp*3
```

Each line shows the resolution of one more special variable. The resolved variables are bold.

```
SRCSRVRG=%sdtrg%
SDTRG=%targ%\%var2%\%fnbks1(%var3%)\%var4%\%fnfile%(%var1%
c:\src\%var2%\%fnbks1(%var3%)\%var4%\%fnfile%(%var1%
c:\src\WIN_SDKTOOLS\%fnbks1(%var3%)\%var4%\%fnfile%(%var1%
c:\src\WIN_SDKTOOLS\%fnbks1(% sdktools/debuggers/srcsrv/shell.cpp )\%var4%\%fnfile%(%var1%
c:\src\WIN_SDKTOOLS\ sdktools/debuggers/srcsrv/shell.cpp\%var4%\%fnfile%(%var1%
c:\src\WIN_SDKTOOLS\ sdktools\debuggers\srcsrv\shell.cpp\3\%fnfile%(%var1%
c:\src\WIN_SDKTOOLS\ sdktools\debuggers\srcsrv\shell.cpp\3\%fnfile%(% c:\db\srcsrv\shell.cpp
c:\src\WIN_SDKTOOLS\ sdktools\debuggers\srcsrv\shell.cpp\3\shell.cpp
```

Notice how this generated target path is unique and does not allow two versions of the same file to be extracted to the same location.

SrcSrv now looks to see if the file is already there. If it is, SrcSrv returns the location to the caller. Otherwise, SrcSrv builds the execution command to extract the file by resolving SRCSRVCMD.

In the following example, each line shows the resolution of one more special variable. The resolved variables are bold.

```

DEPOT=/depot
WIN_SDKTOOLS= sserver.microsoft.com:4444
SRCSRVCMD=%sdcm%
SDCMD=sd.exe -p %fnvar%(%var2%) print -o %srcsrvtrg% -q %depot%/%var3%#%var4%
sd.exe -p %fnvar%(%WIN_SDKTOOLS%) print -o %srcsrvtrg% -q %depot%/%var3%#%var4%
sd.exe -p sserver.microsoft.com:4444 print -o %srcsrvtrg% -q %depot%/%var3%#%var4%
sd.exe -p sserver.microsoft.com:4444 print -
c:\src\WIN_SDKTOOLS\sdkttools\debuggers\srcsrv\shell.cpp\3\shell.cpp -q %depot%/%var3%#%var4%
sd.exe -p sserver.microsoft.com:4444 print -o
c:\src\WIN_SDKTOOLS\sdkttools\debuggers\srcsrv\shell.cpp\3\shell.cpp -q //depot/%var3%#%var4%
sd.exe -p sserver.microsoft.com:4444 print -
c:\src\WIN_SDKTOOLS\sdkttools\debuggers\srcsrv\shell.cpp\3\shell.cpp -q //depot/
sdkttools/debuggers/srcsrv/shell.cpp#%var4%
sd.exe -p sserver.microsoft.com:4444 print -o
c:\src\WIN_SDKTOOLS\sdkttools\debuggers\srcsrv\shell.cpp\3\shell.cpp -q //depot/
sdkttools/debuggers/srcsrv/shell.cpp#3

```

Now SrcSrv executes this command. If the result of this command is a file in the expected location, this path is returned to the caller.

Note that if a variable cannot be resolved, an attempt is made to look it up as an OS environment variable. If that fails, the variable name is deleted from the text being processed.

Two consecutive percent sign characters are interpreted as a single percent sign.

Source Server Data Blocks

SrcSrv relies on two blocks of data within the .pdb file, the source file list and the data block.

The source file list is created automatically when a module is built. This list contains fully qualified paths to the source files used to build the module.

The data block is created during source indexing. At this time, an alternative stream named "srcsrv" is added to the .pdb file. The script that inserts this data is dependent on the specific build process and source control system in use.

The data block is divided into three sections: ini, variables, and source files. The data block has the following syntax.

```

SRCSRV: ini -----
VERSION=1
VERCTRL=<source_control_str>
DATETIME=<date_time_str>
SRCSRV: variables -----
SRCSRVTRG=%sdtrg%
SRCSRVCMD=%sdcm%
SRCSRVENV=var1=string1\bvar2=string2
DEPOT=/depot
SDCMD=sd.exe -p %fnvar%(%var2%) print -o %srcsrvtrg% -q %depot%/%var3%#%var4%
SDTRG=%targ%\%var2%\fnbk1%(%var3%)\%var4%\fnfile%(%var1%)
WIN_SDKTOOLS= sserver.microsoft.com:4444
SRCSRV: source files -----
<path1>*<var2>*<var3>*<var4>
<path2>*<var2>*<var3>*<var4>
<path3>*<var2>*<var3>*<var4>
<path4>*<var2>*<var3>*<var4>
SRCSRV: end -----

```

All text is interpreted literally, except for text enclosed in percent signs (%). Text enclosed in percent signs is treated as a variable name to be resolved recursively, unless it is one of the following functions:

%fnvar%()

The parameter text should be enclosed in percent signs and treated as a variable to be resolved.

%fnbksl%()

All forward slashes (/) in the parameter text should be replaced with backward slashes ().

%fnfile%()

All path information in the parameter text should be stripped out, leaving only the file name.

The [ini] section of the data block contains variables that describe the requirements. The indexing script can add any number of variables to this section. The following are examples:

VERSION

The language specification version. This variable is required. If you develop a script based on the current language specification, set this value to 1. The SrcSrv client code does not attempt to execute any script that has a value greater than its own. Current versions of SrcSrv use a value of 2.

VERCTL

A string that describes the source version control system. This variable is optional.

DATETIME

A string that indicates the date and time the .pdb file was processed. This variable is optional.

The [variables] section of the data block contains variables that describe how to extract a file from source control. It can also be used to define commonly used text as variables to reduce the size of the data block.

SRCSRV

Describes how to build the target path for the extracted file. This is a required variable.

SRCSRVCMD

Describes how to build the command to extract the file from source control. This includes the name of the executable file and its command-line parameters. This is required if any extraction command must be executed.

SRCSRVENV

Lists environment variables to be created during the file extraction. This is a string. Separate multiple entries with a backspace character (\b). This is an optional variable.

SRCSRVERCTRL

Specifies the version control system in use. For Perforce, this is perforce. For Visual SourceSafe, this is vss. For Team Foundation Server, this is tfs. This variable is used to persist server errors. This is an optional variable.

SRCSRVERRDESC

Specifies the text to display when the version control client is unable to contact the server that contains the source files to extract. SrcSrv uses this value to check for connection problems. This is an optional variable.

SRCSRVERRVAR

Indicates which variable in a file entry corresponds to a version control server. It is used by SrcSrv to identify commands that do not work, based on previous failures. The format of the text is **varX** where *X* is the number of the variable being indicated. This is an optional variable.

The [source files] section of the data block contains an entry for each source file that has been indexed. The contents of each line are interpreted as variables with the names VAR1, VAR2, VAR3, and so on until VAR10. The variables are separated by asterisks. VAR1 must specify the fully qualified path to the source file as listed elsewhere in the .pdb file. For example:

```
c:\proj\src\file.cpp*TOOLS_PRJ*tools/mytool/src/file.cpp*3
```

is interpreted as follows:

```
VAR1=c:\proj\src\file.cpp
VAR2=TOOLS_PRJ
VAR3=tools/mytool/src/file.cpp
VAR4=3
```

In this example, VAR4 is a revision number. However, most source control systems support labeling files in such a way that the source state for a given build can be restored. Therefore, you could instead use the label for the build. The sample data block could be modified to contain a variable such as the following:

```
LABEL=BUILD47
```

Then, presuming the source control system uses the at sign (@) to indicate a label, you could modify the SRCSRVCMD variable as follows:

```
sd.exe -p %fnvar%(%var2%) print -o %srcsrvtrg% -q %depot%/%var3%@%label%
```

Handling Server Errors

Sometimes a client is unable to extract any files at all from a single version control server. This can be because the server is down and off the network or because the user does not have appropriate privileges to access the source. However, the time consumed attempting to get this source can slow things down significantly. In this situation, it is best to disable any attempt to extract from a source that has been proven to be unavailable.

Whenever SrcSrv fails to extract a file, it examines the output text produced by the command. If any part of this command contains an exact match for the contents of the SRCSRVERRDESC, all future commands to the same version control server are skipped. Note that you can define multiple error strings by adding numbers or arbitrary text to the end of the SRCSRVERRDESC variable name. Here is an example:

```
SRCSRVERRDESC=lime: server not found
SRCSRVERRDESC_2=pineapple: network error
```

The identity of the server is acquired from SRCSRVERRVAR. So if SRCSRVERRVAR contains "var2" and the file entry in the .pdb file looks like this:

```
c:\proj\src\file.cpp*TOOLS_PRJ*tools/mytool/src/file.cpp*3
```

all future attempts to obtain source using a file entry that contains "TOOLS_PRJ" in variable 2 are bypassed.

You can also add error indicators on the debugger client by editing [Srcsrv.ini](#). See the included sample version of srcsrv.ini for details.

Language Specification 2

5/26/2017 • 1 min to read • [Edit Online](#)

This package ships with a srccrv.dll that can operate without SRCSRVCMD being defined in the srccrv data stream of a .pdb file. While such capability is of no use for normal file extraction from source control systems, it is useful for direct access of files from a UNC share or HTTP site. See [HTTP Sites and UNC Shares](#) for more details.

[Send comments about this topic to Microsoft](#)

HTTP Sites and UNC Shares

5/26/2017 • 1 min to read • [Edit Online](#)

It is possible to set up a Web site that provides version-specific source to WinDbg using SrcSrv. Such a mechanism does not provide dynamic extraction of the source files from version control, but it is a valuable feature because it allows you to set the source path of WinDbg to a single unified path that provides source from many versions of many modules, instead of having to set separate paths for each debugging scenario. This is not of interest to debugging clients that have direct access to the actual version control systems but can be of assistance to those wanting to provide secure HTTP-based access to source from remote locations. The Web sites in question can be secured through HTTPS and smart cards, if desired. This same technique can be used to provide source files through a simple UNC share.

This section includes:

[Setting Up the Web Site](#)

[Extracting Source Files](#)

[Modifying the Source Indexing Streams in a .pdb File](#)

[Using UNC Shares](#)

[Using HTTP Sites and UNC Shares in Conjunction with Regular Version Control](#)

[Send comments about this topic to Microsoft](#)

Setting Up the Web Site

5/26/2017 • 1 min to read • [Edit Online](#)

Set up a Web site from which to share the source files and note the root directory of the site. Your source is then available from a site such as:

```
https://SrcMachineName/source
```

In order to make your source files accessible over the Internet, you must configure the directories containing the source files.

Begin by selecting the directory in which your indexed source resides. In our examples, we call this directory **c:\source** and the name of the server on the network **\SrcMachineName**. Permissions must be set so that users can access the site, and you must add the security groups that must access the source content over the network. The amount of security to enable varies from environment to environment. For some installations, this group is **Everyone**.

To set up the permissions for the directory:

1. Open **Windows Explorer**.
2. Expand **My Computer**.
3. Expand the C: drive.
4. Right-click **c:\source** and choose **Sharing and Security**.
5. Check the **Share this folder** button.
6. Click the **Permissions** button.
7. Verify that the desired security groups have read access by adding them under **Group or user names** and checking the appropriate box.
8. Click **OK** to exit Permissions.
9. Click **OK** to exit Source Properties.

The source directory can now be used for debugging by another computer with a source path of **srv*\\\SrcMachineName\source**.

[Send comments about this topic to Microsoft](#)

Extracting Source Files

5/26/2017 • 1 min to read • [Edit Online](#)

To extract all of the source files from all the modules for which you want to provide source, use the command:

```
srctool.exe -x
```

This tool must be executed on .pdb files that have already been source-indexed for your version control system on a computer that has version control access. This places all source files into a common directory tree. Copy the contents of this tree to the root of the Web site. You can do this as often as you want on any new products or modules that you want to add. There is no worry about files overwriting each other because the directory tree structure keeps dissimilar files separated and uniquely accessible.

Walk

The Walk (Walk.cmd) script is included in Debugging Tools for Windows. This script searches recursively through a directory tree and executes any specified command on any file that matches a specified file mask. The syntax is:

```
walk.cmd FileMask Command
```

where *FileMask* specifies a file mask, with or without an accompanying starting directory, and *Command* specifies the command to be executed.

Here is an example that runs the srctool.exe file extraction command on all .pdb files in c:\symbols and its subdirectories:

```
walk.cmd c:\symbols\*.pdb srctool.exe -x
```

[Send comments about this topic to Microsoft](#)

Modifying the Source Indexing Streams in a .pdb File

5/26/2017 • 1 min to read • [Edit Online](#)

For the debugger clients to use the SrcSrv Web site, the .pdb files must be modified to point to it. To do this manually, you make a copy of all the .pdb files, change them, and make them available from a separate location--usually the Web site itself.

Debugging Tools for Windows provides three files to assist in reconfiguring the .pdb files. The Cv2http.cmd and Cv2http.pl files extract the SrcSrv stream, modify it using a Perl script, and put the altered stream back in the .pdb file. The syntax is as follows:

```
cv2http.cmd PDB Alias URL
```

where *PDB* specifies the name of the .pdbfile to modify, *Alias* specifies the logical name to apply to your Web site, and *URL* specifies the full URL of the site. Note that the *Alias* parameter is stored in the PDB as a variable name that can be overridden on the debugger client in Scrsrv.ini, should you ever move the location of the Web site.

This script requires that all the standard SrcSrv tools be available in the path because it calls both SrcTool and PDBStr. Remember that Cv2http.pl is a Perl script and can be modified to meet your needs.

The third file, the Walk (walk.cmd) script, modifies an entire set of .pdb files. For example:

```
walk.cmd *.pdb cv2http.cmd HttpAlias https://source
```

The preceding command calls Cv2http.cmd on every .pdb file in a tree, using HttpAlias for the alias and <https://server/source> for the URL. For more details on Walk, see [Extracting Source Files](#).

After this command is executed on a tree of .pdb files, they are ready for installation into the Web site or whatever location in which you want to put them. Remember that you can use SrcTool and PDBStr to examine the changes to the .pdb files.

[Send comments about this topic to Microsoft](#)

Using UNC Shares

5/26/2017 • 1 min to read • [Edit Online](#)

The Cv2http.cmd, Cv2http.pl, and Walk (Walk.cmd) scripts are used to provide source files from a simple UNC share. The files Cv2http.cmd and Cv2http.pl extract the SrcSrv stream, modify it using a Perl script, and put the altered stream back in the .pdb file. The syntax is as follows:

```
cv2http.cmd PDB Alias SourceRoot
```

where *PDB* specifies the name of the .pdbfile to modify, *Alias* specifies the logical name to apply to your Web site, and *SourceRoot* specifies the root of the UNC share to which you extracted the source files. Note that the *Alias* parameter is stored in the PDB as a variable name that can be overridden on the debugger client in Scrsrv.ini, should you ever move the location of the Web site.

This script requires that all the standard SrcSrv tools be available in the path because it calls both SrcTool and PDBStr. Remember that Cv2http.pl is a Perl script and can be modified to meet your needs.

The third file, the Walk (walk.cmd) script, modifies an entire set of .pdb files. For example:

```
walk.cmd *.pdb cv2http.cmd SourceRoot \\server\share
```

The preceding command calls Cv2http.cmd on every .pdb file in a tree, using SourceRoot for the alias and \\server\share for the UNC share. For more details on Walk, see [Extracting Source Files](#).

After this command is executed on a tree of .pdb files, they are ready for installation into the Web site or whatever location in which you want to put them. Remember that you can use SrcTool and PDBStr to examine the changes to the .pdb files.

[Send comments about this topic to Microsoft](#)

Using HTTP Sites and UNC Shares in Conjunction with Regular Version Control

5/26/2017 • 1 min to read • [Edit Online](#)

You may find that you must support your developers using the standard SrcSrv functionality that extracts files from version control but must also make source files available through a Web site or UNC share. This could happen if you have set up a test lab that does not have access to version control. It is possible to support both users using the same set of .pdb files.

First, extract the source files using SrcTool; see [Extracting Source Files](#) for details. Make the share available as either a Web site or UNC share. For the current purpose, you should not convert the .pdb files using the Cv2http.cmd script.

Now on the computers that will use the HTTP/UNC shares, edit the [Srcsrv.ini](#) file that is in the debugger directory. In the variables section of the file, add the following three statements:

```
MY_SOURCE_ROOT=\\server\\share
SRCSRVCMD=
SRCSRVTRG=%MY_SOURCE_ROOT%\%var2%\%var3%\%var4%\%fnfile%(%var1%)
```

You should replace \\server\\share with the root of the UNC share that you are providing or the URL of the Web site that contains the source files. You can also change MY_SOURCE_ROOT to be any alias you want to describe this location. With these exceptions, everything else should be entered exactly as described.

All debuggers set up in this fashion ignore the standard version control extraction instructions and instead access the source files from the location specified. Meanwhile, all debuggers without these items included in Srcsrv.ini use the normal version control mechanism to extract source files.

Debug Privilege

5/26/2017 • 1 min to read • [Edit Online](#)

The debug privilege allows someone to debug a process that they wouldn't otherwise have access to. For example, a process running as a user with the debug privilege enabled on its token can debug a service running as local system.

Debug privilege is a security policy setting that allows users to attach a debugger to a process or to the kernel. An administrator can modify a security policy for a user group to include or to remove this functionality. Developers who are debugging their own applications do not need this user privilege. Developers who are debugging system components or who are debugging remote components will need this user privilege. This user privilege provides complete access to sensitive and critical operating system components. By default, this property is enabled for users with Administrator rights. A user with Administrator privileges can enable this property for other user groups.

Modifying Debug Privilege for a Process

The following code example shows how to enable the debug privilege in your process. This enables you to debug other processes that you wouldn't have access to otherwise.

```
//  
// SetPrivilege enables/disables process token privilege.  
//  
BOOL SetPrivilege(HANDLE hToken, LPCTSTR lpszPrivilege, BOOL bEnablePrivilege)  
{  
    LUID luid;  
    BOOL bRet=FALSE;  
  
    if (LookupPrivilegeValue(NULL, lpszPrivilege, &luid))  
    {  
        TOKEN_PRIVILEGE tp;  
  
        tp.PrivilegeCount=1;  
        tp.Privileges[0].Luid=luid;  
        tp.Privileges[0].Attributes=(bEnablePrivilege) ? SE_PRIVILEGE_ENABLED: 0;  
        //  
        // Enable the privilege or disable all privileges.  
        //  
        if (AdjustTokenPrivileges(hToken, FALSE, &tp, NULL, (PTOKEN_PRIVILEGES)NULL, (PDWORD)NULL))  
        {  
            //  
            // Check to see if you have proper access.  
            // You may get "ERROR_NOT_ALL_ASSIGNED".  
            //  
            bRet=(GetLastError() == ERROR_SUCCESS);  
        }  
    }  
    return bRet;  
}
```

The following example shows how to use this function:

```
HANDLE hProcess=GetCurrentProcess();
HANDLE hToken;

if (OpenProcessToken(hProcess, TOKEN_ADJUST_PRIVILEGES, &hToken))
{
    SetPrivilege(hToken, SE_DEBUG_NAME, TRUE);
    CloseHandle(hToken);
}
```

Security During Kernel-Mode Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

Security during kernel-mode debugging is never about protecting the *target* computer. The target is completely vulnerable to the debugger -- this is the very nature of debugging.

If a debugging connection was enabled during boot, it will remain vulnerable through the debugging port until its next boot.

However, you should be concerned about security on the *host* computer. In an ideal situation, the debugger runs as an application on your host computer, but does not interact with other applications on this computer. There are three possible ways in which security problems could arise:

- If you use corrupt or destructive extension DLLs, they could cause your debugger to take unexpected actions, possibly affecting the host computer.
- It is possible that corrupt or destructive symbol files could also cause your debugger to take unexpected actions, possibly affecting the host computer.
- If you are running a remote debugging session, an unexpected client might attempt to link to your server. Or perhaps the client you are expecting might attempt to perform actions that you do not anticipate.

If you want to prevent a remote user from performing actions on your host computer, use [Secure Mode](#).

For suggestions on how to guard against unexpected remote connections, see [Security During Remote Debugging](#).

If you are not performing remote debugging, you should still beware of bad symbol files and extension DLLs. Do not load symbols or extensions that you distrust!

Local Kernel Debugging

Only users who have debug privileges can start a local kernel debugging session. If you are the administrator of a machine that has multiple user accounts, you should be aware that any user with these privileges can start a local kernel debugging session, effectively giving them control of all processes on the computer -- and therefore giving them access to all peripherals as well.

[Send comments about this topic to Microsoft](#)

Security During User-Mode Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

When a user-mode debugger is active, it can effectively control any of the processes on the computer.

There are three possible ways in which security problems could arise during user-mode debugging:

- If you use corrupt or destructive extension DLLs, they could cause your debugger to take unexpected actions, possibly affecting applications other than your target.
- It is possible that corrupt or destructive symbol files could also cause your debugger to take unexpected actions, possibly affecting applications other than your target.
- If you are running a remote debugging session, an unexpected client might attempt to link to your server. Or perhaps the client you are expecting might attempt to perform actions that you do not anticipate.

For suggestions on how to guard against unexpected remote connections, see [Security During Remote Debugging](#).

After a remote client has joined a user-mode debugging session, there is no way to restrict its access to processes on your computer.

If you are not performing remote debugging, you should still beware of bad symbol files and extension DLLs. do not load symbols or extensions that you distrust!

[Send comments about this topic to Microsoft](#)

Security During Postmortem Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

Only an administrator can enable [postmortem debugging](#).

However, postmortem debugging is enabled for the entire system, not just for one user. Thus, after it has been enabled, any application crash will activate the debugger that has been chosen -- even if the current user does not have administrative privileges.

Also, a postmortem debugger inherits the same privileges as the application that crashed. Thus, if a Windows service such as CSRSS and LSASS crashes, the debugger will have very high-level privileges.

You should take this into account when choosing to enable postmortem debugging.

[Send comments about this topic to Microsoft](#)

Security During Remote Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

There are two ways to increase security during remote debugging: by restricting who can connect to your session and by restricting the powers of someone who does connect.

Controlling Access to the Debugging Session

If you are performing [remote debugging through the debugger](#), or using a [process server](#) or [KD connection server](#), any computer on your local network can attempt to attach to your debugging session.

If you are using the TCP, 1394, COM, or named pipe protocols, you can require the Debugging Client to supply a password. However, this password is not encrypted during transmission, and therefore these protocols are not secure.

If you want your Debugging Server to be secure, you must use secure sockets layer (SSL) or secure pipe (SPIPE) protocol.

If you are performing [remote debugging through remote.exe](#), you can use the **/u** parameter to prohibit connections from unauthorized users.

Restricting the Powers of the Client

If you are setting up a kernel-mode debugging session, you can restrict the debugger's ability to interfere with the host machine by using [Secure Mode](#).

In user mode, Secure Mode is not available. You can stop an intrusive client from issuing Microsoft MS-DOS commands and running external programs by issuing the **.noshell (Prohibit Shell Commands)** command. However, there are many other ways for a client to interfere with your computer.

Note that both Secure Mode and **.noshell** will prevent both the Debugging Client and the Debugging Server from taking certain actions. There is no way to place a restriction on the client but not on the server.

Forgotten Process Servers

When you start a process server on a remote machine, the process server runs silently.

If you perform remote debugging through this process server and then end the session, the process server continues to run.

A forgotten process server is a potential target for an attack. You should always shut down an unneeded process server. Use the Kill.exe utility or Task Manager to terminate the process server.

[Send comments about this topic to Microsoft](#)

Secure Mode

5/26/2017 • 1 min to read • [Edit Online](#)

When you are performing kernel-mode debugging, you can run the debugger in *Secure Mode*. This prevents the debugger from affecting the host computer, yet does not significantly decrease its freedom to debug the target computer.

Secure Mode is recommended if you are going to allow remote clients to join your debugging session.

This section includes:

[Features of Secure Mode](#)

[Activating Secure Mode](#)

[Send comments about this topic to Microsoft](#)

Features of Secure Mode

5/26/2017 • 1 min to read • [Edit Online](#)

When Secure Mode is active, all commands that could be used to affect the *host* computer are deactivated, and there are some restrictions on symbol servers and debugger extensions.

The specific effects of Secure Mode are as follows:

- The **.attach (Attach to Process)**, **.create (Create Process)**, **.detach (Detach from Process)**, **.abandon (Abandon Process)**, **.kill (Kill Process)**, **.tlist (List Process IDs)**, **.dump (Create Dump File)**, **.opendump (Open Dump File)**, **.writemem (Write Memory to File)**, **.netuse (Control Network Connections)**, and **.quit_lock (Prevent Accidental Quit)** commands are not available.
- The File | Attach to a Process, File | Open Executable, Debug | Detach Debuggee, Debug | Stop Debugging, File | Open Crash Dump WinDbg menu commands are not available.
- The **.shell (Command Shell)** command is not available.
- Extension DLLs must be loaded from a local disk; they cannot be loaded from UNC paths.
- Only the two standard types of extension DLLs (wdbgexts.h and dbgeng.h) are permitted. Other types of DLLs cannot be loaded as extensions.
- If you are using a symbol server, there are several restrictions. Only SymSrv (symsrv.dll) is permitted; other symbol server DLLs will not be accepted. You may not use a downstream store for your symbols, and any existing downstream store will be ignored. HTTP and HTTPS connections are not permitted.

After it has been activated, Secure Mode cannot be turned off. For more information see, [Activating Secure Mode](#).

[Send comments about this topic to Microsoft](#)

Activating Secure Mode

5/26/2017 • 1 min to read • [Edit Online](#)

Secure Mode is only available for kernel-mode debugging. It must be activated before the debugging session has begun -- either on the debugger's command line, or when the debugger is completely dormant and is not yet being used as a server.

To activate Secure Mode, use one of the following methods:

- The **-secure** command-line option
- The **.secure 1** command
- The **.symopt+0x40000** command

If you have an existing kernel debugging session and need to discover whether you are already in Secure Mode, use the **.secure** command with no arguments. This will tell you the current status of Secure Mode.

After Secure Mode has been activated, it cannot be turned off. Even ending the debugging session will not turn it off. Secure Mode persists as long as the debugger itself is running.

x86 Architecture

5/31/2017 • 9 min to read • [Edit Online](#)

The Intel x86 processor uses complex instruction set computer (CISC) architecture, which means there is a modest number of special-purpose registers instead of large quantities of general-purpose registers. It also means that complicated special-purpose instructions will predominate.

The x86 processor traces its heritage at least as far back as the 8-bit Intel 8080 processor. Many peculiarities in the x86 instruction are due to the backward compatibility with that processor (and with its Zilog Z-80 variant).

Microsoft Win32 uses the x86 processor in *32-bit flat mode*. This documentation will focus only on the flat mode.

Registers

The x86 architecture consists of the following unprivileged integer registers.

eax	Accumulator
ebx	Base register
ecx	Count register
edx	Double-precision register
esi	Source index register
edi	Destination index register
ebp	Base pointer register
esp	Stack pointer

All integer registers are 32 bit. However, many of them have 16-bit or 8-bit subregisters.

ax	Low 16 bits of eax
bx	Low 16 bits of ebx
cx	Low 16 bits of ecx
dx	Low 16 bits of edx

si	Low 16 bits of esi
di	Low 16 bits of edi
bp	Low 16 bits of ebp
sp	Low 16 bits of esp
al	Low 8 bits of eax
ah	High 8 bits of ax
bl	Low 8 bits of ebx
bh	High 8 bits of bx
cl	Low 8 bits of ecx
ch	High 8 bits of cx
dl	Low 8 bits of edx
dh	High 8 bits of dx

Operating on a subregister affects only the subregister and none of the parts outside the subregister. For example, storing to the **ax** register leaves the high 16 bits of the **eax** register unchanged.

When using the [? \(Evaluate Expression\)](#) command, registers should be prefixed with an "at" sign (@). For example, you should use `? @ax` rather than `? ax`. This ensures that the debugger recognizes **ax** as a register rather than a symbol.

However, the (@) is not required in the [r \(Registers\)](#) command. For instance, `r ax=5` will always be interpreted correctly.

Two other registers are important for the processor's current state.

eip	instruction pointer
flags	flags

The instruction pointer is the address of the instruction being executed.

The flags register is a collection of single-bit flags. Many instructions alter the flags to describe the result of the instruction. These flags can then be tested by conditional jump instructions. See [x86 Flags](#) for details.

Calling Conventions

The x86 architecture has several different calling conventions. Fortunately, they all follow the same register preservation and function return rules:

- Functions must preserve all registers, except for **eax**, **ecx**, and **edx**, which can be changed across a function call, and **esp**, which must be updated according to the calling convention.
- The **eax** register receives function return values if the result is 32 bits or smaller. If the result is 64 bits, then the result is stored in the **edx:eax** pair.

The following is a list of calling conventions used on the x86 architecture:

- Win32 (**__stdcall**)

Function parameters are passed on the stack, pushed right to left, and the callee cleans the stack.

- Native C++ method call (also known as **thiscall**)

Function parameters are passed on the stack, pushed right to left, the "this" pointer is passed in the **ecx** register, and the callee cleans the stack.

- COM (**__stdcall** for C++ method calls)

Function parameters are passed on the stack, pushed right to left, then the "this" pointer is pushed on the stack, and then the function is called. The callee cleans the stack.

- **__fastcall**

The first two DWORD-or-smaller arguments are passed in the **ecx** and **edx** registers. The remaining parameters are passed on the stack, pushed right to left. The callee cleans the stack.

- **__cdecl**

Function parameters are passed on the stack, pushed right to left, and the caller cleans the stack. The **__cdecl** calling convention is used for all functions with variable-length parameters.

Debugger Display of Registers and Flags

Here is a sample debugger register display:

```
eax=00000000 ebx=008b6f00 ecx=01010101 edx=fffffff esi=00000000 edi=00465000
eip=77f9d022 esp=05cffc48 ebp=05cffc54 iopl=0 nv up ei ng nz na po nc
cs=001b ss=0023 ds=0023 es=0023 fs=0038 gs=0000
efl=00000286
```

In user-mode debugging, you can ignore the **iopl** and the entire last line of the debugger display.

x86 Flags

In the preceding example, the two-letter codes at the end of the second line are *flags*. These are single-bit registers and have a variety of uses.

The following table lists the x86 flags:

Flag	Code	Flag Name	Value	Flag Status	Status	Description	of
------	------	-----------	-------	-------------	--------	-------------	----

Overflow Flag

0 1 **nfov**

No overflow Overflow **df**

Direction Flag

0 1 **updn**

Direction up Direction down **if**

Interrupt Flag

0 1 **diei**

Interrupts disabled Interrupts enabled **sf**

Sign Flag

0 1 **plng**

Positive (or zero) Negative **zf**

Zero Flag

0 1 **nzzr**

Nonzero Zero **af**

Auxiliary Carry Flag

0 1 **naac**

No auxiliary carry Auxiliary carry **pf**

Parity Flag

0 1 **pepo**

Parity even Parity odd **cf**

Carry Flag

0 1 **nccy**

No carry Carry **tf**

Trap Flag

If **tf** equals 1, the processor will raise a STATUS_SINGLE_STEP exception after the execution of one instruction. This flag is used by a debugger to implement single-step tracing. It should not be used by other applications.

iopl

I/O Privilege Level

This is a two-bit integer, with values between zero and 3. It is used by the operating system to control access to hardware. It should not be used by applications.

When registers are displayed as a result of some command in the Debugger Command window, it is the *flag status* that is displayed. However, if you want to change a flag using the **r (Registers)** command, you should refer to it by the *flag code*.

In the Registers window of WinDbg, the flag code is used to view or alter flags. The flag status is not supported.

Here is an example. In the preceding register display, the flag status **ng** appears. This means that the sign flag is currently set to 1. To change this, use the following command:

```
r sf=0
```

This sets the sign flag to zero. If you do another register display, the **ng** status code will not appear. Instead, the **pl** status code will be displayed.

The Sign Flag, Zero Flag, and Carry Flag are the most commonly-used flags.

Conditions

A *condition* describes the state of one or more flags. All conditional operations on the x86 are expressed in terms of conditions.

The assembler uses a one or two letter abbreviation to represent a condition. A condition can be represented by multiple abbreviations. For example, AE ("above or equal") is the same condition as NB ("not below"). The following table lists some common conditions and their meaning.

CONDITION NAME	FLAGS	MEANING
Z	ZF=1	Result of last operation was zero.
NZ	ZF=0	Result of last operation was not zero.
C	CF=1	Last operation required a carry or borrow. (For unsigned integers, this indicates overflow.)
NC	CF=0	Last operation did not require a carry or borrow. (For unsigned integers, this indicates overflow.)
S	SF=1	Result of last operation has its high bit set.
NS	SF=0	Result of last operation has its high bit clear.
O	OF=1	When treated as a signed integer operation, the last operation caused an overflow or underflow.
NO	OF=0	When treated as signed integer operation, the last operation did not cause an overflow or underflow.

Conditions can also be used to compare two values. The **cmp** instruction compares its two operands, and then sets flags as if subtracted one operand from the other. The following conditions can be used to check the result of **cmp value1, value2**.

CONDITION NAME	FLAGS	MEANING AFTER A CMP OPERATION.
E	ZF=1	<i>value1 == value2</i> .

CONDITION NAME	FLAGS	MEANING AFTER A CMP OPERATION.
NE	ZF=0	$value1 \neq value2$.
GE NL	SF=OF	$value1 \geq value2$. Values are treated as signed integers.
LE NG	ZF=1 or SF!=OF	$value1 \leq value2$. Values are treated as signed integers.
G NLE	ZF=0 and SF=OF	$value1 > value2$. Values are treated as signed integers.
L NGE	SF!=OF	$value1 < value2$. Values are treated as signed integers.
AE NB	CF=0	$value1 \geq value2$. Values are treated as unsigned integers.
BE NA	CF=1 or ZF=1	$value1 \leq value2$. Values are treated as unsigned integers.
A NBE	CF=0 and ZF=0	$value1 > value2$. Values are treated as unsigned integers.
B NAE	CF=1	$value1 < value2$. Values are treated as unsigned integers.

Conditions are typically used to act on the result of a **cmp** or **test** instruction. For example,

```
cmp eax, 5
jz equal
```

compares the **eax** register against the number 5 by computing the expression (**eax** - 5) and setting flags according to the result. If the result of the subtraction is zero, then the **zf** flag will be set, and the **jz** condition will be true so the jump will be taken.

Data Types

- byte: 8 bits
- word: 16 bits
- dword: 32 bits
- qword: 64 bits (includes floating-point doubles)
- tword: 80 bits (includes floating-point extended doubles)
- oword: 128 bits

Notation

The following table indicates the notation used to describe assembly language instructions.

NOTATION	MEANING
r, r1, r2...	Registers
m	Memory address (see the succeeding Addressing Modes section for more information.)
#n	Immediate constant
r/m	Register or memory
r/#n	Register or immediate constant
r/m/#n	Register, memory, or immediate constant
cc	A condition code listed in the preceding Conditions section.
T	"B", "W", or "D" (byte, word or dword)
accT	Size <i>T</i> accumulator: al if <i>T</i> = "B", ax if <i>T</i> = "W", or eax if <i>T</i> = "D"

Addressing Modes

There are several different addressing modes, but they all take the form **T ptr [expr]**, where **T** is some data type (see the preceding Data Types section) and **expr** is some expression involving constants and registers.

The notation for most modes can be deduced without much difficulty. For example, **BYTE PTR [esi+edx*8+3]** means "take the value of the **esi** register, add to it eight times the value of the **edx** register, add three, then access the byte at the resulting address."

Pipelining

The Pentium is dual-issue, which means that it can perform up to two actions in one clock tick. However, the rules on when it is capable of doing two actions at once (known as *pairing*) are very complicated.

Because x86 is a CISC processor, you do not have to worry about jump delay slots.

Synchronized Memory Access

Load, modify, and store instructions can receive a **lock** prefix, which modifies the instruction as follows:

1. Before issuing the instruction, the CPU will flush all pending memory operations to ensure coherency. All data prefetches are abandoned.
2. While issuing the instruction, the CPU will have exclusive access to the bus. This ensures the atomicity of the load/modify/store operation.

The **xchg** instruction automatically obeys the previous rules whenever it exchanges a value with memory.

All other instructions default to nonlocking.

Jump Prediction

Unconditional jumps are predicted to be taken.

Conditional jumps are predicted to be taken or not taken, depending on whether they were taken the last time they were executed. The cache for recording jump history is limited in size.

If the CPU does not have a record of whether the conditional jump was taken or not taken the last time it was executed, it predicts backward conditional jumps as taken and forward conditional jumps as not taken.

Alignment

The x86 processor will automatically correct unaligned memory access, at a performance penalty. No exception is raised.

A memory access is considered aligned if the address is an integer multiple of the object size. For example, all BYTE accesses are aligned (everything is an integer multiple of 1), WORD accesses to even addresses are aligned, and DWORD addresses must be a multiple of 4 in order to be aligned.

The **lock** prefix should not be used for unaligned memory accesses.

[Send comments about this topic to Microsoft](#)

x86 Instructions

5/26/2017 • 9 min to read • [Edit Online](#)

In the lists in this section, instructions marked with an asterisk (*) are particularly important. Instructions not so marked are not critical.

On the x86 processor, instructions are variable-sized, so disassembling backward is an exercise in pattern matching. To disassemble backward from an address, you should start disassembling at a point further back than you really want to go, then look forward until the instructions start making sense. The first few instructions may not make any sense because you may have started disassembling in the middle of an instruction. There is a possibility, unfortunately, that the disassembly will never synchronize with the instruction stream and you will have to try disassembling at a different starting point until you find a starting point that works.

For well-packed **switch** statements, the compiler emits data directly into the code stream, so disassembling through a **switch** statement will usually stumble across instructions that make no sense (because they are really data). Find the end of the data and continue disassembling there.

Instruction Notation

The general notation for instructions is to put the destination register on the left and the source on the right. However, there can be some exceptions to this rule.

Arithmetic instructions are typically two-register with the source and destination registers combining. The result is stored into the destination.

Some of the instructions have both 16-bit and 32-bit versions, but only the 32-bit versions are listed here. Not listed here are floating-point instructions, privileged instructions, and instructions that are used only in segmented models (which Microsoft Win32 does not use).

To save space, many of the instructions are expressed in combined form, as shown in the following example.

*	MOV	r1, r/m/#n	r1 = r/m/#n
---	-----	-------------------	--------------------

means that the first parameter must be a register, but the second can be a register, a memory reference, or an immediate value.

To save even more space, instructions can also be expressed as shown in the following.

*	MOV	r1/m, r/m/#n	r1/m = r/m/#n
---	-----	---------------------	----------------------

which means that the first parameter can be a register or a memory reference, and the second can be a register, memory reference, or immediate value.

Unless otherwise noted, when this abbreviation is used, you cannot choose memory for both source and destination.

Furthermore, a bit-size suffix (8, 16, 32) can be appended to the source or destination to indicate that the parameter must be of that size. For example, r8 means an 8-bit register.

Memory, Data Transfer, and Data Conversion

Memory and data transfer instructions do not affect flags.

Effective Address

*	LEA	r, m	Load effective address. (r = address of m)
---	-----	-------------	---

For example, **LEA eax, [esi+4]** means **eax = esi + 4**. This instruction is often used to perform arithmetic.

Data Transfer

	MOV	r1/m, r2/m/#n	r1/m = r/m/#n
	MOVSX	r1, r/m	Move with sign extension.
*	MOVZX	r1, r/m	Move with zero extension.

MOVSX and **MOVZX** are special versions of the **mov** instruction that perform sign extension or zero extension from the source to the destination. This is the only instruction that allows the source and destination to be different sizes. (And in fact, they must be different sizes.)

Stack Manipulation

The stack is pointed to by the **esp** register. The value at **esp** is the top of the stack (most recently pushed, first to be popped); older stack elements reside at higher addresses.

	PUSH	r/m/#n	Push value onto stack.
	POP	r/m	Pop value from stack.
	PUSHFD		Push flags onto stack.
	POPFD		Pop flags from stack.
	PUSHAD		Push all integer registers.
	POPAD		Pop all integer registers.
	ENTER	#n, #n	Build stack frame.
*	LEAVE		Tear down stack frame

The C/C++ compiler does not use the **enter** instruction. (The **enter** instruction is used to implement nested procedures in languages like Algol or Pascal.)

The **leave** instruction is equivalent to:

```
mov esp, ebp
pop ebp
```

Data Conversion

CBW	Convert byte (al) to word (ax).
CWD	Convert word (ax) to dword (dx:ax).
CWDE	Convert word (ax) to dword (eax).
CDQ	Convert dword (eax) to qword (edx:eax).

All conversions perform sign extension.

Arithmetic and Bit Manipulation

All arithmetic and bit manipulation instructions modify flags.

Arithmetic

	ADD	r1/m, r2/m/#n	r1/m += r2/m/#n
	ADC	r1/m, r2/m/#n	r1/m += r2/m/#n + carry
	SUB	r1/m, r2/m/#n	r1/m -= r2/m/#n
	SBB	r1/m, r2/m/#n	r1/m -= r2/m/#n + carry
	NEG	r1/m	r1/m = -r1/m
	INC	r/m	r/m += 1
	DEC	r/m	r/m -= 1
	CMP	r1/m, r2/m/#n	Compute r1/m - r2/m/#n

The **cmp** instruction computes the subtraction and sets flags according to the result, but throws the result away. It is typically followed by a conditional **jmp** instruction that tests the result of the subtraction.

	MUL	r/m8	ax = al * r/m8
--	-----	-------------	-----------------------

	MUL	r/m16	dx:ax = ax * r/m16
	MUL	r/m32	edx:eax = eax * r/m32
	IMUL	r/m8	ax = al * r/m8
	IMUL	r/m16	dx:ax = ax * r/m16
	IMUL	r/m32	edx:eax = eax * r/m32
	IMUL	r1, r2/m	r1 *= r2/m
	IMUL	r1, r2/m, #n	r1 = r2/m * #n

Unsigned and signed multiplication. The state of flags after multiplication is undefined.

	DIV	r/m8	(ah, al) = (ax % r/m8, ax / r/m8)
	DIV	r/m16	(dx, ax) = dx:ax / r/m16
	DIV	r/m32	(edx, eax) = edx:eax / r/m32
	IDIV	r/m8	(ah, al) = ax / r/m8
	IDIV	r/m16	(dx, ax) = dx:ax / r/m16
	IDIV	r/m32	(edx, eax) = edx:eax / r/m32

Unsigned and signed division. The first register in the pseudocode explanation receives the remainder and the second receives the quotient. If the result overflows the destination, a division overflow exception is generated.

The state of flags after division is undefined.

*	SETcc	r/m8	Set r/m8 to 0 or 1
---	-------	------	--------------------

If the condition *cc* is true, then the 8-bit value is set to 1. Otherwise, the 8-bit value is set to zero.

Binary-coded Decimal

You will not see these instructions unless you are debugging code written in COBOL.

	DAA	Decimal adjust after addition.
	DAS	Decimal adjust after subtraction.

These instructions adjust the **al** register after performing a packed binary-coded decimal operation.

AAA	ASCII adjust after addition.
AAS	ASCII adjust after subtraction.

These instructions adjust the **al** register after performing an unpacked binary-coded decimal operation.

AAM	ASCII adjust after multiplication.
AAD	ASCII adjust after division.

These instructions adjust the **al** and **ah** registers after performing an unpacked binary-coded decimal operation.

Bits

	AND	r1/m, r2/m/#n	r1/m = r1/m and r2/m/#n
	OR	r1/m, r2/m/#n	r1/m = r1/m or r2/m/#n
	XOR	r1/m, r2/m/#n	r1/m = r1/m xor r2/m/#n
	NOT	r1/m	r1/m = bitwise not r1/m
*	TEST	r1/m, r2/m/#n	Compute r1/m and r2/m/#n

The **test** instruction computes the logical AND operator and sets flags according to the result, but throws the result away. It is typically followed by a conditional jump instruction that tests the result of the logical AND.

	SHL	r1/m, cl/#n	r1/m <= cl/#n
	SHR	r1/m, cl/#n	r1/m >= cl/#n zero-fill
*	SAR	r1/m, cl/#n	r1/m >= cl/#n sign-fill

The last bit shifted out is placed in the carry.

	SHLD	r1, r2/m, cl/#n	Shift left double.
--	------	------------------------	--------------------

Shift **r1** left by **cl/#n**, filling with the top bits of **r2/m**. The last bit shifted out is placed in the carry.

SHRD	r1, r2/m, cl/#n	Shift right double.
------	------------------------	---------------------

Shift **r1** right by **cl/#n**, filling with the bottom bits of **r2/m**. The last bit shifted out is placed in the carry.

ROL	r1, cl/#n	Rotate r1 left by cl/#n .
ROR	r1, cl/#n	Rotate r1 right by cl/#n .
RCL	r1, cl/#n	Rotate r1/C left by cl/#n .
RCR	r1, cl/#n	Rotate r1/C right by cl/#n .

Rotation is like shifting, except that the bits that are shifted out reappear as the incoming fill bits. The C-language version of the rotation instructions incorporate the carry bit into the rotation.

BT	r1, r2/#n	Copy bit r2/#n of r1 into carry.
BTS	r1, r2/#n	Set bit r2/#n of r1 , copy previous value into carry.
BTC	r1, r2/#n	Clear bit r2/#n of r1 , copy previous value into carry.

Control Flow

	Jcc	dest	Branch conditional.
	JMP	dest	Jump direct.
	JMP	r/m	Jump indirect.
	CALL	dest	Call direct.
*	CALL	r/m	Call indirect.

The **call** instruction pushes the return address onto the stack then jumps to the destination.

*	RET	#n	Return
---	-----	----	--------

The **ret** instruction pops and jumps to the return address on the stack. A nonzero $#n$ in the **RET** instruction indicates that after popping the return address, the value $#n$ should be added to the stack pointer.

LOOP	Decrement ecx and jump if result is nonzero.
LOOPZ	Decrement ecx and jump if result is nonzero and zr was set.
LOOPNZ	Decrement ecx and jump if result is nonzero and zr was clear.
JECXZ	Jump if ecx is zero.

These instructions are remnants of the x86's CISC heritage and in recent processors are actually slower than the equivalent instructions written out the long way.

String Manipulation

	MOVST	Move T from esi to edi .
	CMPST	Compare T from esi with edi .
	SCAST	Scan T from edi for acc T .
	LODST	Load T from esi into acc T .
	STOST	Store T to edi from acc T .

After performing the operation, the source and destination register are incremented or decremented by $\text{sizeof}(T)$, according to the setting of the direction flag (up or down).

The instruction can be prefixed by **REP** to repeat the operation the number of times specified by the **ecx** register.

The **rep mov** instruction is used to copy blocks of memory.

The **rep stos** instruction is used to fill a block of memory with acc T .

Flags

LAHF	Load ah from flags.
SAHF	Store ah to flags.
STC	Set carry.
CLC	Clear carry.

CMC	Complement carry.
STD	Set direction to <i>down</i> .
CLD	Set direction to <i>up</i> .
STI	Enable interrupts.
CLI	Disable interrupts.

Interlocked Instructions

XCHG	r1, r/m	Swap r1 and r/m .
XADD	r1, r/m	Add r1 to r/m , put original value in r1 .
CMPXCHG	r1, r/m	Compare and exchange conditional.

The **cmpxchg** instruction is the atomic version of the following:

```

    cmp    accT, r/m
    jz     match
    mov    accT, r/m
    jmp    done
match:
    mov    r/m, r1
done:

```

Miscellaneous

	INT	#n	Trap to kernel.
	BOUND	r, m	Trap if r not in range.
*	NOP		No operation.
	XLATB		al = [ebx + al]
	BSWAP	r	Swap byte order in register.

Here is a special case of the **int** instruction.

INT	3	Debugger breakpoint trap.
-----	---	---------------------------

The opcode for **INT 3** is 0xCC. The opcode for **NOP** is 0x90.

When debugging code, you may need to patch out some code. You can do this by replacing the offending bytes with 0x90.

Idioms

	XOR	r, r	r = 0
	TEST	r, r	Check if r = 0 .
*	ADD	r, r	Shift r left by 1.

Annotated x86 Disassembly

5/26/2017 • 13 min to read • [Edit Online](#)

The following section will walk you through a disassembly example.

Source Code

The following is the code for the function that will be analyzed.

```
HRESULT CUserView::CloseView(void)
{
    if (m_fDestroyed) return S_OK;

    BOOL fViewObjectChanged = FALSE;
    ReleaseAndNull(&m_pdtgt);

    if (m_psv) {
        m_psb->EnableModelessSB(FALSE);
        if(m_pws) m_pws->ViewReleased();

        IShellView* psv;

        HWND hwndCapture = GetCapture();
        if (hwndCapture && hwndCapture == m_hwnd) {
            SendMessage(m_hwnd, WM_CANCELMODE, 0, 0);
        }

        m_fHandsOff = TRUE;
        m_fRecursing = TRUE;
        NotifyClients(m_psv, NOTIFY_CLOSING);
        m_fRecursing = FALSE;

        m_psv->UIActivate(SVUIA_DEACTIVATE);

        psv = m_psv;
        m_psv = NULL;

        ReleaseAndNull(&_pctView);

        if (m_pvo) {
            IAdviseSink *pSink;
            if (SUCCEEDED(m_pvo->GetAdvise(NULL, NULL, &pSink)) && pSink) {
                if (pSink == (IAdviseSink *)this)
                    m_pvo->SetAdvise(0, 0, NULL);
                pSink->Release();
            }
        }

        fViewObjectChanged = TRUE;
        ReleaseAndNull(&m_pvo);
    }

    if (psv) {
        psv->SaveViewState();
        psv->DestroyViewWindow();
        psv->Release();
    }

    m_hwndView = NULL;
    m_fHandsOff = FALSE;

    if (m_pcache) {
        GlobalFree(m_pcache);
        m_pcache = NULL;
    }
}
```

```

    m_pcache = NULL;
}

m_psb->EnableModelessSB(TRUE);

CancelPendingActions();
}

ReleaseAndNull(&_psf);

if (fViewObjectChanged)
    NotifyViewClients(DVASPECT_CONTENT, -1);

if (m_pszTitle) {
    LocalFree(m_pszTitle);
    m_pszTitle = NULL;
}

SetRect(&m_rcBounds, 0, 0, 0, 0);
return S_OK;
}

```

Assembly Code

This section contains the annotated disassembly example.

Functions which use the **ebp** register as a frame pointer start out as follows:

```

HRESULT CUserView::CloseView(void)
SAMPLE!CUserView__CloseView:
71517134 55          push    ebp
71517135 8bec        mov     ebp,esp

```

This sets up the frame so the function can access its parameters as positive offsets from **ebp**, and local variables as negative offsets.

This is a method on a private COM interface, so the calling convention is **__stdcall**. This means that parameters are pushed right to left (in this case, there are none), the "this" pointer is pushed, and then the function is called. Thus, upon entry into the function, the stack looks like this:

```

[esp+0] = return address
[esp+4] = this

```

After the two preceding instructions, the parameters are accessible as:

```

[ebp+0] = previous ebp pushed on stack
[ebp+4] = return address
[ebp+8] = this

```

For a function that uses **ebp** as a frame pointer, the first pushed parameter is accessible at **[ebp+8]**; subsequent parameters are accessible at consecutive higher DWORD addresses.

```

71517137 51          push    ecx
71517138 51          push    ecx

```

This function requires only two local stack variables, so a **sub esp, 8** instruction. The pushed values are then available as **[ebp-4]** and **[ebp-8]**.

For a function that uses **ebp** as a frame pointer, stack local variables are accessible at negative offsets from the

ebp register.

```
71517139 56          push    esi
```

Now the compiler saves the registers that are required to be preserved across function calls. Actually, it saves them in bits and pieces, interleaved with the first line of actual code.

```
7151713a 8b7508      mov     esi,[ebp+0x8]    ; esi = this
7151713d 57          push    edi             ; save another registers
```

It so happens that CloseView is a method on ViewState, which is at offset 12 in the underlying object. Consequently, **this** is a pointer to a ViewState class, although when there is possible confusion with another base class, it will be more carefully specified as (ViewState*)**this**.

```
if (m_fDestroyed)
7151713e 33ff          xor     edi,edi        ; edi = 0
```

XORing a register with itself is a standard way of zeroing it out.

```
71517140 39beac000000  cmp     [esi+0xac],edi    ; this->m_fDestroyed == 0?
71517146 7407          jz      NotDestroyed (7151714f) ; jump if equal
```

The **cmp** instruction compares two values (by subtracting them). The **jz** instruction checks if the result is zero, indicating that the two compared values are equal.

The **cmp** instruction compares two values; a subsequent **j** instruction jumps based on the result of the comparison.

```
return S_OK;
71517148 33c0          xor     eax, eax        ; eax = 0 = S_OK
7151714a e972010000    jmp     ReturnNoEBX (715172c1) ; return, do not pop EBX
```

The compiler delayed saving the EBX register until later in the function, so if the program is going to "early-out" on this test, then the exit path needs to be the one that does not restore EBX.

```
BOOL fViewObjectChanged = FALSE;
ReleaseAndNull(&m_pdtgt);
```

The execution of these two lines of code is interleaved, so pay attention.

```
NotDestroyed:
7151714f 8d86c0000000  lea     eax,[esi+0xc0]    ; eax = &m_pdtgt
```

The **lea** instruction computes the effect address of a memory access and stores it in the destination. The actual memory address is not dereferenced.

The **lea** instruction takes the address of a variable.

```
71517155 53          push    ebx
```

You should save that EBX register before it is damaged.

```
71517156 8b1d10195071    mov ebx,[_imp__ReleaseAndNull]
```

Because you will be calling **ReleaseAndNull** frequently, it is a good idea to cache its address in EBX.

```
7151715c 50      push  eax          ; parameter to ReleaseAndNull
7151715d 897dfc  mov   [ebp-0x4],edi ; fViewObjectChanged = FALSE
71517160 ffd3    call   ebx          ; call ReleaseAndNull
if (_psv) {
71517162 397e74  cmp   [esi+0x74],edi ; this->m_psv == 0?
71517165 0f8411010000  je    No_Psv (7151727c) ; jump if zero
```

Remember that you zeroed out the EDI register a while back and that EDI is a register preserved across function calls (so the call to **ReleaseAndNull** did not change it). Therefore, it still holds the value zero and you can use it to quickly test for zero.

```
m_psb->EnableModelessSB(FALSE);
7151716b 8b4638  mov   eax,[esi+0x38] ; eax = this->m_psb
7151716e 57      push  edi          ; FALSE
7151716f 50      push  eax          ; "this" for callee
71517170 8b08    mov   ecx,[eax]    ; ecx = m_psb->lpVtbl
71517172 ff5124  call  [ecx+0x24]  ; __stdcall EnableModelessSB
```

The above pattern is a telltale sign of a COM method call.

COM method calls are pretty popular, so it is a good idea to learn to recognize them. In particular, you should be able to recognize the three IUnknown methods directly from their Vtable offsets: QueryInterface=0, AddRef=4, and Release=8.

```
if(_pws) m_pws->ViewReleased();
71517175 8b8614010000  mov   eax,[esi+0x114] ; eax = this->m_pws
7151717b 3bc7    cmp   eax,edi          ; eax == 0?
7151717d 7406    jz    NoWS (71517185) ; if so, then jump
7151717f 8b08    mov   ecx,[eax]    ; ecx = m_pws->lpVtbl
71517181 50      push  eax          ; "this" for callee
71517182 ff510c  call  [ecx+0xc]  ; __stdcall ViewReleased
NoWS:
    HWND hwndCapture = GetCapture();
71517185 ff15e01a5071  call  [_imp__GetCapture] ; call GetCapture
```

Indirect calls through globals is how function imports are implemented in Microsoft Win32. The loader fixes up the globals to point to the actual address of the target. This is a handy way to get your bearings when you are investigating a crashed machine. Look for the calls to imported functions and in the target. You will usually have the name of some imported function, which you can use to determine where you are in the source code.

```
if (hwndCapture && hwndCapture == m_hwnd) {
    SendMessage(m_hwnd, WM_CANCELMODE, 0, 0);
}
7151718b 3bc7    cmp   eax,edi          ; hwndCapture == 0?
7151718d 7412    jz    No_Capture (715171a1) ; jump if zero
```

The function return value is placed in the EAX register.

```

7151718f 8b4e44      mov    ecx,[esi+0x44]    ; ecx = this->m_hwnd
71517192 3bc1        cmp    eax,ecx        ; hwndCapture = ecx?
71517194 750b        jnz    No_Capture (715171a1) ; jump if not

71517196 57          push   edi          ; 0
71517197 57          push   edi          ; 0
71517198 6a1f        push   0x1f        ; WM_CANCELMODE
7151719a 51          push   ecx          ; hwndCapture
7151719b ff1518195071 call   [_imp__SendMessageW] ; SendMessage
No_Capture:
    m_fHandsOff = TRUE;
    m_fRecursing = TRUE;
715171a1 66818e0c0100000180 or    word ptr [esi+0x10c],0x8001 ; set both flags at once

    NotifyClients(m_psv, NOTIFY_CLOSING);
715171aa 8b4e20      mov    ecx,[esi+0x20]    ; ecx = (CNotifySource*)this.vtbl
715171ad 6a04        push   0x4          ; NOTIFY_CLOSING
715171af 8d4620      lea    eax,[esi+0x20]    ; eax = (CNotifySource*)this
715171b2 ff7674      push   [esi+0x74]      ; m_psv
715171b5 50          push   eax          ; "this" for callee
715171b6 ff510c      call   [ecx+0xc]      ; __stdcall NotifyClients

```

Notice how you had to change your "this" pointer when calling a method on a different base class from your own.

```

m_fRecursing = FALSE;
715171b9 80a60d0100007f and    byte ptr [esi+0x10d],0x7f
    m_psv->UIActivate(SVUIA_DEACTIVATE);
715171c0 8b4674      mov    eax,[esi+0x74]    ; eax = m_psv
715171c3 57          push   edi          ; SVUIA_DEACTIVATE = 0
715171c4 50          push   eax          ; "this" for callee
715171c5 8b08        mov    ecx,[eax]      ; ecx = vtbl
715171c7 ff511c      call   [ecx+0x1c]      ; __stdcall UIActivate
    psv = m_psv;
    m_psv = NULL;
715171ca 8b4674      mov    eax,[esi+0x74]    ; eax = m_psv
715171cd 897e74      mov    [esi+0x74],edi ; m_psv = NULL
715171d0 8945f8      mov    [ebp-0x8],eax ; psv = eax

```

The first local variable is **psv**.

```

    ReleaseAndNull(&_pctView);
715171d3 8d466c      lea    eax,[esi+0x6c]    ; eax = &_pctView
715171d6 50          push   eax          ; parameter
715171d7 ffd3        call   ebx          ; call ReleaseAndNull
    if (m_pvo) {
715171d9 8b86a8000000 mov    eax,[esi+0xa8]    ; eax = m_pvo
715171df 8dbea8000000 lea    edi,[esi+0xa8]    ; edi = &m_pvo
715171e5 85c0        test   eax,eax        ; eax == 0?
715171e7 7448        jz    No_Pvo (71517231) ; jump if zero

```

Note that the compiler speculatively prepared the address of the **m_pvo** member, because you are going to use it frequently for a while. Thus, having the address handy will result in smaller code.

```

if (SUCCEEDED(m_pvo->GetAdvise(NULL, NULL, &pSink)) && pSink) {
715171e9 8b08      mov    ecx,[eax]          ; ecx = m_pvo->lpVtbl
715171eb 8d5508      lea    edx,[ebp+0x8]      ; edx = &pSink
715171ee 52      push   edx          ; parameter
715171ef 6a00      push   0x0          ; NULL
715171f1 6a00      push   0x0          ; NULL
715171f3 50      push   eax          ; "this" for callee
715171f4 ff5120      call   [ecx+0x20]      ; __stdcall GetAdvise
715171f7 85c0      test   eax, eax      ; test bits of eax
715171f9 7c2c      jl    No_Advise (71517227) ; jump if less than zero
715171fb 33c9      xor    ecx,ecx      ; ecx = 0
715171fd 394d08      cmp   [ebp+0x8],ecx      ; _pSink == ecx?
71517200 7425      jz    No_Advise (71517227)

```

Notice that the compiler concluded that the incoming "this" parameter was not required (because it long ago stashed that into the ESI register). Thus, it reused the memory as the local variable pSink.

If the function uses an EBP frame, then incoming parameters arrive at positive offsets from EBP and local variables are placed at negative offsets. But, as in this case, the compiler is free to reuse that memory for any purpose.

If you are paying close attention, you will see that the compiler could have optimized this code a little better. It could have delayed the **lea edi, [esi+0xa8]** instruction until after the two **push 0x0** instructions, replacing them with **push edi**. This would have saved 2 bytes.

```
if (pSink == (IAdviseSink *)this)
```

These next several lines are to compensate for the fact that in C++, **(IAdviseSink *)NULL** must still be **NULL**. So if your "this" is really **"(ViewState*)NULL"**, then the result of the cast should be **NULL** and not the distance between IAdviseSink and IBrowserService.

```

71517202 8d46ec      lea    eax,[esi-0x14]    ; eax = -(IAdviseSink*)this
71517205 8d5614      lea    edx,[esi+0x14]    ; edx = (IAdviseSink*)this
71517208 f7d8      neg    eax          ; eax = -eax (sets carry if != 0)
7151720a 1bc0      sbb    eax,edx      ; eax = eax - eax - carry
7151720c 23c2      and    eax,edx      ; eax = NULL or edx

```

Although the Pentium has a conditional move instruction, the base i386 architecture does not, so the compiler uses specific techniques to simulate a conditional move instruction without taking any jumps.

The general pattern for a conditional evaluation is the following:

```

neg    r
sbb    r, r
and   r, (val1 - val2)
add   r, val2

```

The **neg r** sets the carry flag if **r** is nonzero, because **neg** negates the value by subtracting from zero. And, subtracting from zero will generate a borrow (set the carry) if you subtract a nonzero value. It also damages the value in the **r** register, but that is acceptable because you are about to overwrite it anyway.

Next, the **sbb r, r** instruction subtracts a value from itself, which always results in zero. However, it also subtracts the carry (borrow) bit, so the net result is to set **r** to zero or -1, depending on whether the carry was clear or set, respectively.

Therefore, **sbb r, r** sets **r** to zero if the original value of **r** was zero, or to -1 if the original value was nonzero.

The third instruction performs a mask. Because the **r** register is zero or -1, "this" serves either to leave **r** zero or to

change **r** from -1 to **(val1 - val1)**, in that ANDing any value with -1 leaves the original value.

Therefore, the result of "and r, (val1 - val1)" is to set r to zero if the original value of r was zero, or to "(val1 - val2)" if the original value of r was nonzero.

Finally, you add **val2** to **r**, resulting in **val2** or **(val1 - val2) + val2 = val1**.

Thus, the ultimate result of this series of instructions is to set **r** to **val2** if it was originally zero or to **val1** if it was nonzero. This is the assembly equivalent of **r = r ? val1 : val2**.

In this particular instance, you can see that **val2 = 0** and **val1 = (IAdviseSink*)this**. (Notice that the compiler elided the final **add eax, 0** instruction because it has no effect.)

```
7151720e 394508      cmp      [ebp+0x8],eax ; pSink == (IAdviseSink*)this?
71517211 750b      jnz      No_SetAdvise (7151721e) ; jump if not equal
```

Earlier in this section, you set EDI to the address of the **m_pvo** member. You are going to be using it now. You also zeroed out the ECX register earlier.

```
    m_pvo->SetAdvise(0, 0, NULL);
71517213 8b07      mov      eax,[edi]      ; eax = m_pvo
71517215 51      push     ecx      ; NULL
71517216 51      push     ecx      ; 0
71517217 51      push     ecx      ; 0
71517218 8b10      mov      edx,[eax]      ; edx = m_pvo->lpVtbl
7151721a 50      push     eax      ; "this" for callee
7151721b ff521c      call     [edx+0x1c]      ; __stdcall SetAdvise
No_SetAdvise:
    pSink->Release();
7151721e 8b4508      mov      eax,[ebp+0x8]      ; eax = pSink
71517221 50      push     eax      ; "this" for callee
71517222 8b08      mov      ecx,[eax]      ; ecx = pSink->lpVtbl
71517224 ff5108      call     [ecx+0x8]      ; __stdcall Release
No_Advise:
```

All these COM method calls should look very familiar.

The evaluation of the next two statements is interleaved. Do not forget that EBX contains the address of **ReleaseAndNull**.

```
    fViewObjectChanged = TRUE;
    ReleaseAndNull(&m_pvo);
71517227 57      push     edi      ; &m_pvo
71517228 c745fc01000000      mov      dword ptr [ebp-0x4],0x1 ; fViewObjectChanged = TRUE
7151722f ffd3      call     ebx      ; call ReleaseAndNull
No_Pvo:
    if (psv) {
71517231 8b7df8      mov      edi,[ebp-0x8]      ; edi = psv
71517234 85ff      test     edi,edi      ; edi == 0?
71517236 7412      jz      No_Psv2 (7151724a) ; jump if zero
    psv->SaveViewState();
71517238 8b07      mov      eax,[edi]      ; eax = psv->lpVtbl
7151723a 57      push     edi      ; "this" for callee
7151723b ff5034      call     [eax+0x34]      ; __stdcall SaveViewState
```

Here are more COM method calls.

```

    psv->DestroyViewWindow();
7151723e 8b07      mov     eax,[edi]      ; eax = psv->lpVtbl
71517240 57      push    edi           ; "this" for callee
71517241 ff5028      call    [eax+0x28]    ; __stdcall DestroyViewWindow
    psv->Release();
71517244 8b07      mov     eax,[edi]      ; eax = psv->lpVtbl
71517246 57      push    edi           ; "this" for callee
71517247 ff5008      call    [eax+0x8]     ; __stdcall Release
No_Psv2:
    m_hwndView = NULL;
7151724a 83667c00      and    dword ptr [esi+0x7c],0x0 ; m_hwndView = 0

```

ANDing a memory location with zero is the same as setting it to zero, because anything AND zero is zero. The compiler uses this form because, even though it is slower, it is much shorter than the equivalent **mov** instruction. (This code was optimized for size, not speed.)

```

    m_fHandsOff = FALSE;
7151724e 83a60c010000fe      and    dword ptr [esi+0x10c],0xfe
    if (m_pcache) {
71517255 8b4670      mov     eax,[esi+0x70]    ; eax = m_pcache
71517258 85c0      test    eax, eax        ; eax == 0?
7151725a 740b      jz      No_Cache (71517267) ; jump if zero
    GlobalFree(m_pcache);
7151725c 50      push    eax           ; m_pcache
7151725d ff15b4135071      call    [_imp__GlobalFree]    ; call GlobalFree
    m_pcache = NULL;
71517263 83667000      and    dword ptr [esi+0x70],0x0 ; m_pcache = 0
No_Cache:
    m_psb->EnableModelessSB(TRUE);
71517267 8b4638      mov     eax,[esi+0x38]    ; eax = this->m_psb
7151726a 6a01      push    0x1           ; TRUE
7151726c 50      push    eax           ; "this" for callee
7151726d 8b08      mov     ecx,[eax]      ; ecx = m_psb->lpVtbl
7151726f ff5124      call    [ecx+0x24]    ; __stdcall EnableModelessSB
    CancelPendingActions();

```

In order to call **CancelPendingActions**, you have to move from (ViewState*)this to (CUserView*)this. Note also that **CancelPendingActions** uses the **__thiscall** calling convention instead of **__stdcall**. According to **__thiscall**, the "this" pointer is passed in the ECX register instead of being passed on the stack.

```

71517272 8d4eec      lea    ecx,[esi-0x14]    ; ecx = (CUserView*)this
71517275 e832fbffff  call  CUserView::CancelPendingActions (71516dac) ; __thiscall
    ReleaseAndNull(&_psf);
7151727a 33ff      xor    edi,edi      ; edi = 0 (for later)
No_Psv:
7151727c 8d4678      lea    eax,[esi+0x78]    ; eax = &_psf
7151727f 50          push   eax      ; parameter
71517280 ffd3      call   ebx      ; call ReleaseAndNull
    if (fViewObjectChanged)
71517282 397dfc      cmp    [ebp-0x4],edi    ; fViewObjectChanged == 0?
71517285 740d      jz    NoNotifyViewClients (71517294) ; jump if zero
    NotifyViewClients(DVASPECT_CONTENT, -1);
71517287 8b46ec      mov    eax,[esi-0x14]    ; eax = ((CUserView*)this)->lpVtbl
7151728a 8d4eec      lea    ecx,[esi-0x14]    ; ecx = (CUserView*)this
7151728d 6aff      push   0xff      ; -1
7151728f 6a01      push   0x1      ; DVASPECT_CONTENT = 1
71517291 ff5024      call   [eax+0x24]    ; __thiscall NotifyViewClients
NoNotifyViewClients:
    if (m_pszTitle)
71517294 8b8680000000  mov    eax,[esi+0x80]    ; eax = m_pszTitle
7151729a 8d9e80000000  lea    ebx,[esi+0x80]    ; ebx = &m_pszTitle (for later)
715172a0 3bc7      cmp    eax,edi      ; eax == 0?
715172a2 7409      jz    No_Title (715172ad) ; jump if zero
    LocalFree(m_pszTitle);
715172a4 50          push   eax      ; m_pszTitle
715172a5 ff1538125071  call   [_imp__LocalFree]
    m_pszTitle = NULL;

```

Remember that EDI is still zero and EBX is still &m_pszTitle, because those registers are preserved by function calls.

```

715172ab 893b      mov    [ebx],edi      ; m_pszTitle = 0
No_Title:
    SetRect(&m_rcBounds, 0, 0, 0, 0);
715172ad 57          push   edi      ; 0
715172ae 57          push   edi      ; 0
715172af 57          push   edi      ; 0
715172b0 81c6fc000000  add    esi,0xfc      ; esi = &this->m_rcBounds
715172b6 57          push   edi      ; 0
715172b7 56          push   esi      ; &m_rcBounds
715172b8 ff15e41a5071  call   [_imp__SetRect]

```

Notice that you do not need the value of "this" any more, so the compiler uses the **add** instruction to modify it in place instead of using up another register to hold the address. This is actually a performance win due to the Pentium u/v pipelining, because the v pipe can do arithmetic, but not address computations.

```

    return S_OK;
715172be 33c0      xor    eax,eax      ; eax = S_OK

```

Finally, you restore the registers you are required to preserve, clean up the stack, and return to your caller, removing the incoming parameters.

```

715172c0 5b          pop    ebx      ; restore
ReturnNoEBX:
715172c1 5f          pop    edi      ; restore
715172c2 5e          pop    esi      ; restore
715172c3 c9          leave   ; restores EBP and ESP simultaneously
715172c4 c20400      ret    0x4      ; return and clear parameters

```

[x64 Architecture](#)

[x64 Instructions](#)

[Annotated x64 Disassembly](#)

Note The x64 processor architecture is sometimes referred to as "AMD64", "x86-64", "AMD x86-64" or "Intel64".

[Send comments about this topic to Microsoft](#)

x64 Architecture

5/26/2017 • 3 min to read • [Edit Online](#)

The x64 architecture is a backwards-compatible extension of x86. It provides a legacy 32-bit mode, which is identical to x86, and a new 64-bit mode.

The term "x64" includes both AMD 64 and Intel64. The instruction sets are close to identical.

Registers

x64 extends x86's 8 general-purpose registers to be 64-bit, and adds 8 new 64-bit registers. The 64-bit registers have names beginning with "r", so for example the 64-bit extension of **eax** is called **rax**. The new registers are named **r8** through **r15**.

The lower 32 bits, 16 bits, and 8 bits of each register are directly addressable in operands. This includes registers, like **esi**, whose lower 8 bits were not previously addressable. The following table specifies the assembly-language names for the lower portions of 64-bit registers.

64-BIT REGISTER	LOWER 32 BITS	LOWER 16 BITS	LOWER 8 BITS
rax	eax	ax	al
rbx	ebx	bx	bl
rcx	ecx	cx	cl
rdx	edx	dx	dl
rsi	esi	si	sil
rdi	edi	di	idl
rbp	ebp	bp	bpl
rsp	esp	sp	spl
r8	r8d	r8w	r8b
r9	r9d	r9w	r9b
r10	r10d	r10w	r10b
r11	r11d	r11w	r11b

64-BIT REGISTER	LOWER 32 BITS	LOWER 16 BITS	LOWER 8 BITS
r12	r12d	r12w	r12b
r13	r13d	r13w	r13b
r14	r14d	r14w	r14b
r15	r15d	r15w	r15b

Operations that output to a 32-bit subregister are automatically zero-extended to the entire 64-bit register. Operations that output to 8-bit or 16-bit subregisters are *not* zero-extended (this is compatible x86 behavior).

The high 8 bits of **ax**, **bx**, , and **dx** are still addressable as **ah**, **bh**, **ch**, **dh**, but cannot be used with all types of operands.

The instruction pointer, **eip**, and **flags** register have been extended to 64 bits (**rip** and **rflags**, respectively) as well.

The x64 processor also provides several sets of floating-point registers:

- Eight 80-bit x87 registers.
- Eight 64-bit MMX registers. (These overlap with the x87 registers.)
- The original set of eight 128-bit SSE registers is increased to sixteen.

Calling Conventions

Unlike the x86, the C/C++ compiler only supports one calling convention on x64. This calling convention takes advantage of the increased number of registers available on x64:

- The first four integer or pointer parameters are passed in the **rcx**, **rdx**, **r8**, and **r9** registers.
- The first four floating-point parameters are passed in the first four SSE registers, **xmm0-xmm3**.
- The caller reserves space on the stack for arguments passed in registers. The called function can use this space to spill the contents of registers to the stack.
- Any additional arguments are passed on the stack.
- An integer or pointer return value is returned in the **rax** register, while a floating-point return value is returned in **xmm0**.
- **rax**, **rcx**, **rdx**, **r8-r11** are volatile.
- **rbx**, **rbp**, **rdi**, **rsi**, **r12-r15** are nonvolatile.

The calling convention for C++ is very similar: the **this** pointer is passed as an implicit first parameter. The next three parameters are passed in registers, while the rest are passed on the stack.

Addressing Modes

The addressing modes in 64-bit mode are similar to, but not identical to, x86.

- Instructions that refer to 64-bit registers are automatically performed with 64-bit precision. (For example **mov rax, [rbx]** moves 8 bytes beginning at **rbx** into **rax**.)
- A special form of the **mov** instruction has been added for 64-bit immediate constants or constant addresses. For all other instructions, immediate constants or constant addresses are still 32 bits.

- x64 provides a new **rip**-relative addressing mode. Instructions that refer to a single constant address are encoded as offsets from **rip**. For example, the **mov rax, [addr]** instruction moves 8 bytes beginning at *addr* + **rip** to **rax**.

Instructions, such as **jmp**, **call**, **push**, and **pop**, that implicitly refer to the instruction pointer and the stack pointer treat them as 64 bits registers on x64.

[Send comments about this topic to Microsoft](#)

x64 Instructions

5/26/2017 • 1 min to read • [Edit Online](#)

Most x86 instructions continue to be valid for x64 in 64-bit mode. Some rarely-used operations are no longer supported in 64-bit mode, such as:

- binary-coded decimal arithmetic instructions: AAA, AAD, AAM, AAS, DAA, DAS
- BOUND
- PUSHAD and POPAD
- most operations that dealt with segment registers, such as PUSH DS and POP DS. (Operations that use the FS or GS segment registers are still valid.)

The x64 instruction set includes recent additions to the x86, such as SSE 2. Programs compiled for x64 can freely use these instructions.

Data Transfer

The x64 provides new variants of the MOV instruction that can handle 64-bit immediate constants or memory addresses.

MOV	r ,#n	r = #n
MOV	rax , m	Move contents at 64-bit address to rax .
MOV	m, rax	Move contents of rax to 64-bit address.

The x64 also provides a new instruction to sign-extend 32-bit operands to 64 bits.

MOVSXD	r1 , r/m	Move DWORD with sign extension to QWORD.
--------	-----------------	--

Ordinary MOV operations into 32-bit subregisters automatically zero extend to 64 bits, so there is no MOVZXD instruction.

Two SSE instructions can be used to move 128-bit values (such as GUIDs) from memory to an **xmmn** register or vice versa.

MOVDQA	r1 /m, r2 /m	Move 128-bit aligned value to xmmn register, or vice versa.
MOVDQU	r1 /m, r2 /m	Move 128-bit value (not necessarily aligned) to register, or vice versa.

Data Conversion

CDQE	Convert dword (eax) to qword (rax).
CQO	convert qword (rax) to oword (rdx:rax).

String Manipulation

MOVSQ	Move qword from rsi to rdi .
CMPSQ	Compare qword at rsi with rdi .
SCASQ	Scan qword at rdi . Compares qword at rdi to rax .
LODSQ	Load qword from rsi into rax .
STOSQ	Store qword to rdi from rax .

Annotated x64 Disassembly

5/31/2017 • 7 min to read • [Edit Online](#)

The following very simple function illustrates the x64 calling convention.

```
int Simple(int i, int j)
{
    return i*5 + j + 3;
}
```

This compiles to code like this:

```
01001080 lea    eax,[rdx+rcx*4]      ; eax = rdx+rcx*4
01001083 lea    eax,[rcx+rax+0x3]      ; eax = rcx+rax+3
01001087 ret
```

The *i* and *j* parameters are passed in the **rcx** and **rdx** registers, respectively. Since there are only two parameters, the routine does not use the stack at all.

The particular code generated exploits three tricks, one of which is specific to the x64:

1. The **lea** operation can be used to perform a series of simple arithmetic operations as a single operation. The first instruction stores $j+i*4$ in **eax**, and the second instruction adds $i+3$ to the result, for a total of $j+i*5+3$.
2. Many operations, such as addition and multiplication, can be done with extra precision, and then truncated to the correct precision. In this instance, the code uses 64-bit addition and multiplication. We can safely truncate the result to 32 bits.
3. On the x64, any operation that outputs to a 32-bit register automatically zero-extends the result. In this case, outputting to **eax** has the effect of truncating the result to 32 bits.

Return values are passed in the **rax** register. In this case, the result is already in the **rax** register, so the function returns.

Next we consider a more complicated function to demonstrate typical x64 disassembly:

```

HRESULT Meaningless(IDispatch *pdisp, DISPID dispid, BOOL fUnique, LPCWSTR pszExe)
{
    IQueryAssociations *pqa;
    HRESULT hr = AssocCreate(CLSID_QueryAssociations, IID_IQueryAssociations, (void**)&pqa);
    if (SUCCEEDED(hr)) {
        hr = pqa->Init(ASSOCF_INIT_BYEXENAME, pszExe, NULL, NULL);
        if (SUCCEEDED(hr)) {
            WCHAR wszName[MAX_PATH];
            DWORD cchName = MAX_PATH;
            hr = pqa->GetString(0, ASSOCSTR_FRIENDLYAPPNAME, NULL, wszName, &cchName);
            if (SUCCEEDED(hr)) {
                VARIANTARG rgvarg[2] = { { 0 } };
                V_VT(&rgvarg[0]) = VT_BSTR;
                V_BSTR(&rgvarg[0]) = SysAllocString(wszName);
                if (V_BSTR(&rgvarg[0])) {
                    DISPPARAMS dp;
                    LONG lUnique = InterlockedIncrement(&lCounter);
                    V_VT(&rgvarg[1]) = VT_I4;
                    V_I4(&rgvarg[1]) = fUnique ? lUnique : 0;
                    dp.rgvarg = rgvarg;
                    dp.cArgs = 2;
                    dp.rgdispidNamedArgs = NULL;
                    dp.cNamedArgs = 0;
                    hr = pdisp->Invoke(dispid, IID_NULL, 0, DISPATCH_METHOD, &dp, NULL, NULL, NULL);
                    VariantClear(&rgvarg[0]);
                    VariantClear(&rgvarg[1]);
                } else {
                    hr = E_OUTOFMEMORY;
                }
            }
        }
        pqa->Release();
    }
    return hr;
}

```

We'll go through this function and the equivalent assembly line by line.

When entered, the function's parameters are stored as follows:

- **rcx** = *pdisp*.
- **rdx** = *dispid*.
- **r8** = *fUnique*.
- **r9** = *pszExe*.

Recall that the first four parameters are passed in registers. Since this function has only four registers, none are passed on the stack.

The assembly begins as follows:

```

Meaningless:
010010e0 push    rbx          ; save
010010e1 push    rsi          ; save
010010e2 push    rdi          ; save
010010e3 push    r12d         ; save
010010e5 push    r13d         ; save
010010e7 push    r14d         ; save
010010e9 push    r15d         ; save
010010eb sub     rsp,0x2c0    ; reserve stack
010010f2 mov     rbx,r9       ; rbx = pszExe
010010f5 mov     r12d,r8d     ; r12 = fUnique (zero-extend)
010010f8 mov     r13d,edx     ; r13 = dispid (zero-extend)
010010fb mov     rsi,rcx      ; rsi = pdisp

```

The function begins by saving nonvolatile registers, and then reserving stack space for local variables. It then saves parameters in nonvolatile registers. Note that the destination of the middle two **mov** instructions is a 32-bit register, so they are implicitly zero-extended to 64 bits.

```

IQueryAssociations *pqa;
HRESULT hr = AssocCreate(CLSID_QueryAssociations, IID_IQueryAssociations, (void**)&pqa);

```

The first parameter to **AssocCreate** is a 128-bit CLSID passed by value. Since this doesn't fit in a 64-bit register, the CLSID is copied to the stack, and a pointer to the stack location is passed instead.

```

010010fe movdqu  xmm0,oword ptr [CLSID_QueryAssociations (01001060)]
01001106 movdqu  oword ptr [rsp+0x60],xmm0 ; temp buffer for first parameter
0100110c lea     r8,[rsp+0x58]          ; arg3 = &pqa
01001111 lea     rdx,[IID_IQueryAssociations (01001070)] ; arg2 = &IID_IQueryAssociations
01001118 lea     rcx,[rsp+0x60]          ; arg1 = &temporary
0100111d call    qword ptr [_imp_AssocCreate (01001028)] ; call

```

The **movdqu** instruction transfers 128-bits values to and from **xmmn** registers. In this instance, the assembly code uses it to copy the CLSID to the stack. The pointer to the CLSID is passed in **r8**. The other two arguments are passed in **rcx** and **rdx**.

```

if (SUCCEEDED(hr)) {

01001123 test    eax,eax
01001125 j1     ReturnEAX (01001281)

```

The code checks to see if the return value is a success.

```

hr = pqa->Init(ASSOCF_INIT_BYEXENAME, pszExe, NULL, NULL);

0100112b mov     rcx,[rsp+0x58]          ; arg1 = pqa
01001130 mov     rax,[rcx]              ; rax = pqa.vtbl
01001133 xor     r14d,r14d            ; r14 = 0
01001136 mov     [rsp+0x20],r14          ; arg5 = 0
0100113b xor     r9d,r9d              ; arg4 = 0
0100113e mov     r8,rbx                ; arg3 = pszExe
01001141 mov     r15d,0x2              ; r15 = 2 (for later)
01001147 mov     edx,r15d              ; arg2 = 2 (ASSOCF_INIT_BY_EXENAME)
0100114a call    qword ptr [rax+0x18]    ; call Init method

```

This is an indirect function call using a C++ vtable. The **this** pointer is passed in **rcx** as the first parameter. The first three parameters are passed in registers, while the final parameter is passed on the stack. The function reserves 16 bytes for the parameters passed in registers, so the fifth parameter begins at **rsp+0x20**.

```

if (SUCCEEDED(hr)) {

0100114d mov     ebx, eax           ; ebx = hr
0100114f test    ebx, ebx           ; FAILED?
01001151 jl     ReleasePQA (01001274) ; jump if so

```

The assembly-language code saves the result in **ebx**, and checks to see if it's a success code.

```

WCHAR wszName[MAX_PATH];
DWORD cchName = MAX_PATH;
hr = pqa->GetString(0, ASSOCSTR_FRIENDLYAPPNAME, NULL, wszName, &cchName);
if (SUCCEEDED(hr)) {

01001157 mov     dword ptr [rsp+0x50],0x104 ; cchName = MAX_PATH
0100115f mov     rcx,[rsp+0x58]      ; arg1 = pqa
01001164 mov     rax,[rcx]          ; rax = pqa.vtbl
01001167 lea     rdx,[rsp+0x50]      ; rdx = &cchName
0100116c mov     [rsp+0x28],rdx      ; arg6 = cchName
01001171 lea     rdx,[rsp+0xb0]      ; rdx = &wszName[0]
01001179 mov     [rsp+0x20],rdx      ; arg5 = &wszName[0]
0100117e xor    r9d,r9d          ; arg4 = 0
01001181 mov     r8d,0x4          ; arg3 = 4 (ASSOCSTR_FRIENDLYNAME)
01001187 xor    edx,edx          ; arg2 = 0
01001189 call   qword ptr [rax+0x20] ; call GetString method
0100118c mov     ebx, eax          ; ebx = hr
0100118e test   ebx,ebx          ; FAILED?
01001190 jl     ReleasePQA (01001274) ; jump if so

```

Once again, we set up the parameters and call a function, then test the return value for success.

```

VARIANTARG rgvarg[2] = { 0 };

01001196 lea     rdi,[rsp+0x82]      ; rdi = &rgvarg
0100119e xor    eax, eax          ; rax = 0
010011a0 mov     ecx,0x2e          ; rcx = sizeof(rgvarg)
010011a5 rep     stosb           ; Zero it out

```

The idiomatic method for zeroing out a buffer on x64 is the same as x86.

```

V_VT(&rgvarg[0]) = VT_BSTR;
V_BSTR(&rgvarg[0]) = SysAllocString(wszName);
if (V_BSTR(&rgvarg[0])) {

010011a7 mov     word ptr [rsp+0x80],0x8 ; V_VT(&rgvarg[0]) = VT_BSTR
010011b1 lea     rcx,[rsp+0xb0]      ; arg1 = &wszName[0]
010011b9 call   qword ptr [_imp_SysAllocString (01001010)] ; call
010011bf mov     [rsp+0x88],rax      ; V_BSTR(&rgvarg[0]) = result
010011c7 test   rax, rax          ; anything allocated?
010011ca je     OutOfMemory (0100126f) ; jump if failed

DISPPARAMS dp;
LONG lUnique = InterlockedIncrement(&lCounter);

010011d0 lea     rax,[lCounter (01002000)]
010011d7 mov     ecx,0x1
010011dc lock   xadd [rax],ecx      ; interlocked exchange and add
010011e0 add    ecx,0x1

```

InterlockedIncrement compiles directly to machine code. The **lock xadd** instruction performs an atomic exchange and add. The final result is stored in **ecx**.

```

        V_VT(&rgvarg[1]) = VT_I4;
        V_I4(&rgvarg[1]) = fUnique ? lUnique : 0;

010011e3 mov    word ptr [rsp+0x98],0x3      ; V_VT(&rgvarg[1]) = VT_I4;
010011ed mov    eax,r14d                  ; rax = 0 (r14d is still zero)
010011f0 test   r12d,r12d                ; fUnique set?
010011f3 cmovne eax,ecx                 ; if so, then set rax=lCounter
010011f6 mov    [rsp+0xa0],eax          ; V_I4(&rgvarg[1]) = ...

```

Since x64 supports the **cmov** instruction, the **?:** construct can be compiled without using a jump.

```

dp.rgvarg = rgvarg;
dp.cArgs = 2;
dp.rgdispidNamedArgs = NULL;
dp.cNamedArgs = 0;

010011fd lea    rax,[rsp+0x80]          ; rax = &rgvarg[0]
01001205 mov    [rsp+0x60],rax          ; dp.rgvarg = rgvarg
0100120a mov    [rsp+0x70],r15d          ; dp.cArgs = 2 (r15 is still 2)
0100120f mov    [rsp+0x68],r14          ; dp.rgdispidNamedArgs = NULL
01001214 mov    [rsp+0x74],r14d          ; dp.cNamedArgs = 0

```

This code initializes the rest of the members of DISPPARAMS. Note that the compiler reuses the space on the stack previously used by the CLSID.

```

hr = pdisp->Invoke(dispid, IID_NULL, 0, DISPATCH_METHOD, &dp, NULL, NULL, NULL);

01001219 mov    rax,[rsi]                ; rax = pdisp.vtbl
0100121c mov    [rsp+0x40],r14          ; arg9 = 0
01001221 mov    [rsp+0x38],r14          ; arg8 = 0
01001226 mov    [rsp+0x30],r14          ; arg7 = 0
0100122b lea    rcx,[rsp+0x60]          ; rcx = &dp
01001230 mov    [rsp+0x28],rcx          ; arg6 = &dp
01001235 mov    word ptr [rsp+0x20],0x1  ; arg5 = 1 (DISPATCH_METHOD)
0100123c xor    r9d,r9d                ; arg4 = 0
0100123f lea    r8,[GUID_NULL (01001080)] ; arg3 = &IID_NULL
01001246 mov    edx,r13d                ; arg2 = dispid
01001249 mov    rcx,rsi                ; arg1 = pdisp
0100124c call   qword ptr [rax+0x30]    ; call Invoke method
0100124f mov    ebx,eax                ; hr = result

```

The code then sets up the parameters and calls the **Invoke** method.

```

VariantClear(&rgvarg[0]);
VariantClear(&rgvarg[1]);

01001251 lea    rcx,[rsp+0x80]          ; arg1 = &rgvarg[0]
01001259 call   qword ptr [_imp_VariantClear (01001018)]
0100125f lea    rcx,[rsp+0x98]          ; arg1 = &rgvarg[1]
01001267 call   qword ptr [_imp_VariantClear (01001018)]
0100126d jmp    ReleasePQA (01001274)

```

The code finishes up the current branch of the conditional, and skips over the **else** branch.

```

        } else {
            hr = E_OUTOFMEMORY;
        }
    }

OutOfMemory:
0100126f mov     ebx,0x8007000e          ; hr = E_OUTOFMEMORY
    pqa->Release();

ReleasePQA:
01001274 mov     rcx,[rsp+0x58]          ; arg1 = pqa
01001279 mov     rax,[rcx]                ; rax = pqa.vtbl
0100127c call    qword ptr [rax+0x10]      ; release

```

The **else** branch.

```

        return hr;
}

0100127f mov     eax,ebx          ; rax = hr (for return value)
ReturnEAX:
01001281 add    rsp,0x2c0          ; clean up the stack
01001288 pop    r15d            ; restore
0100128a pop    r14d            ; restore
0100128c pop    r13d            ; restore
0100128e pop    r12d            ; restore
01001290 pop    rdi             ; restore
01001291 pop    rsi             ; restore
01001292 pop    rbx             ; restore
01001293 ret                  ; return (do not pop arguments)

```

The return value is stored in **rax**, and then the non-volatile registers are restored before returning.

Debugger Engine and Extension APIs

5/26/2017 • 3 min to read • [Edit Online](#)

This section includes:

[Debugger Engine Overview](#)

[Using the Debugger Engine API](#)

[Writing DbgEng Extensions](#)

[EngExtCpp Extensions](#)

[Writing WdbgExts Extensions](#)

[Customizing Debugger Output Using DML](#)

[Using JavaScript to Extend the Capabilities of the Debugger](#)

This documentation describes how to use the debugger engine and how to write extensions that will run in WinDbg, KD, CDB, and NTSD. These debugger extensions can be used when performing user-mode or kernel-mode debugging on Microsoft Windows.

Debugger Engine

The debugger engine provides an interface for examining and manipulating debugging targets in user-mode and kernel-mode on Microsoft Windows.

The debugger engine can acquire targets, set breakpoints, monitor events, query symbols, read and write memory, and control threads and processes in a target.

You can use the debugger engine to write both debugger extension libraries and stand-alone applications. Such applications are *debugger engine applications*. A debugger engine application that uses the full functionality of the debugger engine is a *debugger*. For example, WinDbg, CDB, NTSD, and KD are debuggers; the debugger engine provides the core of their functionality.

The debugger engine API is specified by the prototypes in the header file dbgeng.h.

For more information, see [Debugger Engine Overview](#) and [Using the Debugger Engine API](#).

Extensions

You can create your own debugging commands by writing and building an extension DLL. For example, you might want to write an extension command to display a complex data structure.

There are three different types of debugger extension DLLs:

- *DbgEng extension DLLs*. These are based on the prototypes in the dbgeng.h header file. Each DLL of this type may export DbgEng extension commands. These extension commands use the Debugger Engine API and may also use the WdbgExts API.

For more information, see [Writing DbgEng Extensions](#).

- *EngExtCpp extension DLLs*. These are based on the prototypes in the engextcpp.h and dbgeng.h header files. Each DLL of this type may export DbgEng extension commands. These extension commands use both the Debugger Engine API and the EngExtCpp extension framework, and may also use the WdbgExts API.

- *WdbgExts extension DLLs.* These are based on the prototypes in the wdbgexts.h header file. Each DLL of this type exports one or more WdbgExts extension commands. These extension commands use the WdbgExts API exclusively. For more information see [Writing WdbgExts Extensions](#).

The DbgEng API can be used to create extensions or stand-alone applications. The WdbgExts API contains a subset of the functionality of the debugger engine API and can be used only by extensions.

All debugger extensions should be compiled and built by using the Build utility. The Build utility is included in the Windows Driver Kit (WDK).

Extension code samples are installed as part of the Debugging Tools for Windows package if you perform a custom installation and select the **SDK** component and all its subcomponents. They can be found in the sdk\samples subdirectory of the Debugging Tools for Windows installation directory.

The easiest way to write new debugger extensions is to study the sample extensions. Each sample extension includes makefile and sources files for use with the Build utility. Both types of extensions are represented in the samples.

Writing Custom Analysis Debugger Extensions

You can extend the capabilities of the **!analyze** debugger command by writing an analysis extension plugin. By providing an analysis extension plugin, you can participate in the analysis of a bug check or an exception in a way that is specific to your own component or application. When you write an analysis extension plugin, you also write a metadata file that describes the situations for which you want your plugin to be called. When **!analyze** runs, it locates, loads, and runs the appropriate analysis extension plugins. For more information, see [Writing Custom Analysis Debugger Extensions](#)

Customizing Debugger Output Using DML

You can customize debugger output using DML. For more information see [Customizing Debugger Output Using DML](#).

Using JavaScript to Extend the Capabilities of the Debugger

Use JavaScript to create scripts that understand debugger objects and extend and customize the capabilities of the debugger. JavaScript providers bridge a scripting language to the debugger's internal object model. The JavaScript debugger scripting provider, allows the for use of JavaScript with the debugger. For more information, see [JavaScript Debugger Scripting](#).

Debugger Engine Introduction

5/26/2017 • 3 min to read • [Edit Online](#)

This documentation describes how to use the debugger engine and how to write extensions that will run in WinDbg, KD, CDB, and NTSD. These debugger extensions can be used when performing user-mode or kernel-mode debugging on Microsoft Windows.

Debugger Engine

The debugger engine provides an interface for examining and manipulating debugging targets in user-mode and kernel-mode on Microsoft Windows.

The debugger engine can acquire targets, set breakpoints, monitor events, query symbols, read and write memory, and control threads and processes in a target.

You can use the debugger engine to write both debugger extension libraries and stand-alone applications. Such applications are *debugger engine applications*. A debugger engine application that uses the full functionality of the debugger engine is a *debugger*. For example, WinDbg, CDB, NTSD, and KD are debuggers; the debugger engine provides the core of their functionality.

The debugger engine API is specified by the prototypes in the header file `dbgeng.h`.

Incomplete Documentation

This is a preliminary document and is currently incomplete.

For many concepts relating to the debuggers and the debugger engine that are not yet documented here, look in the [Debugging Techniques](#) section of this documentation.

To obtain some of the currently undocumented functionality of the debugger engine API, use the **Execute** method to execute individual debugger commands.

Extensions

You can create your own debugging commands by writing and building an extension DLL. For example, you might want to write an extension command to display a complex data structure.

There are three different types of debugger extension DLLs:

- *DbgEng extension DLLs*. These are based on the prototypes in the `dbgeng.h` header file. Each DLL of this type may export DbgEng extension commands. These extension commands use the Debugger Engine API and may also use the `WdbgExts` API.
- *EngExtCpp extension DLLs*. These are based on the prototypes in the `engextcpp.h` and `dbgeng.h` header files. Each DLL of this type may export DbgEng extension commands. These extension commands use both the Debugger Engine API and the EngExtCpp extension framework, and may also use the `WdbgExts` API.
- *WdbgExts extension DLLs*. These are based on the prototypes in the `wdbgexts.h` header file. Each DLL of this type exports one or more `WdbgExts` extension commands. These extension commands use the `WdbgExts` API exclusively.

The `DbgEng` API can be used to create extensions or stand-alone applications. The `WdbgExts` API contains a subset of the functionality of the debugger engine API and can be used only by extensions.

All debugger extensions should be compiled and built by using the Build utility. The Build utility is included in the Windows Driver Kit (WDK).

Extension code samples are installed as part of the Debugging Tools for Windows package if you perform a custom installation and select the **SDK** component and all its subcomponents. They can be found in the `sdk\samples` subdirectory of the Debugging Tools for Windows installation directory.

The easiest way to write new debugger extensions is to study the sample extensions. Each sample extension includes makefile and sources files for use with the Build utility. Both types of extensions are represented in the samples.

Writing Custom Analysis Debugger Extensions

You can extend the capabilities of the **!analyze** debugger command by writing an analysis extension plugin. By providing an analysis extension plugin, you can participate in the analysis of a bug check or an exception in a way that is specific to your own component or application. When you write an analysis extension plugin, you also write a metadata file that describes the situations for which you want your plugin to be called. When **!analyze** runs, it locates, loads, and runs the appropriate analysis extension plugins. For more information, see [Writing Custom Analysis Debugger Extensions](#)

Customizing Debugger Output Using DML

You can customize debugger output using DML. For more information see [Customizing Debugger Output Using DML](#).

Using JavaScript to Extend the Capabilities of the Debugger

Use JavaScript to create scripts that understand debugger objects and extend and customize the capabilities of the debugger. JavaScript providers bridge a scripting language to the debugger's internal object model. The JavaScript debugger scripting provider, allows the for use of JavaScript with the debugger. For more information, see [JavaScript Debugger Scripting](#).

Debugger Engine Overview

5/26/2017 • 1 min to read • [Edit Online](#)

The *debugger engine* (DbgEng.dll), typically referred to as the *engine*, provides an interface for examining and manipulating debugging targets in [user mode](#) and [kernel mode](#) on Microsoft Windows.

The debugger engine can acquire targets, set [breakpoints](#), monitor [events](#), query [symbols](#), read and write to memory, and control [threads](#) and [processes](#) in a target.

You can use the debugger engine to write both debugger extension libraries and stand-alone applications. Such applications are referred to as *debugger engine applications*. A debugger engine application that uses the full functionality of the debugger engine is called a *debugger*. For example, WinDbg, CDB, NTSD, and KD are debuggers; the debugger engine provides the core of their functionality.

Engine Concepts:

[Debugging Session and Execution Model](#)

[Client Objects](#)

[Input and Output](#)

Examining and Manipulating Targets:

Debugging Session and Execution Model

5/26/2017 • 2 min to read • [Edit Online](#)

The debugger engine can debug multiple targets, simultaneously. A *debugging session* begins when the engine acquires a target and continues until all of the targets have been discarded. A debugging session is *inaccessible* while the targets are executing and *accessible* when the current target is suspended. The engine can only be used to examine and manipulate targets while the session is accessible.

The main loop of a debugger typically consists of setting the execution status, calling the method **WaitForEvent** and handling the generated **events**. When **WaitForEvent** is called, the session becomes inaccessible.

When an event occurs in a target, the engine suspends all targets and the session becomes accessible. The engine then notifies the event callbacks of the event and follows the event filter rules. The event callbacks and event filters determine how execution in the target should proceed. If they determine that the engine should break into the debugger, the **WaitForEvent** method returns and the session remains accessible; otherwise, the engine will resume execution of the target in the manner determined by the event callbacks and event filters, and the session becomes inaccessible again.

For the duration of the **WaitForEvent** call--in particular, while notifying the event callbacks and processing the filter rules--the engine is in a state referred to as "inside a wait". While in this state, **WaitForEvent** cannot be called (it is not reentrant).

There are two steps involved in initiating execution in a target: setting the execution status, and then calling **WaitForEvent**. The execution status can be set using the method **SetExecutionStatus** or by executing a debugger command that sets the execution status--for example, **g (Go)** and **p (Step)**.

If a sequence of debugger commands are executed together--for example, "**g ; ? @\$ip**"--an *implicit wait* will occur after any command that requires execution in the target if that command is not the last command in the sequence. An implicit wait cannot occur when the debugger engine is in the state "inside a wait"; in this case, the execution of the commands will stop and the current command--the one that attempted to cause the implicit wait--will be interpreted as an indication of how execution in the target should proceed. The rest of the commands will be discarded.

Note When determining whether the session is accessible or inaccessible, limited execution of a target (for example, stepping) is considered execution by the engine. When the limited execution is complete, the session becomes accessible.

Host Engine

When debugging remotely, you can use multiple instances of the debugger engine. Exactly one of these instances maintains the debugging session; this instance is called the *host engine*.

All debugger operations are relative to the host engine, for example, symbol loading and extension loading.

[Send comments about this topic to Microsoft](#)

Client Objects

5/26/2017 • 1 min to read • [Edit Online](#)

Almost all interaction with the [debugger engine](#) is through *client objects*, often simply referred to as *clients*. Each client provides an implementation of the top-level engine interfaces. Each interface provides a different set of methods, which can be used to interact with the engine and, through the engine, the targets. An instance of the engine can have many clients, each with its own state.

Primary Clients

A *primary client* is a client that has joined the current debugging session. Initially, when a new client object is created, it is not a primary client. A client becomes a primary client when it is used to acquire a target (for example, by calling [CreateProcess2](#)) or is connected to the debugging session using [ConnectSession](#). The debugger command [.clients](#) lists only the primary clients.

Callback Objects

Callback objects can be registered with each client. There are three types of callback objects:

1. **Input Callback Objects** (or *input callbacks*): the engine calls input callbacks to request input. For example, a debugger with a console window could register an input callback to provide the engine with input from the user, or a debugger might register an input callback to provide the engine with input from a file.
2. **Output Callback Objects** (or *output callbacks*): the engine calls output callbacks to display output. For example, a debugger with a console window could register an output callback to present the debugger's output to the user, or a debugger might register an output callback to send the output to a log file.
3. **Event Callback Objects** (or *event callbacks*): the engine calls event callbacks whenever an event occurs in a target (or there is a change in the engine's state). For example, a debugger extension library could register an event callback to monitor certain events or perform automated actions when a particular event occurs.

Remote Debugging

Client objects facilitate communication to remote instances of the host engine. The [DebugConnect](#) function creates a client object that is connected to a remote engine instance; methods called on this client are executed by the remote engine and callback objects registered locally with the client will be called when the remote engine makes callback calls.

Additional Information

For details about creating and using client objects, see [Using Callback Objects](#). For details about registering callback objects, see [Using Callback Objects](#).

[Send comments about this topic to Microsoft](#)

Input and Output

5/26/2017 • 1 min to read • [Edit Online](#)

The input and output facilities of the [debugger engine](#) can be used for interactive debugger operation and logging.

The input usually represents commands and responses that are typed by the user, and the output usually represents information presented to the user or sent to log files.

The debugger engine maintains an *input stream* and an *output stream*. Input can be requested from the input stream, and output sent to the output stream.

When the [Input](#) method is called to request input from the engine's input stream, the engine will call all the registered [input callbacks](#) to inform them that it is waiting for input. It then waits for the input callbacks to provide the input by calling the [ReturnInput](#) method.

When output is sent to the engine's output stream, the engine will call the registered [output callbacks](#) passing the output to them. When sending output to the output stream, it can be filtered by the client object; in which case, only output callbacks that are registered with particular client objects will receive the output.

The input and output streams are transparently available to the remote clients. Remote clients can request input and send output to the engine's input and output stream, and the engine will call the callbacks registered with remote clients to request input or send output.

Additional Information

For details about using input and output, see [Using Input and Output](#). For more information about client objects and input and output callbacks, see [Client Objects](#).

Remote Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

Remote debugging occurs when a client's communication with a target is indirect, for example, through a network connection. When remote debugging, more than one instance of the debugger engine can be involved in debugging a target. However, exactly one of these instances is responsible for the debugging session; this instance is called the *host engine*.

There are many possible configurations: the client object can be created in the host engine (smart clients), or a different instance of the engine (debugging clients); the host engine can be connected directly to the target (debugging server); or a proxy can be directly connected to the target (process server and kernel connection server).

Multiple clients can simultaneously connect to the host engine. And the host engine can connect to multiple targets in the same debugging session. Optionally, there can be one or more proxies between the clients and the host engine and between the host engine and each target.

Smart clients are client objects that communicate directly with the host engine. A debugging client is created by calling **DebugConnect**; the client communicates with the host engine using RPC calls that represent method calls in the engine's API (including calls that the host engine makes to the client's [callback objects](#)).

A debugging server is an engine instance that communicates directly with the target and is also the host engine. Process servers and kernel connection servers communicate directly with the target but are not the host engine. The host engine communicates with the process server, or kernel connection server, by sending low-level memory, processor, and operating system requests, and the server sends back the results.

Note A typical two-computer setup for kernel debugging--where one computer is the target and the other the host computer--is not considered to be remote debugging as there is only one instance of the engine (on the host computer) and it communicates directly with the target.

Additional Information

For details about performing remote debugging, see [Remote Targets](#).

[Send comments about this topic to Microsoft](#)

Targets

5/26/2017 • 2 min to read • [Edit Online](#)

The [debugger engine](#) supports debugging different types of targets, [user-mode](#) and [kernel-mode](#) targets, live targets and crash dump files, and local and remote targets. There are different methods for connecting the engine to these different types of targets.

Crash Dump Files

Both user-mode, and kernel-mode crash-dump files are opened with [OpenDumpFile](#). The engine is also able to create dump files from a target with [WriteDumpFile2](#).

Live, User-Mode Targets

The debugger engine can both create and attach to user-mode processes.

Creating a process is done by providing a command line, and optionally an initial directory and environment, for the new process. The engine can then connect to the new process, or keep the new process suspended while it connects to another process. For example, when debugging an application that consists of both a client and server, it is possible to create a client in a suspended state and attach to an already running server, allowing server breakpoints to be set before the client runs and provokes server operations.

When detaching from a process, the engine can optionally leave the process running normally, kill the process, or abandon the process (leaving it suspended until another debugger attaches to it or it is killed).

The engine can be queried for information about all of the user-mode processes that are running on the computer, including the process ID and name of the executable image that is used to start the process. This information can be used to help locate a process to debug.

Live, Kernel-Mode Targets

The method [AttachKernel](#) connects the debugger engine to a Windows kernel.

Remote Targets

When using the debugger engine to debug remotely, there are potentially two extra steps:

1. Connect to the host engine. If the host engine is not the local engine instance, use [DebugConnect](#) to create a client object that is connected to the host engine.
2. Connect the host engine to the process server or kernel connection server. If the host engine does not connect directly to the target, it must connect to a process server or kernel connection server that does.

Now the client can tell the host engine to acquire a target through the process server or kernel connection server.

Acquiring Targets

When acquiring a target, the acquisition of the target is not complete until the target generates an event. Typically, this means first calling a method to attach the debugger to the target, then calling [WaitForEvent](#) to let the target generate an event. This still holds true when the target is a crash dump file, as these always store an event—typically the event that caused the dump file to be created.

Additional Information

For details about attaching to targets, see [Connecting to Targets](#).

[Send comments about this topic to Microsoft](#)

Events

5/26/2017 • 1 min to read • [Edit Online](#)

The debugger engine provides facilities for monitoring and responding to events in the target. When an event occurs, the engine suspends the target (often only briefly), it then notifies all of the clients of the event, who in turn instruct the engine on how execution should proceed in the target.

To notify a client of an event, the engine calls the event callback object that is registered with the client. The engine provides each event callback with details of the event, and the event callback instructs the engine on how execution should proceed in the target. When different event callbacks provide conflicting instructions, the engine acts on the instruction with the highest precedence (see **DEBUG_STATUS_XXX**), which typically means choosing the instruction that involves the least execution of the target.

Note While the event callback is handling the event, the target is suspended and the debugging session is accessible; however, because the engine was waiting for an event--either explicitly during a **WaitForEvent** call or implicitly by executing a command such as **g (Go)** or **p (Step)**--the event callback cannot call **WaitForEvent**, and if it attempts to execute any commands that would cause the debugger to execute, for example **g (Go)** or **p (Step)**, the engine will interpret these commands as an instruction on how to proceed.

Event Filters

The debugger engine also provides *event filters*, which are a simpler alternative for basic event monitoring. The event filters provide a few simple rules that specify whether an event should be printed to the debugger's output stream or break into the debugger. They can also be used to execute debugger commands when an event occurs.

Additional Information

For details about monitoring events, see [Monitoring Events](#).

[Send comments about this topic to Microsoft](#)

Breakpoints

5/26/2017 • 1 min to read • [Edit Online](#)

The [debugger engine](#) can create and monitor breakpoints in the target.

There are two types of breakpoints that the engine can insert into a target: software breakpoints and processor breakpoints.

- *Software breakpoints* are inserted into the target's code by modifying the processor instruction at the breakpoint's location. The debugger engine keeps track of such breakpoints; they are invisible to the clients reading and writing memory at that location. A software breakpoint is triggered when the target executes the modified instruction.
- *Processor breakpoints* are inserted into the target's processor by the debugger engine. A processor breakpoint can be triggered by different actions, for example, executing an instruction at the location (like software breakpoints), or reading or writing memory at the breakpoint's location. Support for processor breakpoints is dependent on the processor in the target's computer.

A breakpoint's address can be specified by an explicit address, by an expression that evaluates to an address, or by an expression that might evaluate to an address at a future time. In the last case, each time a module is loaded or unloaded in the target, the engine will attempt to reevaluate the expression and insert the breakpoint if it can determine the address; this makes it possible to set breakpoints in modules before they are loaded.

A number of parameters can be associated with a breakpoint to control its behavior:

- A breakpoint can be associated with a particular thread in the target and will only be triggered by that thread.
- A breakpoint can have debugger commands associated with it; these commands will automatically be executed when the breakpoint is triggered.
- A breakpoint can be flagged as inactive until the target has passed it a specified number of times.
- A breakpoint can be automatically removed the first time it is triggered.

Additional Information

For details about using breakpoints, see [Using Breakpoints](#).

[Send comments about this topic to Microsoft](#)

Symbols

5/26/2017 • 1 min to read • [Edit Online](#)

A *symbol* is a named unit of data or code from a source file that appears in a module. Information about symbols can include the name, type (if applicable), the address or register where it is stored, and any parent or child symbols. Examples of symbols include variables (local and global), functions, and any entry point into a module.

The symbol information is used by the engine to help interpret data and code in the target. With this information, the engine can search for symbols by name or location in memory and provide a description of a symbol.

The engine gets its information about symbols from symbol files, which are located on the local file system or loaded from a symbol server. When using a symbol server, the engine will automatically use the correct version of the symbol file to match the module in the target. Symbol files can be loaded whenever the corresponding module is loaded, or they can be loaded as needed.

Note Often optimizing compilers do not include accurate information in symbol files. This can cause the engine to misinterpret the value of some variables as the variable's location or lifetime might be incorrectly described, causing the engine to look at the wrong piece of memory or think a variable value is live when it is dead (or vice versa). It is also possible for an optimizing compiler to change the order of execution or to split a function into several pieces. Best results are usually obtained when debugging unoptimized code.

Additional Information

For details about using symbols, see [Using Symbols](#). For an overview of using symbol files and symbol servers, see [Symbols](#) in the Debuggers section of this documentation.

[Send comments about this topic to Microsoft](#)

Memory

5/26/2017 • 1 min to read • [Edit Online](#)

The [debugger engine](#) can directly read and write the target's main memory, registers, and other data spaces. In kernel-mode debugging, all of the target's memory is available, including virtual memory, physical memory, registers, Model Specific Registers (MSRs), System Bus Memory, Control-Space Memory, and I/O Memory. In user-mode debugging, only the virtual memory and registers are available.

The engine exposes, to the clients, all memory in the target using 64-bit addresses. If the target uses 32-bit addresses, when communicating with the target and the clients, the engine will automatically convert between 32-bit and 64-bit addresses, as needed. If a 32-bit address is recovered from the target--for example, by reading from memory or a register--it must be sign-extended to 64 bits before it can be used in the debugger engine API. Sign extension is performed automatically by the **ReadPointersVirtual** method.

Additional Information

For details about reading and writing memory, see [Memory Access](#).

[Send comments about this topic to Microsoft](#)

Threads and Processes

5/26/2017 • 1 min to read • [Edit Online](#)

Terminology

Thread and a process concepts are different between user-mode debugging and kernel-mode debugging.

- In *user-mode debugging*, a *process* is an operating system process and a *thread* is an operating system thread.
- In *kernel-mode debugging*, the [debugger engine](#) creates a *virtual process* for each target; this process represents the kernel and does not correspond to any operating system process. For each physical processor in the target computer, the debugger creates a *virtual thread*; these threads represent the processors and do not correspond to any operating system threads.

When an event occurs, the engine sets the *event process* and *event thread* to the process and thread (operating system or virtual) in which the event occurred.

The *current thread* is the thread (operating system or virtual) that the engine is currently controlling. The *current process* is the process (operating system or virtual) that the engine is currently controlling. When an event occurs, the current thread and process are initially set to the event thread and process; but, they can be changed using the clients while the session is accessible.

In kernel mode, the debugger keeps track of an *implicit process* and *implicit thread*. The *implicit process* is the operating system process that determines the translation from virtual to physical memory addresses.

The *implicit thread* is the operating system thread that determines the target's registers, including call stack, stack frame, and instruction offset.

When an event occurs, the implicit thread and implicit process are initially set to the event thread and process; they can be changed while the session is accessible.

Thread and Process Data

The engine maintains several pieces of information about each thread and process. This includes the system thread and process ID and system handles, and the process environment (PEB), the thread environment block (TEB), and their locations in target's memory.

Additional Information

For details about using thread and processes, see [Controlling Threads and Processes](#).

Interacting with the Engine

5/26/2017 • 2 min to read • [Edit Online](#)

Commands and Expressions

The debugger engine API provides methods to execute commands and evaluate expressions, like those typed into WinDbg's [Debugger Command Window](#). To execute a debugger command, use [Execute](#). Or, to execute all of the commands in a file, use [ExecuteCommandFile](#).

The method [Evaluate](#) will evaluate expressions using the C++ or MASM syntax. The syntax used by the debugger engine to evaluate expressions--such as in the [Evaluate](#) method--is given by [GetExpressionSyntax](#) and can be changed using [SetExpressionSyntaxByName](#) and [SetExpressionSyntax](#). The number of different syntaxes that are recognized by the debugger is returned by [GetNumberExpressionSyntaxes](#), and their names are returned by [GetExpressionSyntaxNames](#).

The type of value that is returned by [Evaluate](#) is determined by the symbols and constants used in the string that was evaluated. The value is contained in a [DEBUG_VALUE](#) structure and can be cast to different types using [CoerceValue](#) and [CoerceValues](#).

Aliases

Aliases are character strings that are automatically replaced with other character strings when used in debugger commands and expressions. For an overview of aliases, see [Using Aliases](#). The debugger engine has several classes of aliases.

The *fixed-name aliases* are indexed by number and have the names **\$u0**, **\$u1**, ..., **\$u9**. The values of these aliases can be set using the [SetTextMacro](#) method and can be retrieved using [GetTextMacro](#) method.

The *automatic aliases* and *user-named aliases* can have any name. The automatic aliases are defined by the debugger engine and the user-named aliases are defined by the user through debugger commands or the debugger engine API. To define or remove a user-named alias, use the [SetTextReplacement](#) method. The [GetTextReplacement](#) method returns the name and value of an automatic alias or a user-named alias. All the user-named aliases can be removed using the [RemoveTextReplacements](#) method. The [GetNumberTextReplacements](#) method will return the number of user-name and automatic aliases; this can be used with [GetTextReplacement](#) to iterate over all these aliases. The [OutputTextReplacements](#) method will print a list of all the user-named aliases, including their names and values.

Note if a user-named alias is given the same name as an automatic alias, the user-named alias will hide the automatic alias so that when retrieving the value of the alias by name, the user-named alias will be used.

Engine Options

The engine has a number of options that control its behavior. These options are listed in [DEBUG_ENGOPT_XXX](#). They are returned by [GetEngineOptions](#) and can be set using [SetEngineOptions](#). Individual options can be set using [AddEngineOptions](#) and unset using [RemoveEngineOptions](#).

Interrupts

An interrupt is a way to force a break into the debugger or to tell the engine to stop processing the current command, for example, by pressing Ctrl+Break in WinDbg.

To request a break into the debugger, or to interrupt the debugger's current task, use [SetInterrupt](#). To check if there has been an interrupt, use [GetInterrupt](#).

Note When undertaking a long task from a debugger extension, it is recommended that the extension check [GetInterrupt](#) regularly and stop processing if an interrupt has been requested.

When requesting a break into the debugger, the engine might time out if it takes too long for the target to carry out the break-in. This can occur if the target is in a non-responsive state or if the break-in request is blocked or delayed by resource contention. The length of time the engine will wait is returned by [GetInterruptTimeout](#) and can be set using [SetInterruptTimeout](#).

[Send comments about this topic to Microsoft](#)

Using Client Objects

5/26/2017 • 1 min to read • [Edit Online](#)

For an overview of the role of client objects in interacting with the debugger engine, see [Client Objects](#).

In general, a client's methods may be called only from the thread in which the client was created. Typically, methods called from the wrong thread will fail immediately. The notable exception to this rule is the method [CreateClient](#); this method may be called from any thread, and returns a new client that can be used in the thread from which it was called. Other exceptions are documented in the reference section.

A string describing a client object is returned by the method [GetIdentity](#) or can be written to the engine's output stream using [OutputIdentity](#).

COM Interfaces

The debugger engine API contains several COM like interfaces; they implement the **IUnknown** interface.

The interfaces described in the section [Debug Engine Interfaces](#) is implemented by the client (though not necessarily at the latest version). You may use the COM method [IUnknown::QueryInterface](#) to obtain each of these interfaces from any of the others.

The clients implement the **IUnknown** COM interface and use it for maintaining reference counts and interface selection. However, the clients are not registered COM objects. The method [IUnknown::AddRef](#) is used to increment the reference count on the object, and the method [IUnknown::Release](#) is used to decrement the reference count. When [IUnknown::QueryInterface](#) is called, the reference count is incremented, so when a client interface pointer is no longer needed [IUnknown::Release](#) should be called to decrement the reference count.

The reference count will be initialized to one when the client object is created using [DebugCreate](#) or [DebugConnect](#).

See the Platform SDK for more information about when reference counts should be incremented and decremented.

IUnknown::QueryInterface, **DebugCreate**, and **DebugConnect** each take an interface ID as one of their arguments. This interface ID can be obtained using the `__uuidof` operator. For example:

```
IDebugClient * debugClient;
HRESULT Hr = DebugCreate( __uuidof(IDebugClient), (void **)&debugClient );
```

Important The `IDebug*` interfaces such as [IDebugEventCallbacks](#) interface, although COM like, are not proper COM APIs. Calling these interfaces from managed code is an unsupported scenario. Issues such as garbage collection and thread ownership, lead to system instability when the interfaces are called with managed code.

[Send comments about this topic to Microsoft](#)

Using Callback Objects

5/26/2017 • 2 min to read • [Edit Online](#)

There are three callback COM like interfaces that are used by the engine: [IDebugEventCallbacks](#) for notifying [debugger extensions](#) and applications of changes to the engine or target, [IDebugInputCallbacks](#) for requesting input, and [IDebugOutputCallbacks](#) for sending output.

Callback objects are registered with clients. At most, one instance of each of the three callback interfaces can be registered with each client (the Unicode and ASCII versions of a interface count as the same interface).

When a client is created, the engine remembers the thread in which it was created. The engine uses this same thread whenever it makes a call to a callback instance registered with the client. If the thread is in use, the engine will queue the calls it needs to make. To allow the engine to make these calls, the method [DispatchCallbacks](#) should be called whenever a client's thread is idle. The method [ExitDispatch](#) will cause [DispatchCallbacks](#) to return. If the thread is the same thread that was used to start the debugger session, then the engine can make the callback calls during the [WaitForEvent](#) method, and [DispatchCallbacks](#) does not need to be called.

The method [FlushCallbacks](#) tells the engine to send all buffered output to the output callbacks.

Event Callback Objects

The [IDebugEventCallbacks](#) interface is used by the engine to notify the debugger extensions and applications of [events](#) and changes to the engine and target. An implementation of [IDebugEventCallbacks](#) can be registered with a client using [SetEventCallbacks](#). The current implementation registered with a client can be found using [GetEventCallbacks](#). The number of event callbacks registered across all clients can be found using [GetNumberEventCallbacks](#).

For details on how the engine manages events, see [Monitoring Events](#).

Input Callback Objects

The [IDebugInputCallbacks](#) interface is used by the engine to request input from debugger extensions and applications. An implementation of [IDebugInputCallbacks](#) can be registered with a client using [SetInputCallbacks](#). The current implementation registered with a client can be found using [GetInputCallbacks](#). The number of input callbacks registered across all clients can be found using [GetNumberInputCallbacks](#).

For details on how the engine manages input, see [Input and Output](#).

Output Callback Objects

The [IDebugOutputCallbacks](#) interface is used by the engine to send output to the debugger extensions and applications. An implementation of [IDebugOutputCallbacks](#) can be registered with a client using [SetOutputCallbacks](#). The current implementation registered with a client can be found using [GetOutputCallbacks](#). The number of output callbacks registered across all clients can be found using [GetNumberOutputCallbacks](#).

For details on how the engine manages output, see [Input and Output](#).

Note As is typical for COM objects, the engine will call [IUnknown::AddRef](#) on a callback COM object when it is registered with a client, and [IUnknown::Release](#) when the object is replaced or the client is deleted.

[Send comments about this topic to Microsoft](#)

Using Input and Output

5/26/2017 • 3 min to read • [Edit Online](#)

For an overview of the input and output streams in the debugger engine, see [Input and Output](#).

Input

The engine will ask for input from all its clients if the **Input** method is called on a client. The input is returned to the caller of **Input**.

Input Callbacks

When the engine asks for input from a client, it uses the **IDebugInputCallbacks** object registered with that client.

An **IDebugInputCallbacks** object may be registered with a client using **SetInputCallbacks**. Each client can have at most one **IDebugInputCallbacks** object registered with it.

The request for input begins with the engine calling the **IDebugInputCallbacks::StartInput** method. This informs the **IDebugInputCallbacks** object that the engine is now waiting for input.

If the **IDebugInputCallbacks** object has some input for the engine, it can call the **ReturnInput** method of any client. Once the **ReturnInput** method has been called, the engine will not take any more input. Subsequent callers of this method will be informed that the input was not received.

The engine will then call **IDebugInputCallbacks::EndInput** to indicate that it has stopped waiting for input.

Finally, the engine will echo this input to the registered **IDebugOutputCallbacks** object of every client (except the one used to provide the input) by using **IDebugOutputCallbacks::Output** with the bit-mask set to **DEBUG_OUTPUT_PROMPT**.

Output

Output may be sent to the engine using several client methods -- for example **Output** and **OutputVaList**. Upon receiving output, the engine sends it to some clients.

Clients use an *output mask* to indicate which types of output they are interested in. Whenever output is produced by the engine, it is accompanied by a mask specifying its output type. If the type of output matches the output mask of the client, the client will receive the output. The output mask may be set by calling **SetOutputMask** and queried using **GetOutputMask**. See **DEBUG_OUTPUT_XXX** for details of the output mask values.

The list of clients that the engine will send output to is controlled by the *output control*. Typically, the output control is set to send output to all clients; however, it can be temporarily changed using **ControlledOutput** and **ControlledOutputVaList**. See **DEBUG_OUTCTL_XXX** for details about output control values.

Output may be buffered by the engine. If multiple pieces of output are passed to the engine, it may collect them and send them to the clients in one large piece. To flush this buffer, use **FlushCallbacks**.

Each client object has an *output width*, which is the width of the output display for the client object. While this width is only used as a hint, some commands and extension functions format their output based on this width. The width is returned by the **GetOutputWidth** method and can be set using the **SetOutputWidth** method.

Output Callbacks

When the engine sends output to a client, it uses the **IDebugOutputCallbacks** object registered with the client. An **IDebugOutputCallbacks** object may be registered with a client using **SetOutputCallbacks**. Each client can have at most one **IDebugInputCallbacks** object registered with it.

To send the output, the engine calls the **IDebugOutputCallbacks::Output** method.

Output Line Prefix

Each client object has an *output line prefix* which is prepended to every line of output sent to the output callback associated with the client object. This can be used for indentation or to place identifying marks on each line of output.

The output line prefix is returned by `GetOutputLinePrefix` and can be set using `SetOutputLinePrefix`. To temporarily change the output line prefix and later change it back again, use `PushOutputLinePrefix` and `PopOutputLinePrefix`.

Log Files

The debugger engine supports opening a log file to record a debugging session. At most, one log file can be open at a time. Output sent to the output callbacks is also sent to this log file (unless it is flagged to not be logged).

To open a log file, use [OpenLogFile2](#) (or [OpenLogFile](#)). The method [GetLogFile2](#) (or [GetLogFile](#)) returns the currently open log file. To close the log file, use [CloseLogFile](#).

The method [SetLogMask](#) can be used to filter the output sent to the log file, and [GetLogMask](#) will return the current log file filter.

Prompt

In an interactive debugging session, a prompt can be used to indicate to the user that the debugger is waiting for user input. The prompt is sent to the output callbacks using the [OutputPrompt](#) and [OutputPromptVaList](#) methods. The contents of the standard prompt are returned by [GetPromptText](#).

[Send comments about this topic to Microsoft](#)

Monitoring Events

5/26/2017 • 1 min to read • [Edit Online](#)

For an overview of events in the [debugger engine](#), see [Events](#).

Events occurring in a target or the debugger engine may be monitored using the [IDebugEventCallbacks](#) interface. An **IDebugEventCallbacks** object may be registered with a client using [SetEventCallbacks](#). Each client can only have at most one **IDebugEventCallbacks** object registered with it.

When an **IDebugEventCallbacks** object is registered with a client, the engine will call the object's [IDebugEventCallbacks::GetInterestMask](#) to determine which events the object is interested in. Only events in which the object is interested will be sent to it.

For each type of event, the engine calls a corresponding callback method on [IDebugEventCallbacks](#). For events from the target, the [DEBUG_STATUS_XXX](#) value returned from these calls specifies how the execution of the target should proceed. The engine collects these return values from each **IDebugEventCallbacks** object it calls and acts on the one with the highest precedence.

Events from the Target That Break into the Debugger by Default

The following events break into the debugger by default:

- Breakpoint Events
- Exception Events (not documented here)
- System Error

Events from the Target that Do Not Break into the Debugger by Default

The following events do not break into the debugger by default:

- Create Process Event
- Exit Process Event
- Create Thread Event
- Exit Thread Event
- Load Module Event
- Unload Module Event

Internal Engine Changes

The following are not actual events, but are merely internal engine changes:

- Target Change
- Engine Change
- Engine Symbol Change
- Session Status Change

[Send comments about this topic to Microsoft](#)

Event Filters

5/26/2017 • 4 min to read • [Edit Online](#)

Event filters provide simple event filtering; they influence how the debugger engine proceeds after an event occurs in a target. When an event occurs, the engine determines whether that event matches an event filter. If it does, the break status for the event filter influences whether the debugger will break into the target. If the event is an exception event, the handling status determines whether the exception should be considered handled or not-handled in the target.

Note If more sophisticated event filtering is required, event callbacks can be used.

Event filters are divided into three categories.

1. *Specific event filters*. These are the filters for all the non-exception events. See [DEBUG_FILTER_XXX](#) for a list of these events.
2. *Specific exception filters*. The first specific exception filter is the *default exception filter*. The rest are filters for those exceptions for which the engine has built-in filters. See [Specific Exceptions](#) for a list of the specific exception filters.
3. *Arbitrary exception filters*. These are filters for exception events that have been added manually.

The filters in categories 1 and 2 are collectively known as *specific filters*, and the filters in categories 2 and 3 are collectively known as *exception filters*. The number of filters in each category is returned by

[GetNumberEventFilters](#).

An event matches a specific event filter if the type of the event is the same as the type of the filter. Some event filters have an additional parameter which further restricts the events they match.

An exception event matches an exception filter if the exception code for the exception event is the same as the exception code for the exception filter. If there is no exception filter with the same exception code as the exception event, the exception event will be handled by the default exception filter.

Commands and Parameters

Event filters can have a debugger command associated with them. This command is executed by the engine when an event matching the filter occurs. [GetEventFilterCommand](#) and [SetEventFilterCommand](#) can be used to get and set this command. For exception filters, this command is executed on the first-chance of the exception. A separate second-chance command can be executed upon the second-chance exception event. To get and set the second-chance command, use [GetExceptionFilterSecondCommand](#) and [SetExceptionSecondChanceCommand](#).

[GetEventFilterText](#)

The parameters for specific event filters and exception filters are returned by [GetSpecificFilterParameters](#) and [GetExceptionFilterParameters](#). The break status and handling status for event filters can be set using [SetSpecificFilterParameters](#) and [SetExceptionFilterParameters](#).

[SetExceptionFilterParameters](#) can also be used to add and remove arbitrary exception filters.

A short description of specific filters is returned by [GetEventFilterText](#).

Some specific filters take arguments that restrict which events the filter matches. [GetSpecificFilterArgument](#) and [SetSpecificFilterArgument](#) will get and set arguments for those specific filters which support arguments. If a specific filter has no argument, there is no restriction on which events it matches. The following table lists the event filters that take arguments and how they restrict the events which match them:

EVENT	MATCH CRITERIA
Create Process	The name of the created process must match the argument.1
Exit Process	The name of the exited process must match the argument.1
Load Module	The name of the loaded module must match the argument.1
Unload Module	The base address of the unloaded module must be the same as the argument.2
Target Output	The debug output from the target must match the argument.3

Note

1. The argument uses the [string wildcard syntax](#) and is compared with the image name (ignoring path) when the event occurs. If the name of the module or process is not available, it is considered a match.
2. The argument is an expression that is evaluated by the engine when the argument is set.
3. The argument uses the string wildcard syntax and is compared with the debug output from the target. If the output is not known, it is considered a match.

Index and Exception Code

Each event filter has an index. The index is a number between zero and one less than the total number of filters (inclusive). The index range for each category of filters can be found from the *SpecificEvents*, *SpecificExceptions*, and *ArbitraryExceptions* values returned by [GetNumberEventFilters](#), as described in the following table:

EVENT FILTERS	INDEX OF FIRST FILTER	NUMBER OF FILTERS
Specific event filters	0	<i>SpecificEvents</i>
specific exception filters	<i>SpecificEvents</i>	<i>SpecificExceptions</i>
arbitrary exception filters	<i>SpecificEvents</i> + <i>SpecificExceptions</i>	<i>ArbitraryExceptions</i>

The indices for the specific event filters are found in the first table located in the topic [DEBUG_FILTER_XXX](#). The index of the default exception filter (the first specific exception filter) is *SpecificEvents*. When an arbitrary exception filter is removed, the indices of the other arbitrary exception filters can change.

The exception filters are usually specified by exception code. However, some methods require the index of the exception. To find the index of an exception filter for a given exception, use [GetExceptionFilterParameters](#) to iterate over all the exception filters until you find the one with the same exception code as the exception. The exception codes for the specific exception filters can be found in the topic [Specific Exceptions](#).

System Errors

When a system error occurs, the engine will break into the debugger or print the error to the output stream, if the error occurs at or below specified levels. These levels are returned by [GetSystemErrorControl](#) and can be changed using [SetSystemErrorControl](#).

[Send comments about this topic to Microsoft](#)

Event Information

5/26/2017 • 1 min to read • [Edit Online](#)

Whenever a debugging session is accessible, there is a *last event*. This is the event that caused the session to become accessible. The *event target* is the target which generated the last event. When the session becomes accessible, the current target is set to the event target. The details of the last event are returned by

GetLastEventInformation. The instruction pointer for the last event and the memory at the instruction pointer when the event occurred are returned by the **Request** operations

DEBUG_REQUEST_GET_CAPTURED_EVENT_CODE_OFFSET and

DEBUG_REQUEST_READ_CAPTURED_EVENT_CODE_STREAM.

If the target is a crash dump file, the *last event* is the last event that occurred before the dump file was created. This event is stored in the dump file and the engine generates it for the event callbacks when the dump file is acquired as a debugging target.

If the target is a kernel-mode target and a *bug check* occurred, the bug check code and related parameters can be found using **ReadBugCheckData**.

If the target is a user-mode Minidump, the dump file generator may store an additional event. Typically, this is the event that provoked the generator to save the dump file. Details of this event are returned by

GetStoredEventInformation and the **Request** operations **DEBUG_REQUEST_TARGET_EXCEPTION_CONTEXT**, **DEBUG_REQUEST_TARGET_EXCEPTION_THREAD**, and **DEBUG_REQUEST_TARGET_EXCEPTION_RECORD**.

Dump files may contain a static list of events. Each event represents a snapshot of the target at a particular point in time. The number of events in this list is returned by **GetNumberEvents**. For a description of each event in the list, use **GetEventIndexDescription**. To set an event from this list as the current event, use the method

SetNextEventIndex; after calling **WaitForEvent**, the event becomes the current event. To determine which event in the list is the current event, use **GetCurrentEventIndex**.

Using Breakpoints

5/26/2017 • 1 min to read • [Edit Online](#)

Breakpoints are event triggers which, when the breakpoint's conditions are satisfied, will halt execution of the target and break into the debugger. Breakpoints allow the user to analyze and perhaps modify the target when execution reaches a certain point or when a certain memory location is accessed.

The debugger engine inserts a *software breakpoint* into a target by modifying the processor instruction at the breakpoint's location; this modification is invisible to the engine's clients. A software breakpoint is triggered when the target executes the instruction at the breakpoint location. A *processor breakpoint* is inserted into the target's processor by the debugger engine; its capabilities are processor-specific. It is triggered by the processor when the memory at the breakpoint location is accessed; what type of access will trigger this breakpoint is specified when the breakpoint is created.

This topic includes:

[Setting Breakpoints](#)

[Controlling Breakpoint Flags and Parameters](#)

[Send comments about this topic to Microsoft](#)

Setting Breakpoints

5/26/2017 • 1 min to read • [Edit Online](#)

Breakpoints are created with the **AddBreakpoint** method. This method creates an **IDebugBreakpoint** object that represents the breakpoint. It also set the *breakpoint type* (software breakpoint or processor breakpoint). Once a breakpoint has been created, its type cannot be changed.

Breakpoints are deleted with the **RemoveBreakpoint** method. This also deletes the **IDebugBreakpoint** object; this object may not be used again.

Note Although **IDebugBreakpoint** implements the **IUnknown** interface, the methods **IUnknown::AddRef** and **IUnknown::Release** are not used to control the lifetime of the breakpoint. These methods have no effect on the lifetime of the breakpoint. Instead, an **IDebugBreakpoint** object is deleted after the method **RemoveBreakpoint** is called.

When the breakpoint is created, it is given a unique *breakpoint ID*. This identifier will not change. However, after the breakpoint has been deleted, its ID may be used for another breakpoint. For details on how to receive notification of the removal of a breakpoint, see [Monitoring Events](#).

When a breakpoint is created, it is initially disabled; this means that it will not cause the target to stop executing. This breakpoint may be enabled by using the method **AddFlags** to add the DEBUG_BREAKPOINT_ENABLED flag.

When a breakpoint is first created, it has the memory location 0x00000000 associated with it. The location can be changed by using **SetOffset** with an address, or by using **SetOffsetExpression** with a symbolic expression. The breakpoint's location should be changed from its initial value before it is used.

[Send comments about this topic to Microsoft](#)

Controlling Breakpoint Flags and Parameters

5/26/2017 • 4 min to read • [Edit Online](#)

There are a number of methods that can be used to determine basic information about breakpoints:

- **GetId** returns the breakpoint ID.
- **GetType** returns the breakpoint type (software or processor) and the type of the effective processor on which the breakpoint is set.
- **GetAdder** returns the client that added the breakpoint.
- **GetOffset** returns the address of a breakpoint.
- **GetOffsetExpression** returns the expression string that specifies the location of the breakpoint.

In addition to its location and breakpoint type, a breakpoint has several parameters controlling its behavior.

Breakpoint parameters can be controlled through a variety of specific methods. In addition, most of the parameters may be queried together using **GetParameters**.

Breakpoint Flags

Breakpoint flags are one kind of breakpoint parameters.

Breakpoint flags can be queried using **GetFlags**. They can be changed by using **AddFlags**, **RemoveFlags**, or **SetFlags**.

Breakpoint flags form a bit field. The possible flags that can be used in this bit field, and their meanings, are as follows:

DEBUG_BREAKPOINT_ENABLED

When this flag is set, the breakpoint is *enabled* and will have its normal effect. When this flag is not set, the breakpoint is *disabled* and will not have any effect. If you wish to temporarily deactivate a breakpoint, you can remove this flag; it is then easy to add this flag back when you want to re-enable this breakpoint.

DEBUG_BREAKPOINT_ADDER_ONLY

When this flag is set, the breakpoint is a *private breakpoint*. This breakpoint is visible only to the client that added it. In this case, other clients will not be able to query the engine for the breakpoint, and the engine will not send events generated by the breakpoint to other clients. All callbacks (event and **output**) related to this breakpoint will be sent only to this client. See **GetAdder**.

DEBUG_BREAKPOINT_GO_ONLY

When this flag is set, the breakpoint will only be triggered if the target is in unrestricted execution. It will not be triggered if the engine is stepping through instructions in the target.

DEBUG_BREAKPOINT_ONE_SHOT

When this flag is set, the breakpoint will automatically remove itself the first time it is triggered.

DEBUG_BREAKPOINT_DEFERRED

When this flag is set, the breakpoint is *deferred*. This flag is set by the engine when the offset of the breakpoint is specified using a symbolic expression, and the engine cannot evaluate the expression. Every time a module is loaded or unloaded in the target, the engine will attempt reevaluate the expression for all breakpoints whose location is specified using an expression. Those that cannot be evaluated are flagged as deferred. This flag cannot be modified by any client.

Other Breakpoint Parameters

Breakpoint parameters also include:

Pass count

If the breakpoint has a pass count associated with it, it will not be activated until the target has passed the breakpoint the specified number of times. The pass count that was originally set can be found by using **GetPassCount**. The number of times remaining that the engine will pass the breakpoint before it is activated can be found using **GetCurrentPassCount**. The pass count can be reset to a new value by using **SetPassCount**.

Match thread

If the breakpoint has a thread associated with it, it will be ignored by the engine when it is encountered by any other thread. The thread can be found by using **GetMatchThreadId**, and can be changed by using **SetMatchThreadId**.

Command

The breakpoint may have a command associated with it. The command is executed when the breakpoint is activated. This command can be found by using **GetCommand**, and can be changed by using **SetCommand**.

Size

If the breakpoint is a processor breakpoint, it must have a specified size. This determines the size of the block of memory whose access will activate the breakpoint -- the beginning of the block is the breakpoint's location. The size can be found by using **GetDataParameters**, and can be changed by using **SetDataParameters**.

Access type

If the breakpoint is a processor breakpoint, it must have an access type. This determines the type of access that will activate the breakpoint. For example, the breakpoint may be activated if the target reads from, writes to, or executes the memory specified by the breakpoint. The access type can be found by using **GetDataParameters**, and can be changed by using **SetDataParameters**.

Valid Parameters for Processor Breakpoints

The following access types are available for processor breakpoints:

VALUE	DESCRIPTION
DEBUG_BREAK_READ	The breakpoint will be triggered when the CPU reads memory in the breakpoint's memory block.
DEBUG_BREAK_WRITE	The breakpoint will be triggered when the CPU writes memory in the breakpoint's memory block.
DEBUG_BREAK_READ DEBUG_BREAK_WRITE	The breakpoint will be triggered when the CPU reads or writes memory in the breakpoint's memory block.
DEBUG_BREAK_EXECUTE	The breakpoint will be triggered when the CPU fetches the instruction in the breakpoint's memory block.
DEBUG_BREAK_IO	The breakpoint will be triggered when the I/O port in the breakpoints memory block is accessed. (Windows XP and Microsoft Windows Server 2003 only, kernel mode only, x86 only)

Not all access types and sizes are supported on all processors. The following access types and sizes are supported:

x86

All access types are supported. DEBUG_BREAK_READ behaves like DEBUG_BREAK_READ | DEBUG_BREAK_WRITE. The size must be 1, 2, or 4. The breakpoint's address must be a multiple of the size.

x64

All access types are supported. DEBUG_BREAK_READ behaves like DEBUG_BREAK_READ | DEBUG_BREAK_WRITE. The size must be 1, 2, 4, or 8. The breakpoint's address must be a multiple of the size.

Itanium

All access types except DEBUG_BREAK_IO are supported. The size must be a power of two; for DEBUG_BREAK_EXECUTE, the size must be 16. The breakpoint's address must be a multiple of the size.

Itanium running in x86 mode

The is the same as for x86, except that DEBUG_BREAK_IO is not supported.

Memory Access

5/26/2017 • 1 min to read • [Edit Online](#)

The [debugger engine](#) provides *interfaces* to directly read from and write to the target's main memory, registers, and other data spaces.

In user-mode debugging, only the virtual memory and registers can be accessed; the physical memory and other data spaces cannot be accessed.

The debugger engine API always uses 64-bit addresses when referring to memory locations on the target.

If the target uses 32-bit addresses, the native 32-bit address will automatically be sign-extended by the engine to 64-bit addresses. The engine will automatically convert between 64-bit addresses and native 32-bit addresses when communicating with the target.

This section includes:

[Virtual and Physical Memory](#)

[Registers](#)

[Other Data Spaces](#)

[Send comments about this topic to Microsoft](#)

Virtual and Physical Memory

5/26/2017 • 2 min to read • [Edit Online](#)

The engine provides a number of methods for reading and writing the virtual and physical memory of a target.

Virtual Memory

When specifying a location in the virtual memory of a target, the target's virtual address space is used. In user-mode debugging, this is the virtual address space of the current process. In kernel-mode debugging, this is the virtual address space of the implicit process. See [Threads and Processes](#) for more information about the current and implicit process.

The virtual memory (of the target) can be read by using [ReadVirtual](#) and written using [WriteVirtual](#).

Pointers in the target's memory can be read and written by using the convenience methods [ReadPointersVirtual](#) and [WritePointersVirtual](#). These methods will automatically convert between the 64-bit pointers used by the engine and the native pointers used by the target. These methods are useful when requesting memory that contains pointers that will be used for subsequent requests -- for example, a pointer to a string.

The [SearchVirtual](#) and [SearchVirtual2](#) methods can be used to search the target's virtual memory for a pattern of bytes.

The [FillVirtual](#) method can be used to copy a pattern of bytes, multiple times, to the target's virtual memory.

The target's virtual memory can also be read and written in a way that bypasses the debugger engine's virtual memory cache using the methods [ReadVirtualUncached](#) and [WriteVirtualUncached](#). These uncached versions are useful for reading virtual memory that is inherently volatile, such as memory-mapped device areas, without contaminating or invalidating the cache. Uncached memory access should only be used in situations when it is required, as the performance of uncached access can be significantly lower than cached access.

The engine provides some convenience methods to read strings from the target's virtual memory. To read a multibyte string from the target, use [ReadMultiByteStringVirtual](#) and [ReadMultiByteStringVirtualWide](#). To read a Unicode string from the target, use [ReadUnicodeStringVirtual](#) and [ReadUnicodeStringVirtualWide](#).

To find information about a memory location, use [GetOffsetInformation](#). Not all of the virtual address space in the target contains valid memory. To find valid memory within a region, use [GetValidRegionVirtual](#). When manually searching for valid memory in a target, the method [GetNextDifferentlyValidOffsetVirtual](#) will find the next location where the validity may change.

Physical Memory

The physical memory can only be directly accessed in kernel-mode debugging.

Physical memory on the target can be read by using [ReadPhysical](#) and [ReadPhysical2](#), and written by using [WritePhysical](#) and [WritePhysical2](#).

The [FillPhysical](#) method can be used to copy a pattern of bytes, multiple times, to the target's physical memory.

An address in the target's virtual address space can be translated to a physical address on the target by using the [VirtualToPhysical](#) method. The system's paging structures used to translate a virtual address to a physical address can be found by using [GetVirtualTranslationPhysicalOffsets](#).

Events

When the virtual or physical memory of the target is changed, the [IDebugEventCallbacks::ChangeDebuggeeState](#) callback method is called.

[Send comments about this topic to Microsoft](#)

Registers

5/26/2017 • 2 min to read • [Edit Online](#)

The [debugger engine](#) can be used to examine and alter the target's registers.

The registers available on the target depend on its processor architecture. For a description of the registers for the x86 and Itanium processors, see [Processor Architecture](#). For a complete description of the registers available for a processor, see that processor's documentation.

The Register Set

The [GetNumberRegisters](#) method can be used to find the number of registers on the target.

Each register is referred to by its index. The index of the first register is zero, and the index of the last register is the number of registers minus one. To find the index of a register whose name is known, use [GetIndexByName](#).

The method [GetDescription](#) returns information about a register. This includes the register's name, the type of values it can hold, and whether it is a subregister.

A *subregister* is a register that is contained within another register. When the subregister changes, the register that contains it also changes. For example, on an x86 processor, the **ax** subregister is the same as the low 16 bits of the 32-bit **eax** register.

There are three special registers whose values may be found by using the following methods. The interpretation of the values of these registers is platform dependent.

- The location of the current instruction may be found with [GetInstructionOffset](#) and [GetInstructionOffset2](#).
- The location of the current processor stack slot may be found with [GetStackOffset](#) and [GetStackOffset2](#).
- The location of the stack frame for the current function may be found with [GetFrameOffset](#) and [GetFrameOffset2](#).

Manipulating Registers

The value of a register can be read by using the method [GetValue](#). Multiple registers can be read by using [GetValues](#) and [GetValues2](#).

A value can be written to a register by using the method [SetValue](#). Multiple registers can be written by using [SetValues](#) and [SetValues2](#).

When writing a value to a register, if the value supplied has a different type to the type of the register then the value is converted into the register's type. This conversion is the same as that performed by the method [CoerceValue](#). This conversion may result in data loss if the register's type is not capable of holding the value supplied.

Pseudo-Registers

Pseudo-registers are variables maintained by the debugger engine that hold certain values, for example, **\$teb** is the name of the pseudo-register whose value is the address of the current thread's Thread Environment Block (TEB). For more information, and a list of the pseudo-registers, see [Pseudo-Register Syntax](#).

Each pseudo-register has an index. The index is a number between zero and the number of pseudo-registers - (returned by [GetNumberPseudoRegisters](#)) minus one. To find the index of a pseudo-register by its name, use [GetPseudoIndexByName](#). The values of pseudo-registers can be read using [GetPseudoValues](#), and values can be written to pseudo-registers using [SetPseudoValues](#). For a description of a pseudo-register, including its type,

use [GetPseudoDescription](#).

Note Not all of the pseudo-registers are available in all debugging sessions or at all times in a particular session.

Displaying Registers

The methods [OutputRegisters](#) and [OutputRegisters2](#) format the target's registers and sends them to the clients as output.

Events

Whenever the values of the target's registers change, the engine will call the

[IDebugEventCallbacks::ChangeDebuggeeState](#) callback method with the parameter *Flags* set to DEBUG_CDS_REGISTERS.

[Send comments about this topic to Microsoft](#)

Other Data Spaces

5/26/2017 • 1 min to read • [Edit Online](#)

In kernel-mode debugging, it is possible to read and write data to a variety of data spaces in addition to the main memory and registers. The following data spaces can be accessed:

System Bus

The methods **ReadBusData** and **WriteBusData** read and write system bus data.

Control-Space Memory

The methods **ReadControl** and **WriteControl** read and write control-space memory.

I/O Memory.

The methods **ReadIo** and **WriteIo** read and write system and bus I/O memory.

Model Specific Register (MSR)

The methods **ReadMsr** and **WriteMsr** read and write MSRs, which are control registers that enable and disable features, and support debugging, for a particular model of CPU.

Handles

In user-mode debugging, information about system objects can be obtained using system handles owned by a target process. The method **ReadHandleData** can be used to read this information.

System handles for thread and process system objects can be obtained by using the **GetCurrentThreadHandle** and **GetCurrentProcessHandle** methods. These handles are also provided to the **IDebugEventCallbacks::CreateThread** and **IDebugEventCallbacks::CreateProcess** callback methods when create-thread and create-process debugging event occur.

Note In kernel mode, the process and thread handles are artificial handles. They are not system handles.

[Send comments about this topic to Microsoft](#)

Examining the Stack Trace

5/26/2017 • 1 min to read • [Edit Online](#)

A *call stack* contains the data for the functions calls made by a thread. The data for each function call is called a *stack frame* and includes the return address, parameters passed to the function, and the function's local variables. Each time a function call is made a new stack frame is pushed onto the top of the stack. When that function returns, the stack frame is popped off the stack.

Each thread has its own call stack, representing the calls made in that thread.

To get a stack trace, use the methods [GetStackTrace](#) and [GetContextStackTrace](#). A stack trace can be printed using [OutputStackTrace](#) and [OutputContextStackTrace](#).

[Send comments about this topic to Microsoft](#)

Controlling Threads and Processes

5/26/2017 • 6 min to read • [Edit Online](#)

For an overview of threads and processes in the debugger engine, see [Threads and Processes](#).

When an event occurs, the event thread and event process are set to the thread and process (operating system or virtual) in which the event occurred. They can be found using [GetEventThread](#) and [GetEventProcess](#), respectively.

Implicit Threads and Processes

In kernel-mode debugging the debugger engine will use the *implicit process* to determine which virtual address space to use when performing virtual to physical address translation -- for example, in the methods [VirtualToPhysical](#) and [ReadVirtual](#). When an event occurs, the implicit process is set to the current process.

The implicit process may be changed by using [SetImplicitProcessDataOffset](#). To determine the implicit process use [GetImplicitProcessDataOffset](#).

Note When setting [breakpoints](#) during a live kernel debugging session, the debugger engine will pass the virtual address of the breakpoint to the target, and the target will set the breakpoint. In this case, only the process context of the target is used when handling the breakpoint; the value of the implicit process is irrelevant.

In kernel-mode debugging, the debugger engine will use the *implicit thread* to determine some of the target's [registers](#). This includes the processor stack (see [GetStackOffset](#)), the frame offset (see [GetFrameOffset](#)), and the instruction offset (see [GetInstructionOffset](#)). When an event occurs, the implicit thread is set to the current thread.

The implicit thread may be changed by using [SetImplicitThreadDataOffset](#). To determine the implicit thread, use [GetImplicitThreadDataOffset](#).

Not all registers are determined by the implicit thread. Some registers will remain the same when the implicit thread is changed.

Warning The implicit process and implicit thread are independent. If the implicit thread does not belong to the implicit process, then user and session state for the implicit thread will be in the wrong virtual address space and attempts to access this information will cause errors or provide incorrect results. This problem does not occur when accessing kernel memory, since kernel memory addresses are constant across all virtual address spaces. Thus information for the implicit thread located in kernel memory may be accessed independent of the implicit process.

Threads

The *engine thread ID* is used by the debugger engine to identify each operating system thread and each virtual thread for a target.

While a target is stopped, each thread also has an index relative to the process to which it belongs. For any process, the index of the first thread in the process is zero, and the index of the last thread is the number of threads in the process minus one. The number of threads in the current process can be found by using [GetNumberThreads](#). The total number of threads in all processes in the current target can be found by using [GetTotalNumberThreads](#).

The engine thread ID and system thread ID for one or more threads in the current process can be found from their index by using [GetThreadIdsByIndex](#).

The engine maintains several pieces of information about each thread. This information may be queried for the

current thread, and may be used to find the engine thread ID for a thread.

system thread ID (user-mode debugging only)

The system thread ID of the current thread can be found by using [GetCurrentThreadId](#). For a given system thread ID, the corresponding engine thread ID may be found by using [GetThreadIdBySystemId](#).

thread environment block (TEB)

The address of the TEB for the current thread can be found by using [GetCurrentThreadTeb](#). For a given TEB address, the corresponding engine thread ID may be found by using [GetThreadIdByTeb](#). In kernel-mode debugging, the TEB of a (virtual) thread is the TEB of the system thread that was running on the corresponding processor when the last event occurred.

data offset

In user-mode debugging, the data offset of a (system) thread is the location of the TEB for that thread. In kernel-mode debugging the data offset of a (virtual) thread is the KTHREAD structure for the system thread that was running on the corresponding processor when the last event occurred. The data offset of the current thread can be found by using [GetCurrentThreadDataOffset](#). For a given data offset, the corresponding engine thread ID may be found by using [GetThreadIdByDataOffset](#).

system handle

The system handle of the current thread can be found by using [GetCurrentThreadHandle](#). For a given system handle, the corresponding engine thread ID may be found by using [GetThreadIdByHandle](#). In kernel-mode debugging, an artificial handle is created for each (virtual) process. This handle can only be used with debugger engine API queries.

Processes

The *engine process ID* is used by the debugger engine to identify each operating system process and each virtual process for a target.

While a target is stopped, each process has an index relative to the target. The index of the first process in the target is zero, and the index of the last process is the number of processes in the target minus one. The number of processes in the current target can be found by using [GetNumberProcesses](#).

The engine process ID and system process ID for one or more threads in the current target can be found from their index by using [GetProcessIdsByIndex](#).

The engine maintains several pieces of information about each process. This information may be queried for the current process, and may be used to find the engine process ID for a process.

system process ID (user-mode debugging only)

The system process ID of the current process can be found by using [GetCurrentProcessSystemId](#). For a given system process ID, the corresponding engine process ID may be found by using [GetProcessIdBySystemId](#).

process environment block (PEB)

The address of the PEB for the current process can be found by using [GetCurrentProcessPeb](#). For a given PEB address, the corresponding engine process ID may be found by using [GetProcessIdByPeb](#). In kernel-mode debugging, the PEB of the (virtual) process is the PEB of the system process that was running when the last event occurred.

data offset

In user-mode debugging, the data offset of a (system) process is the location of the PEB of that process. In kernel-mode debugging, the data offset of the (virtual) process is the KPROCESS structure for the system process that was running when the last event occurred. The data offset of the current process can be found by using [GetCurrentProcessDataOffset](#). For a given data offset, the corresponding engine process ID may be found by using [GetProcessIdByDataOffset](#).

system handle

The system handle of the current process can be found by using [GetCurrentProcessHandle](#). For a given system handle, the corresponding engine process ID may be found by using [GetProcessIdByHandle](#). In kernel-mode debugging, an artificial handle is created for the (virtual) process. This handle can only be used with debugger engine queries.

Events

In live user-mode debugging, whenever a thread is created or exits in a target, the create-thread and exit-thread debugging events are generated. These events result in calls to the [IDebugEventCallbacks::CreateThread](#) and [IDebugEventCallbacks::ExitThread](#) callback methods.

In live user-mode debugging, whenever a process is created or exits in a target, the create-process and exit-process debugging events are generated. These events result in calls to the [IDebugEventCallbacks::CreateProcess](#) and [IDebugEventCallbacks::ExitProcess](#) callback methods.

For more information about events, see [Monitoring Events](#).

Additional Information

For more information about threads and processes, including the TEB, KTHREAD, PEB, and KPROCESS structures, see *Microsoft Windows Internals* by David Solomon and Mark Russinovich.

[Send comments about this topic to Microsoft](#)

Using Symbols

5/26/2017 • 2 min to read • [Edit Online](#)

For an overview of symbols, including using symbol files and symbol servers, see [Symbols](#).

Symbol Names and Locations

To find the location of a symbol given its name, use [GetOffsetByName](#). For details on the syntax used to specify symbol names, see [Symbol Syntax and Symbol Matching](#).

If the exact name of a symbol is not known, or multiple symbols have the same name, [StartSymbolMatch](#) will begin a search for symbols whose names match a given pattern. For details on the syntax, see [String Wildcard Syntax](#).

To find the name of a symbol given its location, use [GetNameByOffset](#). To find the names of symbols in a module near a given location, use [GetNearNamebyOffset](#).

Note Whenever possible, qualify the symbol with the module name -- for example **mymodule!main**. Otherwise, if the symbol does not exist (for example, because of a typographical error) the engine will have to load and search the symbols for every module; this can be a slow process, especially for kernel-mode debugging. If the symbol name was qualified with a module name, the engine will only need to search the symbols for that module.

A symbol is uniquely identified using the structure [DEBUG_MODULE_AND_ID](#). This structure is returned by the methods [GetSymbolEntriesByName](#) and [GetSymbolEntriesByOffset](#), which search for symbols based on their name and location, respectively.

The method [GetSymbolEntryInformation](#) returns a description of a symbol using the [DEBUG_SYMBOL_ENTRY](#) structure.

To find the offset of a field within a structure, use [GetFieldOffset](#). To find the name of a field given its index within a structure, use [GetFieldName](#). To find the name of an enumeration constant given its value, use [GetConstantName](#).

The method [GetSymbolInformation](#) can perform several requests for information about symbols.

Symbol Options

A number of options control how the symbols are loaded and unloaded. For a description of these options, see [Setting Symbol Options](#).

Symbol options may be turned on by using [AddSymbolOptions](#), and turned off by using [RemoveSymbolOptions](#).

[GetSymbolOptions](#) returns the current symbol options. To set all the symbol options at once, use [SetSymbolOptions](#).

Reloading Symbols

After loading symbol files, the engine stores the symbol information in an internal cache. To flush this cache, use [Reload](#). These symbols will have to be loaded again now or at a later time.

Synthetic Symbols

Synthetic symbols are a way to label an arbitrary address for easy reference. Synthetic symbols can be created in any existing module. The method [AddSyntheticSymbol](#) creates a new synthetic symbol. Synthetic symbols can be removed using [RemoveSyntheticSymbol](#). Reloading the symbols for the module deletes all synthetic symbols associated with that module.

Symbol Path

To add a directory or symbol server to the symbol path, use the method [AppendSymbolPath](#). The whole symbol path is returned by [GetSymbolPath](#) and can be changed using [SetSymbolPath](#).

[Send comments about this topic to Microsoft](#)

Modules

5/26/2017 • 3 min to read • [Edit Online](#)

An *image* is an executable, DLL, or driver that Windows has loaded as part of a user-mode process or the kernel. The file from which the image was loaded is referred to as its *image file*.

The [debugger engine](#) caches a list of *modules* for each process (or, in kernel-mode, the virtual process). Typically each module in this list represents an image in the process. The engine's module list can be synchronized with the target using **Reload**.

Note In kernel-mode debugging, the engine's module list for the virtual process contains both the system-wide kernel-mode modules and the current process's user-mode modules.

A module can be specified by its base address in the target's virtual address space, or by its index in the list of modules the engine maintains for the target. The module's index equals its position in the list of modules, and therefore this index will change if a module with a lower index is unloaded. All unloaded modules have indexes; these are always higher than the indexes of loaded modules. The base address of a module will not change as long as it remains loaded; in some cases it may change if the module is unloaded and then reloaded.

The index is a number between zero and the number of modules in the target minus one. The number of modules in the current process can be found by calling [GetNumberModules](#).

The index can be used to find the base address by calling [GetModuleByIndex](#). The base address of a module owning a symbol with a given name can be found using [GetSymbolModule](#).

The following methods return both the index and base address of the specified module:

- To find a module with a given module name, use [GetModuleByModuleName](#).
- The module whose virtual address range contains a given address is returned by [GetModuleByOffset](#). This method can be used to find the module index given the base address of the module.

The following methods return information about modules specified either by base address or index:

- The names of a module are returned by [GetModuleNames](#) and [GetModuleNameString](#).
- Version information for the module is returned by [GetModuleVersionInformation](#).
- Some of the parameters used to describe a module are returned by [GetModuleParameters](#). For details on the parameters returned by this method, see [DEBUG_MODULE_PARAMETERS](#).

Unloaded Modules

During user-mode debugging, unloaded modules are tracked only in Windows Server 2003 and later versions of Windows. Earlier versions of Windows only tracked unloaded modules in kernel mode. When they are tracked, they are indexed after the loaded modules. Hence any method that searches the target's modules will search all the loaded modules and then the unloaded modules. Unloaded modules can be used to analyze failures caused by an attempt to call unloaded code.

Synthetic Modules

Synthetic modules can be created as a way to label a region of memory. These modules cannot contain real symbols, but they can contain synthetic symbols. The method [AddSyntheticModule](#) creates a new synthetic module. Synthetic modules can be removed using [RemoveSyntheticModule](#). Reloading all the modules in the target deletes all synthetic modules.

Image Path

The *executable image path* is used by the engine when searching for executable images.

The executable image path can consist of several directories separated by semicolons (:). These directories are searched in order.

For an overview of the executable image path, see [Executable Image Path](#).

To add a directory to the executable image path, use the method [AppendImagePath](#). The whole executable image path is returned by [GetImagePath](#) and can be changed using [SetImagePath](#).

Additional Information

For more information about processes and virtual processes, see [Threads and Processes](#).

[Send comments about this topic to Microsoft](#)

Types

5/26/2017 • 1 min to read • [Edit Online](#)

Type information from a module's symbol file is identified by two pieces of information: a type ID and the base address of the module to which the type belongs. The following methods can be used to find a type ID:

- [GetTypeId](#) returns the type ID for a given type name.
- [GetSymbolTypeId](#) returns the type ID for the type of a symbol with the given name.
- [GetOffsetTypeId](#) returns the type ID for the symbol found at the given location.

The name and size of a type are returned by [GetTypeName](#) and [GetTypeSize](#), respectively.

The following convenience methods can be used for reading and writing typed data in the target's physical and virtual memory:

[ReadTypedDataPhysical](#)

[WriteTypedDataPhysical](#)

[ReadTypedDataVirtual](#)

[WriteTypedDataVirtual](#)

Printing Typed Data

To format typed data and send it to the output callbacks, use [OutputTypedDataPhysical](#) and [OutputTypedDataVirtual](#) for data in the target's physical and virtual memory respectively.

The type options described in [DEBUG_TYPEOPTS_XXX](#) affect how the engine formats typed data before sending it to the output callbacks.

The type options may be turned on by using [AddTypeOptions](#), and turned off by using [RemoveTypeOptions](#).

[GetTypeOptions](#) returns the current type options. To set all the type options at once, use [SetTypeOptions](#).

Interpreting Raw Data Using Type Information

The debugger engine API supports interpreting typed data. This provides a way to walk object hierarchies on the target, including finding members of structures, dereferencing pointers, and locating array elements.

Typed data is described by instances of the [DEBUG_TYPED_DATA](#) structure and represents regions of memory on the target cast to a particular type. The [DEBUG_REQUEST_EXT_TYPED_DATA_ANSI](#)**Request** operation is used to manipulate these instances. They can be initialized to the result of expressions or by casting regions of memory to a specified type. For a list of all the sub-operations that the [DEBUG_REQUEST_EXT_TYPED_DATA_ANSI](#) **Request** operation supports, see [EXT_TDOP](#).

Additional Information

For details on output callbacks, see [Input and Output](#).

[Send comments about this topic to Microsoft](#)

Scopes and Symbol Groups

5/26/2017 • 4 min to read • [Edit Online](#)

A *symbol group* contains a set of symbols for efficient manipulation as a group. A symbol group can be created and populated manually or can be automatically generated and updated based on symbols in lexical scopes, such as local variables and function arguments. The interface [IDebugSymbolGroup](#) is used to represent a symbol group.

There are two ways to create a symbol group. An empty symbol group is returned by [CreateSymbolGroup](#), and the symbol group for the current lexical scope is returned by [GetScopeSymbolGroup](#).

Note The symbol group generated from the current scope is a snapshot of the local variables. If any execution occurs in the target, the symbols may no longer be accurate. Also, if the current scope changes, the symbol group will no longer represent the *current* scope (because it will continue to represent the scope for which it was created).

Symbols can be added to a symbol group using [AddSymbol](#), and removed using [RemoveSymbolByIndex](#) or [RemoveSymbolByName](#). The method [OutputAsType](#) tells the debugger to use a different symbol type when handling a symbol's data.

Note The values for scoped symbols may not be accurate. In particular, the machine architecture and compiler optimizations may prevent the debugger from accurately determining a symbol's value.

The *symbol entry information* is a description of a symbol, including its location and its type. To find this information for a symbol in a module, use the [IDebugSymbols3::GetSymbolEntryInformation](#). To find this information for a symbol in a symbol group, use [IDebugSymbolGroup2::GetSymbolEntryInformation](#). See [DEBUG SYMBOL ENTRY](#) for details of the symbol entry information.

The following methods return information about a symbol in a symbol group:

- [GetSymbolName](#) returns the name of the symbol.
- [GetSymbolOffset](#) returns the absolute address in the target's virtual address space of the symbol, if the symbol has an absolute address.
- [GetSymbolRegister](#) returns the register containing the symbol, if the symbol is contained in a register.
- [GetSymbolSize](#) returns the size of the data for the symbol.
- [GetSymbolTypeName](#) returns the name of the symbol's type.
- [GetSymbolValueText](#) returns the value of the symbol as a string.

If a symbol is stored in a register or in a memory location known to the debugger engine, its value can be changed using [WriteSymbol](#).

A symbol is a *parent symbol* if it contains other symbols. For example, a structure contains its members. A symbol is a *child symbol* if it is contained in another symbol. A symbol may be both a parent and child symbol. Each symbol group has a flat structure and contains parent symbols and their children. Each symbol has a *depth* -- symbols without parents in the symbol group have a depth of zero, and the depth of each child symbol is one greater than the depth of its parent. The children of a parent symbol may or may not be present in the symbol group. When the children are present in the symbol group, the parent symbol is referred to as *expanded*. To add or remove the children of a symbol in a symbol group, use [ExpandSymbol](#).

The number of symbols in a symbol group is returned by [GetNumberSymbols](#). The *index* of a symbol in a symbol group is an identification number; the index ranges from zero to the number of symbols minus one. Each time a symbol is added to or removed from a symbol group -- for example, by expanding a symbol -- the index of all the

symbols in the symbol group may change.

The symbol parameters, including information about parent-child relationships, can be found by using [GetSymbolParameters](#). This method returns a [DEBUG_SYMBOL_PARAMETERS](#) structure.

The symbols in a symbol group can be printed to the debugger's output stream using the method [OutputSymbols](#).

Scopes

The *current scope*, or *current local context*, determines the local variables exposed by the debugger engine. The scope has three components:

1. A stack frame.
2. A current instruction.
3. A register context.

If the stack frame is at the top of the call stack, the current instruction is the instruction that resulted in the last event. Otherwise the current instruction is the function call which resulted in the next higher stack frame.

The methods [GetScope](#) and [SetScope](#) can be used to get and set the current scope. When an event occurs, the current scope is set to the scope of the event. The current scope can be reset to the scope of the last event using [ResetScope](#).

Thread Context

The *thread context* is the state preserved by Windows when switching threads. This is similar to the register context, except that there is some kernel-only processor state that is part of the register context but not the thread context. This extra state is available as registers during kernel-mode debugging.

The thread context is represented by the CONTEXT structure defined in ntddk.h. This structure is platform-dependent and its interpretation depends on the effective processor type. The methods [GetThreadContext](#) and [SetThreadContext](#) can be used to get and set the thread context.

[Send comments about this topic to Microsoft](#)

Using Source Files

5/26/2017 • 1 min to read • [Edit Online](#)

The [debugger engine](#) maintains a *source path*, which is a list of directories and source servers that contain source code files associated with the current targets. The debugger engine can search these directories and source servers for the source files. With the help of symbol files, the debugger engine can match lines in the source files with locations in the target's memory.

For an overview of using source files with debuggers, see [Debugging in Source Mode](#). For an overview of source paths, see [Source Path](#). For an overview of using source servers from the debugger engine, see [Using a Source Server](#).

Source Path

To add a directory or source server to the source path, use the method [AppendSourcePath](#). The whole source path is returned by [GetSourcePath](#) and can be changed using [SetSourcePath](#). A single directory or source server can be retrieved from the source path using [GetSourcePathElement](#).

To find a source file relative to the source path, use [FindSourceFile](#) or, for more advanced options when using source servers, use [FindSourceFileAndToken](#). [FindSourceFileAndToken](#) can also be used along with [GetSourceFileInformation](#) to retrieve variables related to a file on a source server.

Matching Source Files to Code in Memory

The debugger engine provides three methods for locating the memory locations that correspond to lines in a source file. To map a single line of source code to a memory location, use [GetOffsetByLine](#). To search for memory locations for more than one source line or for nearby source lines, use [GetSourceEntriesByLine](#). The [GetSourceFileLineOffsets](#) method will return the memory location of every line in a source file.

To perform the opposite operation and find the line of a source file that matches a location in the target's memory, use [GetLineByOffset](#).

Note The relationship between memory locations and lines in a source file is not necessarily one-to-one. It is possible for a single line of source code to correspond to multiple memory locations and for a single memory location to correspond to multiple lines of source code.

[Live Kernel-Mode Targets](#)

[Dump-File Targets](#)

[Remote Targets](#)

[Send comments about this topic to Microsoft](#)

Live User-Mode Targets

5/26/2017 • 2 min to read • [Edit Online](#)

The methods for creating and attaching to processes that are listed in this topic can be used for the local computer and for a remote computer running a process server.

A user-mode process can be created using [Create Process](#) or [CreateProcess2](#), which execute a given command to create a process. The method [AttachProcess](#) can be used to attach the [debugger engine](#) to an existing user-mode process. [CreateProcessAndAttach](#) and [CreateProcessAndAttach2](#) create a new user-mode process and attach to it or another user-mode process on the same computer. The [Request](#) operations

[DEBUG_REQUEST_GET_ADDITIONAL_CREATE_OPTIONS](#),

[DEBUG_REQUEST_SET_ADDITIONAL_CREATE_OPTIONS](#), and

[DEBUG_REQUEST_SET_LOCAL_IMPLICIT_COMMAND_LINE](#) can be used to set some of the default options for creating processes.

Note The engine doesn't completely attach to the process until the [WaitForEvent](#) method has been called. Only after the process has generated an event -- for example, the process creation event -- does it become available in the debugger session. See [Debugging Session and Execution Model](#) for more details.

The method [GetRunningProcessSystemIds](#) will return the process IDs of all the running processes on the computer. The process ID of a particular program can be found using

[GetRunningProcessSystemIdByExecutableName](#). Given a process ID, a description of the process is returned by [GetRunningProcessDescription](#).

Process Options

The process options determine part of the engine's behavior when attached to a user-mode process, including whether or not the debugger engine will automatically attach to child processes created by the target process and what the engine does with the target processes when it exits. See [DEBUG_PROCESS_XXX](#) for a description of the process options.

The process options can be queried using [GetProcessOptions](#). They can be changed using [AddProcessOptions](#), [RemoveProcessOptions](#), and [SetProcessOptions](#).

Disconnecting from Processes

There are three different ways for the engine to disconnect from a process.

1. *Detach*. Resume all the threads in the process so that it will continue running, no longer being debugged. [DetachCurrentProcess](#) will detach the engine from the current process and [DetachProcesses](#) will detach the engine from all processes. Not all targets support detaching. The [Request](#) operation [DEBUG_REQUEST_TARGET_CAN_DETACH](#) can be used to check if the target supports detaching.
2. *Terminate*. Attempt to kill the process. [TerminateCurrentProcess](#) will terminate the current process and [TerminateProcesses](#) will terminate all processes in the debugger session.
3. *Abandon*. Remove the process from the list of processes being debugged. The operating system will still consider the process as being debugged and it will remain suspended until another debugger attaches to it or it is killed. [AbandonCurrentProcess](#) will abandon the current process.

[Send comments about this topic to Microsoft](#)

Live Kernel-Mode Targets

5/26/2017 • 1 min to read • [Edit Online](#)

To attach the [debugger engine](#) to a target computer for kernel-mode debugging, use the method [AttachKernel](#).

Note The engine doesn't completely attach to the kernel until the [WaitForEvent](#) method has been called. Only after the kernel has generated an event -- for example, the [initial breakpoint](#) -- does it become available in the debugger session. See [Debugging Session and Execution Model](#) for more details.

If the debugger engine is attached to a kernel which is not the local kernel and the connection is not an eXDI connection, the connection options used to find the target computer can be queried using

[GetKernelConnectionOptions](#). The connection can also be re-synchronized or the connection speed changed using [SetKernelConnectionOptions](#).

The debugger can attach to the local kernel, but only in a limited way and only if the computer was booted with the [/debug](#) boot switch. (In some Windows installations, local kernel debugging is supported when other switches are used, such as [/debugport](#), but this is not a guaranteed feature of Windows and should not be relied on.)

[IsKernelDebuggerEnabled](#) is used to determine if the local computer is available for debugging. For more information about kernel debugging on a single machine, see [Performing Local Kernel Debugging](#).

[Send comments about this topic to Microsoft](#)

Dump-File Targets

5/26/2017 • 1 min to read • [Edit Online](#)

For an introduction and overview of crash dump files, see [Crash Dump Files](#).

Opening Dump Files

To open a crash dump file for use as a debugger target, use [OpenDumpFile](#) or [OpenDumpfileWide](#). These methods are similar to the [.opendump](#) debugger command.

Note The engine doesn't completely attach to the dump file until the [WaitForEvent](#) method has been called. When a dump file is created from a process or kernel, information about the last event is stored in the dump file. After the dump file is opened, the next time execution is attempted, the engine will generate this event for the event callbacks. Only then does the dump file become available in the debugging session. See [Debugging Session and Execution Model](#) for more details.

Additional files can be used to assist in debugging a crash dump file. The methods [AddDumpInformationFile](#) and [AddDumpInformationFileWide](#) register files containing page-file information to be used when the next dump file is opened. These methods must be called before the dump file is opened. [GetNumberDumpFiles](#) will return the number of such files that were used when the current dump file was opened and [GetDumpFile](#) will return a description of these files.

User-mode minidump files contain several streams of information. These streams can be read using the [Request](#) operation [DEBUG_REQUEST_READ_USER_MINIDUMP_STREAM](#).

Creating Dump Files

To create a crash dump file of the current target -- user-mode or kernel-mode -- use [WriteDumpFile2](#). This method is similar to the [.dump](#) debugger command.

[Send comments about this topic to Microsoft](#)

Remote Targets

5/26/2017 • 2 min to read • [Edit Online](#)

There are two different forms of remote debugging, depending on which computer (remote client or server) is the host computer. The *host computer* is the computer on which the **debugger engine** is active. On the other computer, the debugger engine is merely acting as a proxy relaying commands and data to the host engine.

All debugger operations -- such as executing commands and [extensions](#), and symbol loading -- are performed by the host engine. A debugger session is also relative to the host engine.

To list the debugging servers and process servers currently running on a computer, use [OutputServers](#).

Debugging Servers and Debugging Clients

A *debugging server* is an instance of the debugger engine acting as a host and listening for connections from debugging clients. The method [StartServer](#) will tell the debugger engine to start listening for connections from debugging clients.

A *debugging client* is an instance of the debugger engine acting as a proxy, sending debugger commands and I/O to the debugging server. The function [DebugConnect](#) can be used to connect to the debugging server.

The client object returned by [DebugConnect](#) is not automatically joined to the debugger session on the debugging server. The method [ConnectSession](#) can be used to join the session, synchronizing input and output.

The communication between a debugging server and a debugging client mostly consists of debugger commands and RPC calls sent to the server, and command output sent back to the client.

Process Servers, Kernel Connection Servers, and Smart Clients

Process servers and *kernel connection servers* are both instances of the debugger engine acting as proxies, listening for connections from smart clients, and performing memory, processor, or operating system operations as requested by these remote clients. A *process server* facilitates the debugging of processes that are running on the same computer. A *kernel connection server* facilitates the debugging of a Windows kernel debugging target that is connected to the computer that is running the connection server. A process server can be started using the method [StartProcessServer](#) or the program [DbgSrv](#). The method [WaitForProcessServerEnd](#) will wait for a process server started with [StartProcessServer](#) to end. A kernel connection server can be activated using the program [KdSrv](#).

A *smart client* is an instance of the debugger engine acting as a host engine and connected to a process server. The method [ConnectProcessServer](#) will connect to a process server. Once connected, the methods described in [Live User-Mode Targets](#) can be used.

When the remote client is finished with the process server, it can disconnect using [DisconnectProcessServer](#), or it can use [EndProcessServer](#) to request that the process server shut down. To shut down the process server from the computer that it is running on, use Task Manager to end the process. If the instance of the debugger engine that used [StartProcessServer](#) is still running, it can use [Execute](#) to issue the debugger command `.endsrv 0`, which will end the process server (this is an exception to the usual behavior of `.endsrv`, which generally does not affect process servers).

The communication between a process server and a smart client typically consists of low-level memory, processor, and operating system operations and requests that are sent from the remote client to the server. Their results are then sent back to the client.

[Send comments about this topic to Microsoft](#)

Target Information

5/26/2017 • 1 min to read • [Edit Online](#)

The method [GetDebuggeeType](#) returns the nature of the current target (for example, whether it is a kernel-mode or user-mode target), and how the [debugger engine](#) is connected to it.

If the target is a crash dump file file, the method [GetDumpFormatFlags](#) will indicate what information is contained in the dump.

Target's Computer

The page size of the target's computer is returned by [GetPageSize](#). [IsPointer64Bit](#) will indicate if the computer uses 32-bit or 64-bit addresses.

Note Internally, the debugger engine always uses 64-bit addresses for the target. If the target only uses 32-bit addresses, the engine automatically converts them when communicating with the target.

The number of processors in the target's computer is returned by [GetNumberProcessors](#).

There are three different processor types associated with the target's computer:

- The *actual processor type* is the type of the physical processor in the target's computer. This is returned by [GetActualProcessorType](#).
- The *executing processor type* is the type of the processor used in the currently executing processor context. This is returned by [GetExecutingProcessorType](#).
- The *effective processor type* is the processor type the debugger uses when interpreting information from the target -- for example, setting breakpoints, accessing registers, and getting stack traces. The effective processor type is returned by [GetEffectiveProcessorType](#) and can be changed using [SetEffectiveProcessorType](#).

The effective processor type and executing processor type may differ from the actual processor type -- for example, when the physical processor is an x64 processor and it is running in x86 mode.

The different executing processor types that are supported by the physical processor on the target's computer are returned by [GetPossibleExecutingProcessorTypes](#). The number of these is returned by [GetNumberPossibleExecutingProcessorTypes](#).

The list of processor types that is supported by the debugger engine is returned by [GetSupportedProcessorTypes](#). The number of supported processor types is returned by [GetNumberSupportedProcessorTypes](#).

The names (full and abbreviated) of a processor type are returned by [GetProcessorTypeNames](#).

The current time on the target's computer is returned by [GetCurrentTimeDate](#). The length of time the target's computer has been running since the last boot is returned by [GetCurrentSystemUpTime](#). Time information may not be available for all targets.

Target Versions

The Windows version running on the target's computer is returned by [GetSystemVersionValues](#) and the [Request](#) operation [DEBUG_REQUEST_GET_WIN32_MAJOR_MINOR_VERSIONS](#), and a description of the Windows version is returned by [GetSystemVersionString](#). Some of this information is also returned by [GetSystemVersion](#).

[Send comments about this topic to Microsoft](#)

Target State

5/26/2017 • 1 min to read • [Edit Online](#)

The method **OutputCurrentState** will print the current state of the target to the debugger's output stream.

The current execution status of the target is returned by **GetExecutionStatus**. If the target is suspended, the method **SetExecutionStatus** can be used to resume execution in one of the execution modes.

The method **GetReturnOffset** returns the address of the instruction that will execute when the current function returns.

GetNearInstruction returns the location of an instruction relative to a given address.

Examining the Stack Trace

A *call stack* contains the data for the function calls that are made by a thread. The data for each function call is called a *stack frame* and includes the return address, parameters passed to the function, and the function's local variables. Each time a function call is made, a new stack frame is pushed onto the top of the stack. When that function returns, the stack frame is popped off the stack. Each thread has its own call stack, which represents the calls that are made in that thread.

Note Not all of the data for a function call can be stored in the stack frame. Parameters and local variables, at times, can be stored in registers.

To retrieve the call stack or *stack trace*, use the methods **GetStackTrace** and **GetContextStackTrace**. The stack trace can be printed using **OutputStackTrace** and **OutputContextStackTrace**.

[Send comments about this topic to Microsoft](#)

Calling Extensions and Extension Functions

5/26/2017 • 1 min to read • [Edit Online](#)

To load an extension library (or to obtain a handle for an already loaded extension library), use [AddExtension](#). An extension library can be unloaded with [RemoveExtension](#).

Extension commands can be called using [CallExtension](#).

Extension Functions

Extension functions are functions that are exported by extension libraries. They can use any function prototype and are called directly using C function pointers.

They are not extension commands and are not available via debugger commands. Extension functions cannot be called remotely; they must be called directly. Hence they cannot be used from debugging clients. They can only be called when the client object is inside the host engine - when not remotely debugging or when using a smart client.

Extension functions are identified within extension libraries by the "_EFN_" prepended to their names.

To obtain a pointer to an extension function, use [GetExtensionFunction](#). The type of this function pointer should match the prototype of the extension function. The extension function can now be called just like any other function pointer in C.

Example

If the following extension function was included in an extension library and loaded into the debugger engine:

```
HRESULT CALLBACK
_EFN_GetObject(IDebugClient * client, SomeObject * obj);
```

It could be called using:

```
typedef ULONG (CALLBACK * GET_OBJECT)(IDebugClient * client, SomeObject * obj);

HRESULT status = S_OK;
GET_OBJECT extFn = NULL;
SomeObject myObj;

if (g_DebugControl->
    GetExtensionFunction(0,
                        "GetObject",
                        (FARPROC *) &extFn ) == S_OK &&
    extFn)
{
    status = (*extFn)(client, &myObj);
}
```

[Send comments about this topic to Microsoft](#)

Assembling and Disassembling Instructions

5/26/2017 • 1 min to read • [Edit Online](#)

The debugger engine supports the use of assembly language for displaying and changing code in the target. For an overview of the use of assembly language in the debugger, see [Debugging in Assembly Mode](#).

Note Assembly language is not supported for all architectures. And on some architectures not all instructions are supported.

To assemble a single assembly-language instruction and place the resulting processor instruction in the target's memory, use [Assemble](#).

To disassemble a single instruction by taking a processor instruction from the target and producing a string that represents the assembly instruction, use [Disassemble](#).

The method [GetDisassembleEffectiveOffset](#) returns the first effective address of the last instruction to be disassembled. For example, if the last instruction to be disassembled is `move ax, [ebp+4]`, the effective address is the value of `ebp+4`. This corresponds to the `$ea` pseudo-register.

To send disassembled instructions to the output callbacks, use the methods [OutputDisassembly](#) and [OutputDisassemblyLines](#).

The debugger engine has some options that control the assembly and disassembly. These options are returned by [GetAssemblyOptions](#). They can be set using [SetAssemblyOptions](#) and some options can be turned on with [AddAssemblyOptions](#) or turned off with [RemoveAssemblyOptions](#).

Anatomy of a DbgEng Extension DLL

5/26/2017 • 2 min to read • [Edit Online](#)

A DbgEng extension DLL exports a number of callback functions, some of which may be implementations of extension commands.

These extension DLLs are loaded by the [debugger engine](#) and can provide extra functionality or automation of tasks while performing user-mode or kernel-mode debugging on Microsoft Windows.

If you performed a full install of Debugging Tools for Windows, a sample DbgEng extension called "exts" can be found in the `sdk\samples\exts` subdirectory of the installation directory.

Extension Commands

An extension DLL may export any number of functions that are used to execute extension commands. Each function is explicitly declared as an export in the `.def` file, and its name must consist entirely of lowercase letters.

Functions used to implement extension commands must match the prototype [`PDEBUG_EXTENSION_CALL`](#).

These functions are named according to the standard C++ convention, except that uppercase letters are not permitted. The exported function name and the extension command name are identical, except that the extension command begins with an exclamation point (!). For example, when you load `myextension.dll` into the debugger and then type `!stack` into the Debugger Command window, the debugger looks for an exported function named `stack` in `myextension.dll`.

If `myextension.dll` is not already loaded, or if there may be other extension commands with the same name in other extension DLLs, you can type `!myextension.stack` into the Debugger Command window to indicate the extension DLL and the extension command in that DLL.

Other Exported Functions

A DbgEng extension DLL must export [`DebugExtensionInitialize`](#). This will be called when the DLL is loaded, to initialize the DLL. It may be used by the DLL to initialize global variables.

An extension DLL may export [`DebugExtensionUninitialize`](#). If this is exported, it will be called before the extension DLL is unloaded. It may be used by the DLL to clean up before it is unloaded.

An extension DLL may export [`DebugExtensionNotify`](#). If this is exported, it will be called when a session begins or ends, and when a target starts or stops executing. These notifications are also provided to [`IDebugEventCallbacks`](#) objects registered with a client.

An extension DLL may export [`KnownStructOutput`](#). If this is exported, it will be called when the DLL is loaded. This function returns a list of structures that the DLL knows how to print on a single line. It may be called later to format instances of these structures for printing.

Engine Procedure for Loading a DbgEng Extension DLL

When an extension DLL is loaded, the callback functions are called by the engine in the following order:

1. **DebugExtensionInitialize** is called so the extension DLL can initialize.
2. If exported, **DebugExtensionNotify** is called if the engine has an active session, and called again if the session is suspended and accessible.
3. If exported, **KnownStructOutput** is called to request a list of structures the DLL knows how to print on a single line.

See [Loading Debugger Extension DLLs](#) for information about how to use the debugger to load and unload an extension DLL, and see [Using Debugger Extension Commands](#) for information about executing an extension command.

The debugger engine will place a **try / except** block around a call to an extension DLL. This protects the engine from some types of bugs in the extension code; but, since the extension calls are executed in the same thread as the engine, they can still cause it to crash.

[Send comments about this topic to Microsoft](#)

Using Clients and the Engine

5/26/2017 • 1 min to read • [Edit Online](#)

A DbgEng extension interacts with the [debugger engine](#) through a client object.

When an extension function is called, it is passed a client. The extension function should use this client for all its interaction with the debugger engine, unless it has a specific reason to use another client.

An extension library may create its own client object upon initialization by using [DebugCreate](#). This client can be used to register callback objects from the DLL.

Note Care should be taken when modifying the client passed to an extension function. In particular, registering callbacks with this client could disrupt the input, output, or event handling of the debugger. It is recommended that a new client be created to register callbacks.

[Send comments about this topic to Microsoft](#)

Writing DbgEng Extension Code

5/26/2017 • 1 min to read • [Edit Online](#)

DbgEng extension commands can include any standard C++ code. They can also include the C++ interfaces that appear in the dbgeng.h header file, in addition to the C functions that appear in the wdbgexts.h header file.

If you intend to use functions from wdbgexts.h, you need to define KDEXT_64BIT before wdbgexts.h is included. For example:

```
#define KDEXT_64BIT
#include wdbgexts.h
#include dbgeng.h
```

For a full list of interfaces in dbgeng.h that can be used in an extension command, see [Debugger Engine Reference](#).

For a full list of functions in wdbgexts.h that can be used in an extension command, see [WdbgExts Functions](#). A number of these functions appear in 32-bit versions and 64-bit versions. Typically, the 64-bit versions end in "64" and the 32-bit versions have no numerical ending -- for example, **ReadIoSpace64** and **ReadIoSpace**. When calling a wdbgexts.h function from a DbgEng extension, you should always use the function name ending in "64". This is because the [debugger engine](#) always uses 64-bit pointers internally, regardless of the target platform.

If you include wdbgexts.h in your DbgEng extension, you should call **GetWindbgExtensionApis64** during the initialization of your extension DLL (see [DebugExtensionInitialize](#)).

Note You must not attempt to call any DbgHelp or ImageHlp routines from any debugger extension. Calling these routines is not supported and may cause a variety of problems.

Building DbgEng Extensions

5/26/2017 • 1 min to read • [Edit Online](#)

All debugger extensions should be compiled and built by using Visual Studio. The Build utility is no longer used with debugger extensions.

For documentation on the Building projects in Visual Studio refer to [Building C++ Projects in Visual Studio](#).

To build an extension, use the following procedure:

To build a debugger extension

1. Open the **dbgsdk.sln** sample project in Visual Studio.
2. Check the include and lib file project settings. If `%debuggers%` represents the root of your Debugging Tools for Windows installation, they should be set as follows:

```
Include Path  
%debuggers%\sdk\inc  
Library Path  
%debuggers%\sdk\lib
```

If you have moved these headers and libraries to a different location, specify that location instead.

3. Select **Build** and then **Build Solution** from the menu in Visual Studio.

EngExtCpp Extension Libraries

5/26/2017 • 1 min to read • [Edit Online](#)

An EngExtCpp extension library is a DLL that uses the EngExtCpp extension framework found in EngExtCpp.h. When this library is loaded by the debugger engine, its methods and functions can provide extra functionality or automation of tasks while performing user-mode or kernel-mode debugging on Microsoft Windows.

The EngExtCpp extension framework is built on top of the [DbgEng extension framework](#). It offers the same debugger engine API for interaction with the debugger engine, but it also provides additional features to make common tasks simpler.

If you performed a full install of Debugging Tools for Windows, a sample EngExtCpp extension called "extcpp" can be found in the sdk\samples\extcpp subdirectory of the installation directory.

EXT_CLASS and **ExtExtension**

At the core of an EngExtCpp extension library is a single instance of the **EXT_CLASS** class. An EngExtCpp extension library will provide the implementation of this class, which contains all the extension commands and methods for formatting structures that are exported by the library.

EXT_CLASS is a subclass of **ExtExtension**. The single instance of this class is created using the **EXT_DECLARE_GLOBALS** macro which must appear exactly once in the source files for the extension library.

When the extension library is loaded, the **Initialize** method of the class is called by the engine, and the **Uninitialize** method is called before unloading the class. Additionally, the methods **OnSessionActive**, **OnSessionInactive**, **OnSessionAccessible**, and **OnSessionInaccessible** are called by the engine to notify the extension library of the state of the debugging session.

Extension Commands

The **EXT_CLASS** class can contain a number of methods that are used to execute extension commands. Each extension command is declared in the **EXT_CLASS** class by using the **EXT_COMMAND_METHOD** macro. The implementation of a command is defined by using the **EXT_COMMAND** macro.

Known Structures

The **EXT_CLASS** class can contain a number of methods that use the **ExtKnownStructMethod** prototype. The methods can be used by the engine to format instances of certain structure types for output.

Provided Values

The **EXT_CLASS** class can contain a number of methods that use the **ExtProvideValueMethod** prototype. The methods can be used by the engine to evaluate some pseudo-registers provided by the extension.

[Send comments about this topic to Microsoft](#)

Client Objects and the Engine

5/26/2017 • 1 min to read • [Edit Online](#)

An EngExtCpp extension interacts with the [debugger engine](#) through a client object. Interface pointers to the client object are available to the extension through members of the [ExtExtension](#) base class. The following members provide access to the first version of the engine API interfaces.

ENGINE API INTERFACE	EXTENSION MEMBER
IDebugAdvanced	m_Advanced
IDebugClient	m_Client
IDebugControl	m_Control
IDebugDataSpaces	m_Data
IDebugRegisters	m_Registers
IDebugSymbols	m_Symbols
IDebugSystemObjects	m_System

The following members provide access to later versions of the engine API interfaces. These interfaces may not be available in all versions of the debugger engine. If they are not available, any attempt to use them will result in an exception being thrown.

ENGINE API INTERFACE	EXTENSION MEMBER
IDebugAdvanced2	m_Advanced2
IDebugAdvanced3	m_Advanced3
IDebugClient2	m_Client2
IDebugClient3	m_Client3
IDebugClient4	m_Client4
IDebugClient5	m_Client5

ENGINE API INTERFACE	EXTENSION MEMBER
IDebugControl2	m_Control2
IDebugControl3	m_Control3
IDebugControl4	m_Control4
IDebugData2	m_Data2
IDebugData3	m_Data3
IDebugData4	m_Data4
IDebugRegisters2	m_Registers2
IDebugSymbols2	m_Symbols2
IDebugSymbols3	m_Symbols3
IDebugSystemObjects2	m_System2
IDebugSystemObjects3	m_System3
IDebugSystemObjects4	m_System4

The members in these tables are initialized each time the extension library is used to execute an extension command or format a structure for output. Once a task is completed, these members are uninitialized. Consequently, extensions should not cache the values of these members and should use the **ExtExtension** members directly.

An extension library can also create its own client objects using the method **IDebugClient::CreateClient** or the functions **DebugCreate** or **DebugConnect**.

For an overview of client objects, see [Client Objects](#).

[Send comments about this topic to Microsoft](#)

Writing EngExtCpp Extensions

5/26/2017 • 1 min to read • [Edit Online](#)

The EngExtCpp extension library can include any standard C++ code. It can also include the C++ interfaces that appear in the engextcpp.h and dbgeng.h header files, in addition to the C functions that appear in the wdbgexts.h header file. Both dbgeng.h and wdbgexts.h are included from engextcpp.h.

For a full list of interfaces in dbgeng.h that can be used in an extension command, see [Debugger Engine Reference](#).

For a full list of functions in wdbgexts.h that can be used in an extension command, see [WDbgExts Functions](#). A number of these functions appear in 32-bit versions and 64-bit versions. Typically, the 64-bit versions end in "64" and the 32-bit versions have no numerical ending -- for example, **ReadIoSpace64** and **ReadIoSpace**. When calling a wdbgexts.h function from a DbgEng extension, you should always use the function name ending in "64". This is because the [debugger engine](#) always uses 64-bit pointers internally, regardless of the target platform. When including wdbgexts.h, engextcpp.h selects the 64-bit version of the API. The **ExtensionApis** global variable used by the WDbgExts API is automatically initialized on entry to a EngExtCpp method and cleared on exit.

When an EngExtCpp extension is used with remote DbgEng interfaces, the WDbgExts interfaces will not be available and the **ExtensionApis** structure can be zeroed. If an EngExtCpp extension is expected to function in such an environment, it should avoid using the WDbgExts API.

Note You must not attempt to call any DbgHelp or ImageHlp routines from any debugger extension. Calling these routines is not supported and may cause a variety of problems.

[Send comments about this topic to Microsoft](#)

Building EngExtCpp Extensions

5/26/2017 • 1 min to read • [Edit Online](#)

The EngExtCpp extension libraries are built almost the same way as the DbgEng extension libraries. For more information, see [Building DbgEng Extensions](#).

The EngExtCpp implementation code (engextcpp.cpp) is used instead of linking with a static library.

Because the EngExtCpp extension framework is built on top of the DbgEng extension framework, an EngExtCpp extension DLL should export the same functions as a DbgEng extension DLL.

Each extension should be exported. When you use the **EXT_COMMAND** macro to define an extension function, this macro also creates a C function with the same name as the extension. This function should be exported from the DLL.

The following functions are provided by engextcpp should be exported from the EngExtCpp DLL.

- **DebugExtensionInitialize** -- so that the **Initialize** method can be called to initialize the library.
- **DebugExtensionUninitialize** -- so that the **Uninitialize** method can be called to uninitialize the library.
- **KnownStructOutputEx** -- so that the engine can call the *ExtKnownStructMethod* methods to format known structures for output.
- **DebugExtensionNotify** -- so that the engine can call the **OnSessionActive**, **OnSessionInactive**, **OnSessionAccessible**, and **OnSessionInaccessible** methods to notify the extension library of changes to the debugging session's state.
- **help** -- so that the EngExtCpp extension framework can automatically provide a **!help** extension.

These functions can be exported even if the functionality they provide is not needed. Moreover, if they are not exported, the functionality they provide will be lost.

DebugExtensionInitialize must be exported in order for the debugger engine to recognize the DLL as a valid DbgEng extension DLL.

[Send comments about this topic to Microsoft](#)

Parsing Extension Arguments

5/31/2017 • 5 min to read • [Edit Online](#)

The EngExtCpp extension framework provides methods to aid in parsing the command-line arguments passed to an extension. To take advantage of these methods, the extension must first declare the format of the command-line arguments in the **EXT_COMMAND** macro.

To bypass the command-line argument parsing done by the framework and let the extension itself parse the arguments, set the command-line description to `"{{custom}}"` and use the method **GetRawArgStr** to get the command-line arguments for parsing.

Command-line description strings will automatically be wrapped when printed, to fit the column width of the display. However, newline characters can be embedded in the description strings - using '`\n`' - to start new lines.

The command-line description can be **NULL** or the empty string. If either occurs, it indicates that the extension command does not take any arguments.

Command-Line Description

The description of the command-line arguments is a sequence that contains two types of components: directives and arguments. The description can optionally contain one of each directive and can contain up to 64 arguments.

Directives

Directives specify how the arguments are parsed. They are enclosed by double braces (`'{{'` and `'}}'`). Each directive can optionally appear zero or one times in the string that describes the arguments.

The following directives are available:

`custom`

Turns off the parsing done by the extension framework and lets the extension perform its own parsing.

`1:str`

Overrides the default long description of the command-line arguments. The extension framework will use `str` for the full description of all the arguments.

`opt:str`

Overrides the default prefix characters for named commands. The default value is `"/-"`, allowing '`/`' or '`-`' to be used as the prefix that identifies named arguments.

`s:str`

Overrides the default short description of the command-line arguments. The extension framework will use `str` for the short description of all the arguments.

Here are some examples of directives. The following string is used by an extension command that parses its own arguments. It also provides short and long descriptions for use with the automatic **!help** extension command:

```
 {{custom}}{{s:<arg1> <arg2>}}{{1:arg1 - Argument 1\narg2 - Argument 2}}
```

The following string changes the argument option prefix characters to '`/`' or '`-`'. With this directive, the arguments will be specified using '`+arg`' and '`:arg`' instead of '`/arg`' and '`-arg`':

```
 {{opt:+:}}
```

Arguments

Arguments can be of two types: named and unnamed. Unnamed arguments are read positionally. Both types of argument also have a display name, used by the help command.

Argument descriptions are enclosed by single braces ('{' and ' }').

Each argument description has the following syntax:

```
{[optname];[type[,flags]];[argname];[argdesc]}
```

where:

optname

The name of the argument. This is the name used in commands and in methods that fetch arguments by name. This name is optional. If it is present, the argument becomes a "named argument"; it can appear anywhere on the command-line and is referenced by name. If it is not present, the argument becomes an "unnamed argument"; its position on the command-line is important and it is referenced by its position relative to the other unnamed arguments.

type

The type of the argument. This affects how the argument is parsed and how it is retrieved. The *type* parameter can have one of the following values:

b

Boolean type. The argument is either present or not present. Named Boolean arguments can be retrieved using [HasArg](#).

e[d][s][bits]

Expression type. The argument has a numeric value. Named expression arguments can be retrieved using [GetArgU64](#) and unnamed expression arguments can be retrieved using [GetUnnamedArgU64](#).

d

The expression is limited to the next space character in the argument string. If this is not present, the expression evaluator will consume characters from the command line until it determines that it reached the end of the expression.

s

The value of the expression is signed. Otherwise, the value of the expression is unsigned.

bits

The number of bits in the value of the argument. The maximum value for *bits* is 64.

s

String type. The string is limited to the next space character. Named string arguments can be retrieved using [GetArgStr](#) and unnamed string arguments can be retrieved using [GetUnnamedArgStr](#).

x

String type. The argument is the rest of the command line. The argument is retrieved using [GetArgStr](#) or [GetUnnamedArgStr](#), as with the s string type.

flags

The argument flags. These determine how the argument will be treated by the parser. The *flags* parameter can have one of the following values:

d=expr

The default value of the argument. If the argument is not present on the command line, then the argument is set to *expr*. The default value is a string that is parsed according to the type of the argument.

ds

The default value will not be displayed in the argument description provided by the help.

o

The argument is optional. This is the default for named arguments.

r

The argument is required. This is the default for unnamed arguments.

argname

The display name of the argument. This is the name used by the automatic **!help** extension command and by the automatic **/?** or **-?** command-line arguments. Used when printing a summary of the command-line options.

argdesc

A description of the argument. This is the description printed by the automatic **!help** extension and by the automatic **/?** or **-?** command-line arguments.

Here are some examples of argument descriptions. The following expression defines a command which takes a single optional expression argument. The argument must fit in 32 bits. If the argument isn't present on the command line, the default value of 0x100 will be used.

```
{;e32,o,d=0x100;flags;Flags to control command}
```

The following expression defines a command with an optional Boolean **/v** argument and a required unnamed string argument.

```
{v;b;;Verbose mode}{;s;name;Name of object}
```

The following expression defines a command that has an optional named expression argument **/oname expr** and an optional named string argument **/eol str**. If **/eol** is present, its value will be set to the remainder of the command line and no further arguments will be parsed.

```
{oname;e;expr;Address of object}{eol;x;str;Commands to use}
```

Command Line

The following is a list of some ways that arguments are parsed on the command line:

- The values of named expression and string arguments follow the name on the command line. For example, **/name expr** or **/name str**.
- For named Boolean arguments, the value is true if the name appears on the command line; false otherwise.
- Multiple single-character-named Boolean options can be grouped together on the command line. For example, **/a /b /c** can be written using the shorthand notation **/abc** (unless there is already an argument named **abc**).
- If the command line contains the named argument **"?"** - for example, **"/?"** and **"-?"** - the argument parsing ends, and the help text for the extension is displayed.

Parsing Internals

Several methods are used by the argument parser to set arguments.

The method **SetUnnamedArg** will change the value of an unnamed argument. And, for convenience, the methods **SetUnnamedArgStr** and **SetUnnamedArgU64** will set unnamed string and expression arguments respectively.

Similar methods exist for named arguments. **SetArg** is used to change the value of any named argument and **SetArgStr** and **SetArgU64** are used for named string and expression arguments respectively.

[Send comments about this topic to Microsoft](#)

Typed Data

5/26/2017 • 1 min to read • [Edit Online](#)

The EngExtCpp extension framework provides a few classes to help manipulate the target's memory. The **ExtRemoteData** class describes a small piece of the target's memory. If the type of this memory is known, it is referred to as *typed data* and is described by **ExtRemoteTyped** objects.

Windows lists can be iterated over by using **ExtRemoteList** and, if the type of the objects in the list is known, **ExtRemoteTypedList**.

Note Like the client objects in **ExtExtension**, instances of these classes are only valid while the extension library is used to execute an extension command or format a structure for output. In particular, they should not be cached. For more information about when client objects are valid, see [Client Objects and the Engine](#).

Remote Data

Remote data should be handled using the class **ExtRemoteData**. This class is a wrapper around a small section of a target's memory. **ExtRemoteData** automatically retrieves the memory and wraps other common requests with throwing methods.

Remote Typed Data

If the type of the remote data is known, it should be handled using the **ExtRemoteTyped** class. This class is an enhanced remote data object that understands data typed with type information from symbols. It is initialized to a particular object by symbol or cast, after which it can be used like an object of the given type.

Remote Lists

To handle remote lists, use the **ExtRemoteList** class. This class can be used for either a singly linked or doubly linked list. If the list is doubly linked, it is assumed that the previous pointer immediately follows the next pointer. The class contains methods that can iterate over the list and retrieve nodes both forward and backward.

ExtRemoteList can be used with either null-terminated or circular lists also.

Remote Typed Lists

To handle remote lists when the type of the nodes in the list is known, use the **ExtRemoteTypedList** class. This is an enhanced version of **ExtRemoteList**. In addition to the basic functionality of **ExtRemoteList**, **ExtRemoteTypedList** automatically determines link offsets from type information.

Writing WdbgExts Extensions

5/26/2017 • 1 min to read • [Edit Online](#)

WdbgExts extensions are the original kind of debugger extensions. They are less powerful than DbgEng extensions, but they still offer a wide range of functionality when performing user-mode or kernel-mode debugging on Microsoft Windows.

If you performed a full install of Debugging Tools for Windows, a sample WdbgExts extension called "simplext" can be found in the `sdk\samples\simplext` subdirectory of the installation directory.

This section includes:

[WdbgExts Extension Design Guide](#)

WdbgExts Extension API Overview

5/26/2017 • 1 min to read • [Edit Online](#)

Each WdbgExts extension DLL exports one or more functions that are used to implement *extension commands*.

These functions are named according to the standard C convention, except that upper-case letters are not permitted.

The function name and the extension command name are identical, except that the extension command begins with an exclamation point (!). For example, when you load Myextension.dll into the debugger and then type **!stack** into the Debugger Command window, the debugger looks for an exported function named **stack** in Myextension.dll.

If Myextension.dll is not already loaded, or if there are other extension commands with the same name in other extension DLLs, you can type **!myextension.stack** into the Debugger Command window to indicate the extension DLL and the extension command in that DLL.

Each WdbgExts extension DLL also exports a number of *callback functions*. These functions are called by the debugger when the DLL is loaded and when extension commands are used.

The debugger engine will place a **try / except** block around a call to an extension DLL. This protects the engine from some types of bugs in the extension code. However, since the extension calls are executed in the same thread as the engine, they can still cause the engine to crash.

[Send comments about this topic to Microsoft](#)

32-Bit Pointers and 64-Bit Pointers

5/26/2017 • 1 min to read • [Edit Online](#)

The WdbgExts.h header file supports both 32-bit and 64-bit pointers. To use 64-bit pointers, simply include the following two lines in your code, in the following order:

```
#define KDEXT_64BIT  
#include wdbgexts.h
```

It is recommended that you always use 64-bit pointers in your code. This allows your extension to work on any platform, because the debugger will automatically cast 64-bit pointers to 32 bits when the target is 32-bit.

If you intend to use your extension only on 32-bit platforms, you can write a 32-bit extension instead. In that case, you only need to include the following line in your code:

```
#include wdbgexts.h
```

[Send comments about this topic to Microsoft](#)

Using WdbgExts Extension Callbacks

5/26/2017 • 1 min to read • [Edit Online](#)

When you write a WdbgExts extension DLL, you can export certain functions:

- You must export a function named *WinDbgExtensionDllInit*. When the debugger loads your extension DLL, it first calls *WinDbgExtensionDllInit* and passes it three arguments.
 - A pointer to a **WINDBG_EXTENSION_APIS64** structure, which contains pointers to functions that are implemented by the debugger and declared in Wdbgexts.h. You must copy the entire structure to a global variable that you create in your DLL.
 - A major version number. You must copy the major version number to a global variable that you create in your DLL.
 - A minor version number. You must copy the minor version number to a global variable that you create in your DLL.

For example, you could create global variables named ExtensionApis, SavedMajorVersion, and SavedMinorVersion as shown in the following example.

```
WINDBG_EXTENSION_APIS64 ExtensionApis;
USHORT SavedMajorVersion;
USHORT SavedMinorVersion;

VOID WinDbgExtensionDllInit(PWINDBG_EXTENSION_APIS64 lpExtensionApis,
    USHORT MajorVersion, USHORT MinorVersion)
{
    ExtensionApis = *lpExtensionApis;
    SavedMajorVersion = MajorVersion;
    SavedMinorVersion = MinorVersion;
    ...
}
```

- You must export a function called *ExtensionApiVersion*. The debugger calls this function and expects back a pointer to an **EXT_API_VERSION** structure that contains the version number of the extension DLL. The debugger uses this version number when executing commands like **.chain** and **version** that display the extension version number.
- You can optionally export a function called *CheckVersion*. The debugger calls this routine every time you use an extension command. You can use this to print out version mismatch warnings when your DLL is of a slightly different version than the debugger, but not different enough to prevent it from running.

[Send comments about this topic to Microsoft](#)

Using the DECLARE_API Macro

5/26/2017 • 1 min to read • [Edit Online](#)

Each extension command in a WdbgExts extension DLL is declared using the DECLARE_API macro. This macro is defined in wdbgexts.h.

The basic format of the code for an extension command is:

```
DECLARE_API( myextension )
{
    code for myextension
}
```

The DECLARE_API macro sets up a standard interface for extension commands. For example, if the user passed any arguments to the extension command, the entire argument string will be stored as a string, and a pointer to this string (PCSTR) will be passed to the extension function as **args**.

If you are using 64-bit pointers, the DECLARE_API macro is defined as follows:

```
#define DECLARE_API(s) \
    CPPMOD VOID \
    s( \
        HANDLE hCurrentProcess, \
        HANDLE hCurrentThread, \
        ULONG64 dwCurrentPc, \
        ULONG dwProcessor, \
        PCSTR args \
    )
```

If you are using 32-bit pointers, DECLARE_API remains the same, except that **dwCurrentPc** will be of the type ULONG instead of ULONG64. However, 64-bit pointers are recommended for any extension that you are writing. See [32-Bit Pointers and 64-Bit Pointers](#) for details.

[Send comments about this topic to Microsoft](#)

Writing WdbgExts Extension Code

5/26/2017 • 1 min to read • [Edit Online](#)

WdbgExts extension commands can call any standard C function, as well as the debugger-related functions that appear in the WdbgExts.h header file.

The WdbgExts functions are intended for use in debugger extension commands only. They are useful for controlling and inspecting the computer or application that is being debugged. The WdbgExts.h header file should be included by any code that is calling these WdbgExts functions.

A number of these functions have 32-bit versions as well as 64-bit versions. Typically, the names of the 64-bit WdbgExts functions end in "64," for example **ReadIoSpace64**. The 32-bit versions have no numerical ending, for example, **ReadIoSpace**. If you are using 64-bit pointers, you should use the function name ending in "64"; if you are using 32-bit pointers, you should use the "undecorated" function name. 64-bit pointers are recommended for any extension that you are writing. See [32-Bit Pointers and 64-Bit Pointers](#) for details.

WdbgExts extensions cannot use the C++ interfaces that appear in the DbgEng.h header file. If you wish to use these interfaces, you should write a DbgEng extension or an EngExtCpp extension instead. Both DbgEng extensions and EngExtCpp extensions can use all the interfaces in DbgEng.h as well as those in WdbgExts.h. For details, see [Writing DbgEng Extensions](#) and [Writing EngExtCpp Extensions](#).

Note You must not attempt to call any DbgHelp or ImageHlp routines from a debugger extension. This is not supported and may cause a variety of problems.

The following topics give an overview of various categories of WdbgExts functions:

[WdbgExts Input and Output](#)

[WdbgExts Memory Access](#)

[WdbgExts Threads and Processes](#)

[WdbgExts Symbols](#)

[WdbgExts Target Information](#)

For a full list of these functions, see [WdbgExts Functions](#).

WdbgExts Input and Output

5/26/2017 • 1 min to read • [Edit Online](#)

This topic provides a brief overview of how input and output can be performed using the WdbgExts API. For an overview of the input and output streams in the [debugger engine](#), see [Input and Output](#) in the [Debugger Engine Overview](#) section of this documentation.

The function **dprintf** works in a way similar to the standard C **printf** function and prints a formatted string to the Debugger Command window or, more precisely, the formatted string is sent to the [output callbacks](#). To read a line of input from the debugger engine, use the function [GetInputLine](#).

To check for a user-initiated interrupt, use **CheckControlC**. This function should be used in loops to determine if the user has attempted to cancel execution of an extension.

For a more powerful input and output API, see [Using Input and Output](#) in the [Using the Debugger Engine API](#) section of this documentation.

[Send comments about this topic to Microsoft](#)

WdbgExts Memory Access

5/26/2017 • 1 min to read • [Edit Online](#)

This topic provides a brief overview of how memory access can be performed using the WdbgExts API. For an overview of memory access in the [debugger engine](#), see [Memory](#) in the [Debugger Engine Overview](#) section of this documentation.

Virtual Memory

The virtual memory of the target can be read by using the [ReadMemory](#) function and written using the [WriteMemory](#) function. Pointers in the target's memory can be read and written by using the [ReadPointer](#), [ReadPtr](#), and [WritePointer](#) functions.

To search the virtual memory for a pattern of bytes, use the [SearchMemory](#) function.

The [TranslateVirtualToPhysical](#) function can be used to convert a virtual memory address to a physical memory address.

The [Disasm](#) function can be used to disassemble a single assembly instruction on the target.

To check the low 4 GB of memory for corruption when using physical address extension (PAE), use the [loctl](#) operation [IG_LOWMEM_CHECK](#).

Physical Memory

Physical memory can only be directly accessed in kernel-mode debugging.

The physical memory on the target can be read by using the [ReadPhysical](#) and [ReadPhysicalWithFlags](#) functions, and written by using the [WritePhysical](#) and [WritePhysicalWithFlags](#) functions.

To search the physical memory for pointers to locations within a specified range, use the [loctl](#) operation [IG_POINTER_SEARCH_PHYSICAL](#).

Other Data Spaces

In kernel-mode debugging, it is possible to read and write data to a variety of data spaces in addition to the main memory. The following data spaces can be accessed:

Control-Space Memory

The functions [ReadControlSpace](#), [ReadControlSpace64](#), [ReadTypedControlSpace32](#), and [ReadTypedControlSpace64](#) will read data from a control space. The [WriteControlSpace](#) function will write data to a control space.

I/O Memory

The functions [ReadIoSpace](#), [ReadIoSpace64](#), [ReadIoSpace64](#), [ReadIoSpaceEx64](#) will read data from system I/O memory and bus I/O memory. The functions [WriteIoSpace](#), [WriteIoSpace64](#), [WriteIoSpaceEx](#), and [WriteIoSpaceEx64](#) will write data to system I/O memory and bus I/O memory.

Model Specific Register (MSR)

The functions [ReadMsr](#) and [WriteMsr](#) read and write MSRs.

System Bus

The [loctl](#) operations [IG_GET_BUS_DATA](#) and [IG_SET_BUS_DATA](#) read and write system bus data.

Additional Information

For a more powerful memory access API, see [Memory Access](#) in the [Using the Debugger Engine API](#) section of this documentation.

[Send comments about this topic to Microsoft](#)

WdbgExts Threads and Processes

5/26/2017 • 1 min to read • [Edit Online](#)

This topic provides a brief overview of how threads and processes can be manipulated using the WdbgExts API. For an overview of threads and processes in the [debugger engine](#), see [Threads and Processes in the Debugger Engine Overview](#) section of this documentation.

Threads

To get the address of the thread environment block (TEB) that describes the current thread, use the method **GetTebAddress**. In kernel-mode debugging, the KTHREAD structure is also available to describe a thread. This structure is returned by **GetCurrentThreadAddr** (in user-mode debugging, **GetCurrentThreadAddr** returns the address of the TEB).

The [thread context](#) is the state preserved by Windows when switching threads; it is represented by the CONTEXT structure. This structure varies with the operating system and platform and care should be taken when using the CONTEXT structure. The thread context is returned by the **GetContext** function and can be set using the **SetContext** function.

To examine the stack trace for the current thread, use the **StackTrace** function. To temporarily change the thread used for examining the stack trace, use the **SetThreadForOperation** or **SetThreadForOperation64** functions. See [Examining the Stack Trace](#) in the [Using the Debugger Engine API](#) section of this documentation for additional methods for examining the stack.

To get information about an operating system thread in the target, use the **!octl** operation **IG_GET_THREAD_OS_INFO**.

Processes

To get the address of the process environment block (PEB) that describes the current process use the method **GetPebAddress**. In kernel-mode debugging, the KPROCESS structure is also available to describe a process. This structure is returned by **GetCurrentProcessAddr** (in user-mode debugging, **GetCurrentProcessAddr** returns the address of the PEB).

The method **GetCurrentProcessHandle** returns the system handle for the current process.

Additional Information

For a more powerful thread manipulation and process manipulation API, see [Controlling Threads and Processes](#) in the [Using the Debugger Engine API](#) section of this documentation.

[Send comments about this topic to Microsoft](#)

WdbgExts Symbols

5/26/2017 • 1 min to read • [Edit Online](#)

This topic provides a brief overview of how symbols can be manipulated using the WdbgExts API. For an overview of using symbols in the [debugger engine](#), see [Symbols](#) in the [Debugger Engine Overview](#) section of this documentation.

To evaluate a MASM or C++ expression, use the functions [GetExpression](#) or [GetExpressionEx](#).

To read the value of a member in a structure, use the [GetFieldData](#) function or, if, the member contains a primitive value, [GetFieldValue](#) can be used. To determine the size of an instance of a symbol in the target's memory, use the [GetTypeSize](#) function.

To locate the offset of a member in a structure, use the [GetFieldOffset](#) function.

To read multiple members in a structure, first use the [InitTypeRead](#) function to initialize the structure. Then, you can use the [ReadField](#) function to read the members with size less than or equal to 8 bytes one at a time. For structure addresses in physical memory, use the [InitTypeReadPhysical](#) function instead of [InitTypeRead](#).

There are two functions that you can use for iterating over linked lists. For doubly-linked lists that use the LIST_ENTRY32 or LIST_ENTRY64 structures, the function [ReadListEntry](#) can be used to find the next and previous entries. The function [ListType](#) will iterate over all the entries in a linked list and call a callback function for each entry.

To locate a symbol near a specified address in the target's memory, use the [GetSymbol](#) function.

To delete all the symbol information from the debugger engine's cache, use the [ReloadSymbols](#) function. To read or change the symbol path, which is used to search for symbol files, use the [GetSetSympath](#) function.

Almost all symbol operations provided by the debugger engine can be executed using the [loctl](#) operation [IG_DUMP_SYMBOL_INFO](#). However, while being a very flexible function, it is advanced and we recommend that you use the above simpler functions where applicable.

Additional Information

For a more powerful symbols API, see [Using Symbols](#) in the [Using the Debugger Engine API](#) section of this documentation.

[Send comments about this topic to Microsoft](#)

WdbgExts Target Information

5/26/2017 • 1 min to read • [Edit Online](#)

To determine if the target uses 32-bit or 64-bit pointers for memory addresses, use the function [IsPtr64](#).

For information about the target's operating system, use the [Ioctl](#) operation [IG_GET_KERNEL_VERSION](#). To get the total number of processors on the target and find out which one is the current processor, use the function [GetKdContext](#).

The [GetDebuggerData](#) function returns a KDDEBUGGER_DATA64 or KDDEBUGGER_DATA32 structure that contains information about the target that the [debugger engine](#) has queried or determined during the current session. This information includes certain key target locations and specific status values.

The debugger caches some information obtained from the target. The function [GetDebuggerCacheSize](#) will return the size of this cache.

Additional Information

For a more powerful target API, see [Target Information](#) in the [Using the Debugger Engine API](#) section of this documentation.

[Send comments about this topic to Microsoft](#)

Building WdbgExts Extensions

5/26/2017 • 2 min to read • [Edit Online](#)

All debugger extensions should be compiled and built with the Build utility. The Build utility is included in the Windows Driver Kit (WDK) and in earlier versions of the Windows DDK.

For more information on the Build utility, see the WDK documentation.

Note the following points:

- The WDK has several different build environment windows. Each of these has a corresponding shortcut placed in the **Start** menu when the WDK is installed. To build a debugger extension, you must use the latest Windows build environment, regardless of what platform you will be running the extension on.
- The Build utility is usually not able to compile code that is located in a directory path that contains spaces. Your extension code should be located in a directory whose full path contains no spaces. (In particular, this means that if you install Debugging Tools for Windows to the default location -- Program Files\Debugging Tools for Windows -- you will not be able to build the sample extensions.)

To build a debugger extension

1. Open the window for the latest Windows build environment. (You can choose either the "free" version or the "checked" version -- they will give identical results unless you have put **#ifdef DBG** statements in your code.)
2. Set the variable `_NT_TARGET_VERSION` to indicate the oldest version of Windows on which you want to run the extension. `_NT_TARGET_VERSION` can be set to the following values.

VALUE	VERSIONS OF WINDOWS
<code>_NT_TARGET_VERSION_WIN2K</code>	Windows 2000 and later.
<code>_NT_TARGET_VERSION_WINXP</code>	Windows XP and later.
<code>_NT_TARGET_VERSION_WS03</code>	Windows Server 2003 and later.
<code>_NT_TARGET_VERSION_LONGHORN</code>	Windows Vista and later.

If `_NT\TARGET\VERSION` is not set, the extension will only run on the version of Windows for which the build window was opened (and later versions). For example, putting the following line in your Sources file will build an extension that will run on Windows XP and later versions of Windows:

```
...
_NT_TARGET_VERSION = $(_NT_TARGET_VERSION_WINXP)
...
```

1. 3. Set the `DBGSDK_INC_PATH` and `DBGSDK_LIB_PATH` environment variables to specify the paths to the debugger SDK headers and the debugger SDK libraries, respectively. If `%debuggers%` represents the root of your Debugging Tools for Windows installation, these variables should be set as follows:

```
set DBGSDK_INC_PATH=%debuggers%\sdk\inc
set DBGSDK_LIB_PATH=%debuggers%\sdk\lib
```

If you have moved these headers and libraries to a different location, specify that location instead.

2. 4.Change the current directory to the directory that contains your extension's Dirs file or Sources file.

3. 5.Run the Build utility:

```
build -cZMg
```

For a full explanation of these steps, and for a description of how to create a Dirs file and a Sources file, see the Build utility documentation in the WDK.

Writing Custom Analysis Debugger Extensions

5/26/2017 • 1 min to read • [Edit Online](#)

In this section

- [Writing an Analysis Extension Plug-in to Extend !analyze](#)
- [Metadata Files for Analysis Extension Plug-ins](#)
- [Failure Analysis Entries](#)

[Send comments about this topic to Microsoft](#)

Writing an Analysis Extension Plugin to Extend !analyze

5/31/2017 • 7 min to read • [Edit Online](#)

You can extend the capabilities of the **!analyze** debugger command by writing an analysis extension plugin. By providing an analysis extension plugin, you can participate in the analysis of a bug check or an exception in a way that is specific to your own component or application.

When you write an analysis extension plugin, you also write a metadata file that describes the situations for which you want your plugin to be called. When **!analyze** runs, it locates, loads, and runs the appropriate analysis extension plugins.

To write an analysis extension plugin and make it available to **!analyze**, follow these steps.

- Create a DLL that exports an **_EFN_Analyze** function.
- Create a metadata file that has the same name as your DLL and an extension of .alz. For example, if your DLL is named MyAnalyzer.dll, your metadata file must be named MyAnalyzer.alz. For information about how to create a metadata file, see [Metadata Files for Analysis Extensions](#). Place the metadata file in the same directory as your DLL.
- In the debugger, use the **.extpath** command to add your directory to the extension file path. For example, if your DLL and metadata file are in the folder named c:\MyAnalyzer, enter the command **.extpath+ c:\MyAnalyzer**.

When the **!analyze** command runs in the debugger, the analysis engine looks in the extension file path for metadata files that have the .alz extension. The analysis engine reads the metadata files to determine which analysis extension plugins should be loaded. For example, suppose the analysis engine is running in response to Bug Check 0xA IRQL_NOT_LESS_OR_EQUAL, and it reads a metadata file named MyAnalyzer.alz that contains the following entries.

```
PluginId      MyPlugin
DebuggeeClass  Kernel
BugCheckCode   0xA
BugCheckCode   0xE2
```

The entry **BugCheckCode 0x0A** specifies that this plugin wants to participate in the analysis of Bug Check 0xA, so the analysis engine loads MyAnalyzer.dll (which must be in the same directory as MyAnalyzer.alz) and calls its **_EFN_Analyze** function.

Note The last line of the metadata file must end with a newline character.

Skeleton Example

Here is a skeleton example that you can use as a starting point.

1. Build a DLL named MyAnalyzer.dll that exports the **_EFN_Analyze** function shown here.

```

#include <windows.h>
#define KDEXT_64BIT
#include <wdbgexts.h>
#include <dbgeng.h>
#include <extsfns.h>

extern "C" __declspec(dllexport) HRESULT _EFN_Analyze(_In_ PDEBUG_CLIENT4 Client,
    _In_ FA_EXTENSION_PLUGIN_PHASE CallPhase, _In_ PDEBUG_FAILURE_ANALYSIS2 pAnalysis)
{
    HRESULT hr = E_FAIL;

    PDEBUG_CONTROL pControl = NULL;
    hr = Client->QueryInterface(__uuidof(IDebugControl), (void**)&pControl);

    if(S_OK == hr && NULL != pControl)
    {
        IDebugFAEntryTags* pTags = NULL;
        pAnalysis->GetDebugFATagControl(&pTags);

        if(NULL != pTags)
        {
            if(FA_PLUGIN_INITIALIZATION == CallPhase)
            {
                pControl->Output(DEBUG_OUTPUT_NORMAL, "My analyzer: initialization\n");
            }
            else if(FA_PLUGIN_STACK_ANALYSIS == CallPhase)
            {
                pControl->Output(DEBUG_OUTPUT_NORMAL, "My analyzer: stack analysis\n");
            }
            else if(FA_PLUGIN_PRE_BUCKETING == CallPhase)
            {
                pControl->Output(DEBUG_OUTPUT_NORMAL, "My analyzer: prebucketing\n");
            }
            else if(FA_PLUGIN_POST_BUCKETING == CallPhase)
            {
                pControl->Output(DEBUG_OUTPUT_NORMAL, "My analyzer: post bucketing\n");
                FA_ENTRY_TYPE entryType = pTags->GetType(DEBUG_FLR_BUGCHECK_CODE);
                pControl->Output(DEBUG_OUTPUT_NORMAL, "The data type for the DEBUG_FLR_BUGCHECK_CODE tag is
0x%x.\n\n", entryType);
            }
        }

        pControl->Release();
    }
    return hr;
}

```

2. Create a metadata file named MyAnalyzer.alz that has the following entries.

```

PluginId      MyPlugin
DebuggeeClass Kernel
BugCheckCode  0xE2

```

Note The last line of the metadata file must end with a newline character.

3. Establish a kernel-mode debugging session between a host and target computer.
4. On the host computer, put MyAnalyzer.dll and MyAnalyzer.alz in the folder c:\MyAnalyzer.
5. On the host computer, in the debugger, enter these commands.

```
.extpath+ c:\MyAnalyzer
```

```
.crash
```

6. The **.crash** command generates Bug Check 0xE2 MANUALLY_INITIATED_CRASH on the target computer, which causes a break in to the debugger on the host computer. The bug check analysis engine (running in the debugger on the host computer) reads MyAnalyzer.alz and sees that MyAnalyzer.dll is able to participate in analyzing bug check 0xE2. So the analysis engine loads MyAnalyzer.dll and calls its **_EFN_Analyze** function.

Verify that you see output similar to the following in the debugger.

```
*           Bugcheck Analysis           *
*
*****
Use !analyze -v to get detailed debugging information.

BugCheck E2, {0, 0, 0, 0}

My analyzer: initialization
My analyzer: stack analysis
My analyzer: prebucketing
My analyzer: post bucketing
The data type for the DEBUG_FLR_BUGCHECK_CODE tag is 0x1.
```

The preceding debugger output shows that the analysis engine called the **_EFN_Analyze** function four times: once for each phase of the analysis. The analysis engine passes the **_EFN_Analyze** function two interface pointers. *Client* is an **IDebugClient4** interface, and *pAnalysis* is an **IDebugFailureAnalysis2** interface. The code in the preceding skeleton example shows how to obtain two more interface pointers. `Client->QueryInterface` gets an **IDebugControl** interface, and `pAnalysis->GetDebugFATagControl` gets an **IDebugFAEntryTags** interface.

Failure Analysis Entries, Tags, and Data Types

The analysis engine creates a **DebugFailureAnalysis** object to organize the data related to a particular code failure. A **DebugFailureAnalysis** object has a collection of **failure analysis entries** (FA entries), each of which is represented by an **FA_ENTRY** structure. An analysis extension plugin uses the **IDebugFailureAnalysis2** interface to get access to this collection of FA entries. Each FA entry has a tag that identifies the kind of information that the entry contains. For example, an FA entry might have the tag **DEBUG_FLR_BUGCHECK_CODE**, which tells us that the entry contains a bug check code. Tags are values in the **DEBUG_FLR_PARAM_TYPE** enumeration (defined in extsfns.h), which is also called the **FA_TAG** enumeration.

```
typedef enum _DEBUG_FLR_PARAM_TYPE {
    ...
    DEBUG_FLR_BUGCHECK_CODE,
    ...
    DEBUG_FLR_BUILD_VERSION_STRING,
    ...
} DEBUG_FLR_PARAM_TYPE;

typedef DEBUG_FLR_PARAM_TYPE FA_TAG;
```

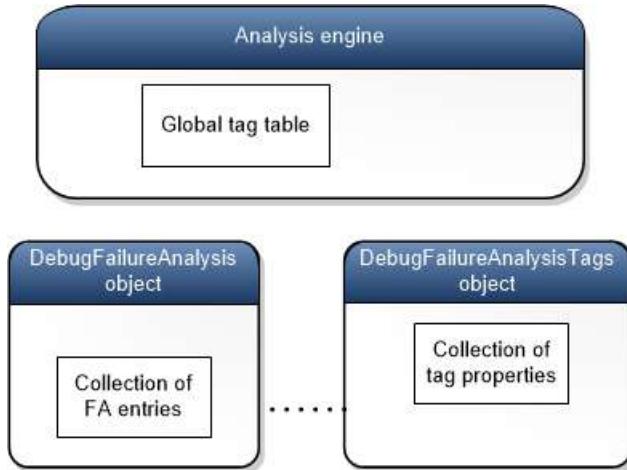

Most **FA entries** have an associated data block. The **DataSize** member of the **FA_ENTRY** structure holds the size of the data block. Some FA entries do not have an associated data block; all the information is conveyed by the tag. In those cases, the **DataSize** member has a value of 0.

```

typedef struct _FA_ENTRY
{
    FA_TAG Tag;
    USHORT FullSize;
    USHORT DataSize;
} FA_ENTRY, *PFA_ENTRY;

```

Each tag has a set of properties: for example, name, description, and data type. A [DebugFailureAnalysis](#) object is associated with a [DebugFailureAnalysisTags](#) object, which contains a collection of tag properties. The following diagram illustrates this association.

A [DebugFailureAnalysis](#) object has a collection of [FA entries](#) that belong to a particular analysis session. The associated [DebugFailureAnalysisTags](#) object has a collection of tag properties that includes only the tags used by that same analysis session. As the preceding diagram shows, the analysis engine has a global tag table that holds limited information about a large set of tags that are generally available for use by analysis sessions.

Typically most of the tags used by an analysis session are standard tags; that is, the tags are values in the [FA_TAG](#) enumeration. However, an analysis extension plug-in can create custom tags. An analysis extension plug-in can add an [FA entry](#) to a [DebugFailureAnalysis](#) object and specify a custom tag for the entry. In that case, properties for the custom tag are added to the collection of tag properties in the associated [DebugFailureAnalysisTags](#) object.

You can access a [DebugFailureAnalysisTags](#) through an [IDebugFAEntry](#) tags interface. To get a pointer to an [IDebugFAEntry](#) interface, call the [GetDebugFATagControl](#) method of the [IDebugFailureAnalysis2](#) interface.

Each tag has a data type property that you can inspect to determine the data type of the data in a failure analysis entry. A data type is represented by a value in the [FA_ENTRY_TYPE](#) enumeration.

The following line of code gets the data type of the [DEBUG_FLR_BUILD_VERSION_STRING](#) tag. In this case, the data type is [DEBUG_FA_ENTRY_ANSI_STRING](#). In the code, `pAnalysis` is a pointer to an [IDebugFailureAnalysis2](#) interface.

```

IDebugFAEntryTags* pTags = pAnalysis->GetDebugFATagControl(&pTags);

if(NULL != pTags)
{
    FA_ENTRY_TYPE entryType = pTags->GetType(DEBUG_FLR_BUILD_VERSION_STRING);
}

```

If a failure analysis entry has no data block, the data type of the associated tag is [DEBUG_FA_ENTRY_NO_TYPE](#).

Recall that a [DebugFailureAnalysis](#) object has a collection of [FA entries](#). To inspect all the FA entries in the collection, use the [NextEntry](#) method. The following example shows how to iterate through the entire collection of FA entries. Assume that `pAnalysis` is a pointer to an [IDebugFailureAnalysis2](#) interface. Notice that we get the first

entry by passing **NULL** to **NextEntry**.

```
PFA_ENTRY entry = pAnalysis->NextEntry(NULL);

while(NULL != entry)
{
    // Do something with the entry

    entry = pAnalysis->NextEntry(entry);
}
```

A tag can have a name and a description. In the following code, *pAnalysis* is a pointer to an **IDebugFailureAnalysis** interface, *pControl* is a pointer to an **IDebugControl** interface, and *pTags* is a pointer to an **IDebugFAEntryTags** interface. The code shows how to use the **GetProperties** method to get the name and description of the tag associated with an [FA entry](#).

```
#define MAX_NAME_LENGTH 64
#define MAX_DESCRIPTION_LENGTH 512

CHAR name[MAX_NAME_LENGTH] = {0};
ULONG nameSize = MAX_NAME_LENGTH;
CHAR desc[MAX_DESCRIPTION_LENGTH] = {0};
ULONG descSize = MAX_DESCRIPTION_LENGTH;

PFA_ENTRY pEntry = pAnalysis->NextEntry(NULL);
pTags->GetProperties(pEntry->Tag, name, &nameSize, desc, &descSize, NULL);
pControl->Output(DEBUG_OUTPUT_NORMAL, "The name is %s\n", name);
pControl->Output(DEBUG_OUTPUT_NORMAL, "The description is %s\n", desc);
```

Metadata Files for Analysis Extension Plug-ins

5/31/2017 • 3 min to read • [Edit Online](#)

When you write an analysis extension plug-in, you also write a metadata file that describes the situations for which you want your plug-in to be called. When the **!analyze** debugger command runs, it uses metadata files to determine which plug-ins to load.

Create a metadata file that has the same name as your analysis extension plug-in and an extension of .alz. For example, if your analysis extension plug-in is named MyAnalyzer.dll, your metadata file must be named MyAnalyzer.alz. Place the metadata file in the same directory as your analysis extension plug-in.

A metadata file for an analysis extension plug-in is an ASCII text file that contains key-value pairs. Keys and values are separated by white space. A key can have any non-whitespace character. Keys are not case sensitive.

After the key and the following white space, the corresponding value begins. A value can have one of the following forms.

- Any set of characters to the end of the line. This form works for values that do not contain any newline characters.

Important If the last value in the metadata file has a value of this form, the line must end with a newline character.

- Any set of characters between braces { }. The form works for values that contain newline characters.

A line beginning with # is a comment and is ignored. Comments can start only where keys are expected.

You can use the following keys in a metadata file.

KEY	DESCRIPTION
PluginId	String - Identifies the plug-in.
DebuggeeClass	String - Possible values are "Kernel" and "User". Indicates that the plug-in is interested in analyzing only kernel-mode failures or only user-mode failures.
BugCheckCode	32-bit bug check code - Indicates that the plug-in is interested in analyzing this bug check code . A single metadata file can specify multiple bug check codes.
ExceptionCode	32-bit exception code - Indicates that the plug-in is interested in analyzing this exception code . A single metadata file can specify multiple exception codes.
ExecutableName	String - Indicates that the plug-in is interested only in sessions where this is the running executable of the process to be analyzed. A single metadata file can specify multiple executable names.

KEY	DESCRIPTION
ImageName	String - Indicates that the plug-in is only interested only in sessions where the default analysis considers this image (dll, sys, or exe) to be at fault. The plug-in is invoked after analysis has determined which image is at fault. A single metadata file can specify multiple image names.
MaxTagCount	Integer - The maximum number of custom tags that the plug-in needs. Custom tags are tags other than the ones defined in extsfns.h.

Example Metadata Files

The following metadata file describes a plug-in that is interested in analyzing bug check code 0xE2. (Recall that the last line must end with a newline character.)

```
PluginId      MyPlugin
DebuggeeClass Kernel
BugCheckCode  0xE2
```

The following metadata file describes a plug-in that is interested in analyzing bug checks 0x8, 0x9, and 0xA if MyDriver.sys is considered to be the module at fault.

```
PluginId      MyPlugin
DebuggeeClass Kernel
BugCheckCode  0x8
BugCheckCode  0x9
BugCheckCode  0xA
ImageName     MyDriver.sys
```

The following metadata file describes a plug-in that is interested in analyzing exception code 0xC0000005 if MyApp.exe is the running executable of the process being analyzed. Also, the plug-in might create as many as three custom tags.

```
PluginId      MyPlugin
DebuggeeClass User
ExceptionCode  0xC0000005
ExecutableName MyApp.exe
```

Debugging Tools for Windows has a sample that you can use to build a debugger extension module named dbgexts.dll. This extension module implements several debugger extension commands, but it can also serve as an analysis extension plug-in; that is, it exports an [_EFN_Analyze](#) function. Here is a metadata file that describes dbgexts.dll as an analysis extension plug-in.

```
PluginId      PluginSample
DebuggeeClass  User
ExceptionCode  0xc0000005
ExecutableName cdb.exe
ExecutableName windbg.exe
#
# Custom tag descriptions
#

Failure Analysis Entries

5/26/2017 • 1 min to read • [Edit Online](#)

A **DebugFailureAnalysis** object has a collection of failure analysis entries. For more information, see [Failure Analysis Entries, Tags, and Data Types](#).

A *failure analysis entry* (also called an *FA entry*) is one of the following:

- An **FA_ENTRY** structure
- An **FA_ENTRY** structure followed by a data block

The **ContentSize** member of the **FA_ENTRY** structure holds the size, in bytes, of the data block. If there is no data block, **ContentSize** is equal to 0. The **Tag** member of an **FA_ENTRY** structure identifies the kind of information that is stored in the FA entry. For example, the tag **DEBUG_FLR_BUGCHECK_CODE** indicates that the data block of the **FA_ENTRY** holds a bug check code.

In some cases, there is no need for a data block; all the information is conveyed by the tag. For example, an **FA_ENTRY** with tag **DEBUG_FLR_KERNEL_VERIFIER_ENABLED** has no data block.

Each tag is associated with one of the data types in the **FA_ENTRY_TYPE** enumeration. For example, the tag **DEBUG_FLR_BUGCHECK_CODE** is associated with the data type **DEBUG_FA_ENTRY_ULONG**. To determine the data type of a tag, call the **GetType** method of the **IDebugFAEntryTags** interface.

To get or set the data block of an FA entry, use the **IDebugFailureAnalysis2** interface.

Customizing Debugger Output Using DML

5/31/2017 • 20 min to read • [Edit Online](#)

The debugger markup language (DML) provides a mechanism for enhancing output from the debugger and extensions. Similar to HTML, the debugger's markup support allows output to include display directives and extra non-display information in the form of tags. The debugger user interfaces, such as WinDbg parse out the extra information provided in DML to enhance the display of information and provide new behaviors, such as grid displays and sorting. This topic describes how you can customize your debug output using DML. For general information on enabling and using DML in the debuggers, see [Using Debugger Markup Language](#).

DML is available in Windows 10 and later.

DML Overview

One of DML's primary benefits is to provide the ability to link to related information in debugger output. One of the primary DML tags is the `<link>` tag which lets an output producer indicate that information related to a piece of output can be accessed via the link's stated action. As with HTML links in a web browser, this allows the user to navigate hyperlinked information.

A benefit of providing hyperlinked content is that it can be used to enhance the discoverability of debugger and debugger extension functionality. The debugger and its extensions contain a large amount of functionality but it can be difficult to determine the appropriate command to use in different scenarios. Users must simply know what commands are available to use in specific scenarios. Differences between user and kernel debugging add further complexity. This often means that many users are unaware of debug commands which could help them. DML links provides the ability for arbitrary debug commands to be wrapped in alternate presentations, such as descriptive text, clickable menu systems or linked help. Using DML, the command output can be enhanced to guide the user to additional related commands relevant for the task at hand.

Debugger DML Support

- The command window in WinDbg supports all DML behavior and will show colors, font styles and links.
- The console debuggers – ntsd, cdb and kd – only support the color attributes of DML, and only when running in a true console with color mode enabled.
- Debuggers with redirected I/O, ntsd –d or remote.exe sessions will not display any colors.

DML Content Specification

DML is not intended to be a full presentation language such as HTML. DML is deliberately very simple and has only a handful of tags.

Because not all debugger tools support rich text, DML is designed to allow simple translation between DML and plain text. This allows DML to function in all existing debugger tools. Effects such as colors can easily be supported since removing them does not remove the text carrying the actual information.

DML is not XML. DML does not attempt to carry semantic nor structured information. As mentioned above, there must be a simple mapping between DML and plain text, for this reason, DML tags are all discardable.

DML is not extensible; all tags are pre-defined and validated to work across all of the existing debugger tools.

Tag Structure

Similar to XML, DML tags are given as a starting `<tagname [args]>` and a following `</tagname>`.

Special Characters

DML content roughly follows the XML/HTML rules for special characters. The characters &, <, > and " are special and cannot be used in plain text. The equivalent escaped versions are <, > and ". For example this text:

"Alice & Bob think 3 < 4"

would be converted to the following DML.

```
&quot;Alice & Bob think 3 &lt; 4&quot;
```

C programming language formatting characters

A significant departure from XML/HTML rules is that DML text can include C programming language stream-style formatting characters such as \b, \t, \r and \n. This is to support compatibility with existing debugger text production and consumption.

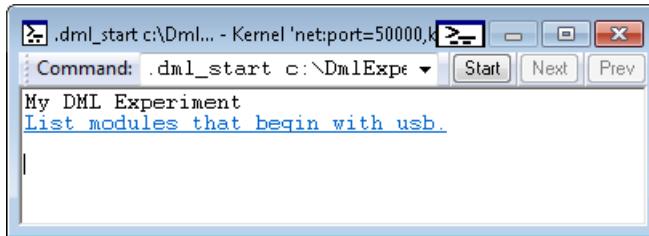

Example DML

Suppose the file C:\Dml_Experiment.txt contains the following lines.

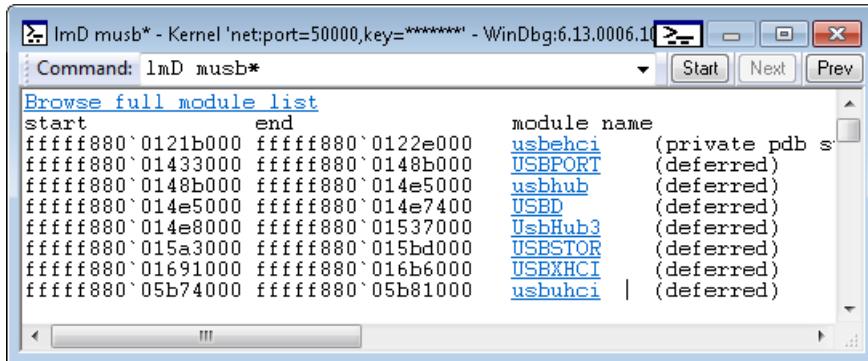

```
My DML Experiment
<link cmd="lmD musb*">>List modules that begin with usb.</link>
```

The following command displays the text and link in the Command Browser window.

```
.browse .dml_start c:\Dml_Experiment.txt
```

If you click the **List modules that begin with usb** link, you see output similar to the following image.

start	end	module name
fffff880`0121b000	fffff880`0122e000	usbehci (private pdb s)
fffff880`01433000	fffff880`0148b000	USBPORT (deferred)
fffff880`0148b000	fffff880`014e5000	usbhub (deferred)
fffff880`014e5000	fffff880`014e7400	USBBD (deferred)
fffff880`014e8000	fffff880`01537000	UsbHub3 (deferred)
fffff880`015a3000	fffff880`015bd000	USBSTOR (deferred)
fffff880`01691000	fffff880`016b6000	USBXHCI (deferred)
fffff880`05b74000	fffff880`05b81000	usbuhci (deferred)

Right-Click Behavior in DML

Right-click behavior is available in DML. This sample shows how to define right click behavior using <altlink> to send a breakpoint **bp (Set Breakpoint)** command and send the **u (Unassemble)** with a regular click.

```
<link cmd="u MyProgram!memcpy">
<altlink name="Set Breakpoint (bp)" cmd="bp MyProgram!memcpy" />
u MyProgram!memcpy
</link>
```

DML Tag Reference

<link>

```
<link [name="text"] [cmd="debugger_command"] [alt="Hover text to display"] [section="name"]>link text</link>
```

The link tag is the basic hyper linking mechanism in DML. It directs user interfaces which support DML presentation to display the link text as a clickable link. When a link with a cmd specification is clicked the debugger command is executed and its output should replace the current output.

The name and section arguments allow for navigation between named links, similar to HTML's <a name> and #name support. When a link that has a section argument is clicked on the UI will scan for a link named with a matching name and will scroll that into view. This allows links to point to different sections of the same page (or a particular section of a new page). DML's section name is separate to avoid having to define a new syntax which would allow a section name at the end of the command string.

Conversion to plain text drops the tags.

Example

```
<b> Handy Links </b>
<link cmd="!dml_proc">Display process information with DML rendering.</link>
<link cmd="kM">Display stack information with DML rendering.</link>
```

Example

This example shows the use of the alt attribute to create text that will appear when you hover over the DML link.

```
<b>Hover Example</b>
<link cmd="!lMD" alt="This link will run the list modules command and display the output in DML
format">LMD</link>
```

<altlink>

```
<altlink [name="text"] [cmd="debugger_command"] [section="name"]>alt link text</altlink>
```

The <altlink> tag provides right-click behavior is available in DML. When a link with a cmd specification is clicked the debugger command is executed and its output should replace the current output. The <altlink> tab is normally paired with the <link> tag to support regular and right click behavior.

Conversion to plain text drops the tags.

Example

This example shows how to define right click behavior using <altlink> to send a breakpoint **bp (Set Breakpoint)** command and send the **u (Unassemble)** with a regular click.

```
<link cmd="u MyProgram!memcpy">
<altlink name="Set Breakpoint (bp)" cmd="bp MyProgram!memcpy" />
u MyProgram!memcpy
</link>
```

<exec>

```
<exec cmd="debugger_command">descriptive text</exec>
```

An exec tag is similar to a link tag in that the descriptive text should be presented as a clickable item. However, when the exec tag is used in a command browser window, the given command is executed without replacing the current output, this tag provides a way to have commands executed with a click, from a menu.

Conversion to plain text drops the tags.

Example

This example shows how to define two commands with a regular click.

```
<b>Exec Sample</b>
<exec cmd="!dml_proc">Display process information with DML rendering.</exec>
<exec cmd="kM">Display stack information with DML rendering.</exec>
```

```
<b>bold text</b>
```

This tag requests bold. The ****, *<i>* and <u> can be nested to have a mix of the properties.

Conversion to plain text drops the tags.

Example

This example shows how to bold text.

```
<b>This is bold Text</b>
```

<i>

```
<i>italicized text</i>
```

This tag requests italics. The ****, *<i>* and <u> can be nested to have a mix of the properties.

Conversion to plain text drops the tags.

Example

This example shows how to italicize text.

```
<i>This is italicized Text</i>
```

<u>

```
<i>underlined text</i>
```

This tag requests underlined text. The ****, *<i>* and <u> can be nested to have a mix of the properties.

Conversion to plain text drops the tags.

Example

This example shows how to underlined text.

```
<u>This is underlined Text</u>
```

Example

This example shows how to combine tags to bold, underline and italicize text.

```
<b><u><i>This is bold, underlined and italicized text. </i></u></b>
```

<col>

```
<col fg="name" bg="name">text</col>
```

Request foreground and background colors for the text. The colors are given as names of known colors instead of absolute values as that allows customers to control what kind of color they see. Current color names (defaults only apply to WinDbg).

Foreground and Background Element Tags

Setting	Description / Example
wbg - Windows background wfg - Windows foreground	Default window background and foreground colors. Default to system colors for window and window text. <col fg="wfg" bg="wbg"> This is standard foreground / background text </col>
clbg - Current line foreground clfg - Current line background	Current line background and foreground colors. Default to system colors for highlight and highlight text. <col fg="clfg" bg="clbg"> Test Text - Current Line</col>
empbg - Emphasized background emphfg - Emphasized foreground	Emphasized text. Defaults to light blue. <col fg="emphfg" bg="empbg"> This is emphasis foreground / background text </col>
subbg - Subdued background subfg - Subdued foreground	Subdued text. Default to system color for inactive caption text and inactive captions. <col fg="subfg" bg="subbg"> This is subdued foreground / background text </col>
normbg - Normal background normfg - Normal foreground	Normal <col fg="normfg" bg="normbg"> Test Text - Normal (normfg / normbg) </col>
warnbg - Warning background warnfg - Warning foreground	Warning <col fg="warnfg" bg="warnbg"> Test Text - Warning (warnfg / warnbg) </col>
errbg - Error background errfg - Error foreground	Error <col fg="errfg" bg="errbg"> Test Text - Error (errfg / errbg) </col>
verbbg - Verbose background verbfg - Verbose foreground	Verbose <col fg="verbfg" bg="verbbg"> Test Text - Verbose (verbfg / verbbg) </col>

Source Code Single Element Tags

srcnum - Source numeric constant	Source element colors. <col fg="srcnum" bg="wbg"> Test Text - srcnum </col>
srcchar - Source character constant	<col fg="srcchar" bg="wbg"> Test Text - srcchar </col>
srcstr - Source string constant	<col fg="srcstr" bg="wbg"> Test Text - srcstr </col>
srcid - Source identifier	<col fg="srcid" bg="wbg"> Test Text - srcid </col>
srckw - Keyword	<col fg="srckw" bg="wbg"> Test Text - srckw </col>
srcpair - Source brace or matching symbol pair	<col fg="srcpair" bg="empbbg"> Test Text - srcpair </col>
srccmnt - Source comment	<col fg="srccmnt" bg="wbg"> Test Text - srccmnt </col>
srcdrct - Source directive	<col fg="srcdrct" bg="wbg"> Test Text - srcdrct </col>
srcspid - Source special identifier	<col fg="srcspid" bg="wbg"> Test Text - srcspid </col>
srcannot - Source annotation	<col fg="srcannot" bg="wbg"> Test Text - srcannot </col>
changed - Changed data	Used for data that has changed since a previous stop point, such as changed registers in WinDbg. Defaults to red. <col fg="changed" bg="wbg"> Test Text - Changed </col>

DML Example Code

This example code illustrates the following.

- Calling debug commands
- Implementing right click commands
- Implementing hover over text
- Using color and rich text

```

<col fg="srckw" bg="wbg"> <b>
*****

```

DML Additions to the dbgeng Interface

The [Debugger Engine and Extension APIs](#) provide an interface to use the debugger engine to create custom applications. You can also write custom extensions that will run in WinDbg, KD, CDB, and NTSD. For more information see [Writing DbgEng Extensions](#). This section describes the available DML enhancements to the debugger engine interfaces.

The dbgeng already has a set of text handling input methods and output interfaces, the use of DML only requires specification of the type of content carried in input and output text.

Providing DML Content to dbgeng

The output control flag DEBUG_OUTCTL_DML indicates that the text generated by a dbgeng method should be handled as DML content. If this flag is not given the text is treated as plain text context. DEBUG_OUTCTL_DML can be used with the following methods.

- [IDebugControl4::ControlledOutput](#)
- [IDebugControl4::ControlledOutputVaList](#)
- [IDebugControl4::ControlledOutputWide](#)
- [IDebugControl4::ControlledOutputVaListWide](#)

Text given must follow the DML rules for valid characters.

All output routines have been enhanced to allow a new format specifier %[h|w]Y{t}. This format specifier has a string pointer as an argument and indicates that the given text is plain text and should be converted to DML format during output processing. This gives callers a simple way of including plain text in DML content without having to pre-convert to DML format themselves. The h and w qualifiers indicate ANSI or Unicode text, as with %.

The following table summarizes the use of the %Y format specifier.

%Y{t}	Quoted string. Will convert text to DML if the output format (first arg) is DML.
%Y{T}	Quoted string. Will always convert text to DML regardless of the output format.
%Y{S}	Unquoted string. Will convert text to DML if the output format (first arg) is DML.
%Y{S}	Unquoted string. Will always convert text to DML regardless of the output format.
%Y{as}	ULONG64. Adds either an empty string or 9 characters of spacing for padding the high 32-bit portion of debugger formatted pointer fields. The extra space outputs 9 spaces which includes the upper 8 zeros plus the ` character.
%Y{ps}	ULONG64. Extra space for padding debugger formatted pointer fields (includes the upper 8 zeros plus the ` character).
%Y{I}	ULONG64. Address as source line information.

This code snippet illustrates the use of the %Y format specifier.

```

HRESULT CALLBACK testout(_In_ PDEBUG_CLIENT pClient, _In_ PCWSTR /*pwszArgs*/)
{
    HRESULT hr = S_OK;

    ComPtr<IDebugControl4> spControl;
    IfFailedReturn(pClient->QueryInterface(IID_PPV_ARGS(&spControl)));

    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{t}: %Y{t}\n",
    L"Hello <World>");
    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{T}: %Y{T}\n",
    L"Hello <World>");
    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{s}: %Y{s}\n",
    L"Hello <World>");
    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{S}: %Y{S}\n",
    L"Hello <World>");

    spControl->ControlledOutputWide(0, DEBUG_OUTPUT_NORMAL, L"TEXT/NORMAL Y{t}: %Y{t}\n", L"Hello <World>");
    spControl->ControlledOutputWide(0, DEBUG_OUTPUT_NORMAL, L"TEXT/NORMAL Y{T}: %Y{T}\n", L"Hello <World>");
    spControl->ControlledOutputWide(0, DEBUG_OUTPUT_NORMAL, L"TEXT/NORMAL Y{s}: %Y{s}\n", L"Hello <World>");
    spControl->ControlledOutputWide(0, DEBUG_OUTPUT_NORMAL, L"TEXT/NORMAL Y{S}: %Y{S}\n", L"Hello <World>");

    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{a}: %Y{a}\n",
    (ULONG64)0x00007ffa7da163c0);
    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{as} 64bit  : "
    '%Y{as}'\n, (ULONG64)0x00007ffa7da163c0);
    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{as} 32value : "
    '%Y{as}'\n, (ULONG64)0x1);

    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{ps} 64bit  : "
    '%Y{ps}'\n, (ULONG64)0x00007ffa7da163c0);
    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{ps} 32value : "
    '%Y{ps}'\n, (ULONG64)0x1);

    spControl->ControlledOutputWide(DEBUG_OUTCTL_DML, DEBUG_OUTPUT_NORMAL, L"DML/NORMAL Y{l}: %Y{l}\n",
    (ULONG64)0x00007ffa7da163c0);

    return hr;
}

```

This sample code would generate the following output.

```

0:004> !testout
DML/NORMAL Y{t}: "Hello <World>"
DML/NORMAL Y{T}: "Hello <World>"
DML/NORMAL Y{s}: Hello <World>
DML/NORMAL Y{S}: Hello <World>
TEXT/NORMAL Y{t}: "Hello <World>"
TEXT/NORMAL Y{T}: "Hello <World>`;
TEXT/NORMAL Y{s}: Hello <World>
TEXT/NORMAL Y{S}: Hello <World>
DML/NORMAL Y{a}: 00007ffa`7da163c0
DML/NORMAL Y{as} 64bit  : ' '
DML/NORMAL Y{as} 32value : ' '
DML/NORMAL Y{ps} 64bit  : ' '
DML/NORMAL Y{ps} 32value : ' '
DML/NORMAL Y{l}: [d:\th\minkernel\kernelbase\debug.c @ 443]

```

An additional control flag, DEBUG_OUTCTL_AMBIENT_DML, allows specification of DML context text without modifying any out output control attributes. DEBUG_OUTCTL_AMBIENT_TEXT has been added also as a more descriptive alias for the previously-existing DEBUG_OUTCTL_AMBIENT. The output control flags are defined in dbgeng.h.

```

#define DEBUG_OUTCTL_DML           0x00000020

// Special values which mean leave the output settings
// unchanged.
#define DEBUG_OUTCTL_AMBIENT_DML   0xfffffffffe
#define DEBUG_OUTCTL_AMBIENT_TEXT  0xffffffffff

// Old ambient flag which maps to text.
#define DEBUG_OUTCTL_AMBIENT      DEBUG_OUTCTL_AMBIENT_TEXT

```

Providing DML Content From a Debuggee

The dbgeng has been enhanced to scan debuggee output for a special marker -- that indicates the remaining text in a piece of debuggee output should be treated as DML. The mode change only applies to a single piece of debuggee output, such as a single OutputDebugString string, and is not a global mode switch.

This example shows a mix of plain and DML output.

```
OutputDebugString("This is plain text\n<?dml?>This is <col fg=\"emphfg\">DML</col> text\n");
```

The output produced, will have a line of plain text followed by a line of DML where the acronym DML is displayed in a different color.

IDebugOutputCallbacks2

IDebugOutputCallbacks2 allows dbgeng interface clients to receive full DML content for presentation. IDebugOutputCallbacks2 is an extension of IDebugOutputCallbacks (not IDebugOutputCallbacksWide) so that it can be passed in to the existing SetOutputCallbacks method. The engine will do a QueryInterface for IDebugOutputCallbacks2 to see which interface the incoming output callback object supports. If the object supports IDebugOutputCallbacks2 all output will be sent through the extended IDebugOutputCallbacks2 methods; the basic IDebugOutputCallbacks::Output method will not be used.

The new methods are:

- IDebugOutputCallbacks2::GetInterestMask – Allows the callback object to describe which kinds of output notifications it wants to receive. The basic choice is between plain text content (DEBUG_OUTCBI_TEXT) and DML content (DEBUG_OUTCBI_DML). In addition, the callback object can also request notification of explicit flushes (DEBUG_OUTCBI_EXPLICIT_FLUSH).
- IDebugOutputCallbacks2::Output2 – All IDebugOutputCallbacks2 notifications come through Output2. The Which parameter indicates what kind of notification is coming in while the Flags, Arg and Text parameters carry the notification payload. Notifications include:
 - DEBUG_OUTCB_TEXT – Plain text output. Flags are from DEBUG_OUTCBF_*, Arg is the output mask and Text is the plain text. This will only be received if DEBUG_OUTCBI_TEXT was given in the interest mask.
 - DEBUG_OUTCB_DML – DML content output. Flags are from DEBUG_OUTCBF_*, Arg is the output mask and Text is the DML content. This will only be received if DEBUG_OUTCBI_DML was given in the interest mask.
 - DEBUG_OUTCB_EXPLICIT_FLUSH – A caller has called FlushCallbacks with no buffered text. Normally when buffered text is flushed the DEBUG_OUTCBF_COMBINED_EXPLICIT_FLUSH flag will be set, folding the two notifications into one. If no text is buffered a flush-only notification is sent.

The flags are defined in dbgeng.h as shown here.

```
// IDebugOutputCallbacks2 interest mask flags.  
//  
  
// Indicates that the callback wants notifications  
// of all explicit flushes.  
#define DEBUG_OUTCBI_EXPLICIT_FLUSH 0x00000001  
// Indicates that the callback wants  
// content in text form.  
#define DEBUG_OUTCBI_TEXT 0x00000002  
// Indicates that the callback wants  
// content in markup form.  
#define DEBUG_OUTCBI_DML 0x00000004  
  
#define DEBUG_OUTCBI_ANY_FORMAT 0x00000006
```

Note that an output object can register for both text and DML content if it can handle them both. During output processing of the callback the engine will pick the format that reduces conversions, thus supporting both may reduce conversions in the engine. It is not necessary, though, and supporting only one format is the expected mode of operation.

Automatic Conversions

The dbgeng will automatically convert between plain text and DML as necessary. For example, if a caller sends DML content to the engine the engine will convert it to plain text for all output clients which only accept plain text. Alternately, the engine will convert plain text to DML for all output callbacks which only accept DML.

JavaScript Debugger Scripting

5/31/2017 • 21 min to read • [Edit Online](#)

This topic describes how to use JavaScript to create scripts that understand debugger objects and extend and customize the capabilities of the debugger.

Overview of JavaScript Debugger Scripting

Script providers bridge a scripting language to the debugger's internal object model. The JavaScript debugger scripting provider, allows the for use of JavaScript with the debugger.

When a JavaScript is loaded via the `.scriptload` command, the root code of the script is executed, the names which are present in the script are bridged into the root namespace of the debugger (dx Debugger) and the script stays resident in memory until it is unloaded and all references to its objects are released. The script can provide new functions to the debugger's expression evaluator, modify the object model of the debugger, or can act as a visualizer in much the same way that a NatVis visualizer does.

This topic describes some of what you can do with JavaScript debugger scripting.

[Native Objects in JavaScript Extensions](#)

The Debugger JavaScript Provider

The JavaScript provider included with the debugger takes full advantage of the latest ECMAScript6 object and class enhancements. For more information, see [ECMAScript 6 — New Features: Overview & Comparison](#).

JsProvider.dll

JsProvider.dll is the JavaScript provider that is loaded to support JavaScript Debugger Scripting.

Requirements

JavaScript Debugger Scripting is designed to work with all supported versions of Windows.

Loading the JavaScript Scripting Provider

Before using any of the .script commands, a scripting provider needs to be loaded using the [.load \(Load Extension DLL\)](#) command. To load the JavaScript provider, use the following command.

```
0:000> .load jsprovider.dll
```

Use the .scriptproviders command to confirm that the JavaScript provider is loaded.

```
0:000> .scriptproviders
Available Script Providers:
  NatVis (extension '.NatVis')
  JavaScript (extension '.js')
```

JavaScript Scripting Meta Commands

The following commands are available to work with JavaScript Debugger Scripting.

- [.scriptproviders \(List Script Providers\)](#)
- [.scriptload \(Load Script\)](#)
- [.scriptunload \(Unload Script\)](#)
- [.scriptrun \(Run Script\)](#)
- [.scriptlist \(List Loaded Scripts\)](#)

Requirements

Before using any of the .script commands, a scripting provider needs to be loaded using the [.load \(Load Extension DLL\)](#) command. To load the JavaScript provider, use the following command.

```
0:000> .load jsprovider.dll
```

.scriptproviders (List Script Providers)

The .scriptproviders command will list all the script languages which are presently understood by the debugger and the extension under which they are registered.

In the example below, the JavaScript and NatVis providers are loaded.

```
0:000> .scriptproviders
Available Script Providers:
  NatVis (extension '.NatVis')
  JavaScript (extension '.js')
```

Any file ending in ".NatVis" is understood as a NatVis script and any file ending in ".js" is understood as a JavaScript script. Either type of script can be loaded with the .scriptload command.

For more information, see [.scriptproviders \(List Script Providers\)](#)

.scriptload (Load Script)

The .scriptload command will load a script and execute the root code of a script and the *initializeScript* function. If there are any errors in the initial load and execution of the script, the errors will be displayed to console. The following command shows the successful load of TestScript.js.

```
0:000> .scriptload C:\WinDbg\Scripts\TestScript.js
JavaScript script successfully loaded from 'C:\WinDbg\Scripts\TestScript.js'
```

Any object model manipulations made by the script will stay in place until the script is subsequently unloaded or is run again with different content.

For more information, see [.scriptload \(Load Script\)](#)

.scriptrun

The .scriptrun command will load a script, execute the root code of the script, the *initializeScript* and the *invokeScript* function. If there are any errors in the initial load and execution of the script, the errors will be displayed to console.

```
0:000> .scriptrun C:\WinDbg\Scripts\helloWorld.js
JavaScript script successfully loaded from 'C:\WinDbg\Scripts\helloWorld.js'
Hello World!  We are in JavaScript!
```

Any debugger object model manipulations made by the script will stay in place until the script is subsequently unloaded or is run again with different content.

For more information, see [.scriptrun \(Run Script\)](#).

.scriptunload (Unload Script)

The .scriptunload command unloads a loaded script and calls the *uninitializeScript* function. Use the following command syntax to unload a script

```
0:000:x86> .scriptunload C:\WinDbg\Scripts\TestScript.js
JavaScript script unloaded from 'C:\WinDbg\Scripts\TestScript.js'
```

For more information, see [.scriptunload \(Unload Script\)](#).

.scriptlist (List Loaded Scripts)

The .scriptlist command will list any scripts which have been loaded via the .scriptload or the .scriptrun command. If the TestScript was successfully loaded using .scriptload, the .scriptlist command would display the name of the loaded script.

```
0:000> .scriptlist
Command Loaded Scripts:
  JavaScript script from 'C:\WinDbg\Scripts\TestScript.js'
```

For more information, see [.scriptlist \(List Loaded Scripts\)](#).

Get Started with JavaScript Debugger Scripting

HelloWorld Example Script

This section describes how to create and execute a simple JavaScript debugger script that prints out, Hello World.

```
// WinDbg JavaScript sample
// Prints Hello World
function initializeScript()
{
    host.diagnostics.debugLog("****> Hello World! \n");
}
```

Use a text editor such as Notepad to create a text file named *HelloWorld.js* that contains the JavaScript code shown above.

Use the [.load \(Load Extension DLL\)](#) command to load the JavaScript provider.

```
0:000> .load jsprovider.dll
```

Use the [.scriptload](#) command to load and execute the script. Because we used the function name *initializeScript*, the code in the function is run when the script is loaded.

```
0:000> .scriptload c:\WinDbg\Scripts\HelloWorld.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\HelloWorld.js'
****> Hello World!
```

After the script is loaded the additional functionality is available in the debugger. Use the [dx \(Display NatVis Expression\)](#) command to display *Debugger.State.Scripts* to see that our script is now resident.

```
0:000> dx Debugger.State.Scripts
Debugger.State.Scripts
    HelloWorld
```

In the next example, we will add and call a named function.

Adding Two Values Example Script

This section describes how to create and execute a simple JavaScript debugger script that adds takes input and adds two numbers.

This simple script provides a single function, *addTwoValues*.

```
// WinDbg JavaScript sample
// Adds two functions
function addTwoValues(a, b)
{
    return a + b;
}
```

Use a text editor such as Notepad to create a text file named *FirstSampleFunction.js*

Use the [.load \(Load Extension DLL\)](#) command to load the JavaScript provider.

```
0:000> .load jsprovider.dll
```

Use the [.scriptload](#) command to load the script.

```
0:000> .scriptload c:\WinDbg\Scripts\FirstSampleFunction.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\FirstSampleFunction.js'
```

After the script is loaded the additional functionality is available in the debugger. Use the **dx (Display NatVis Expression)** command to display *Debugger.State.Scripts* to see that our script is now resident.

```
0:000> dx Debugger.State.Scripts
Debugger.State.Scripts
FirstSampleFunction
```

We can click on the *FirstSampleFunction*, to see what functions it provides.

```
0:000> dx -r1 Debugger.State.Scripts.FirstSampleFunction.Contents
Debugger.State.Scripts.FirstSampleFunction.Contents : [object Object]
  host      : [object Object]
  addTwoValues
```

To make the script a bit more convenient to work with, assign a variable in the debugger to hold the contents of the script using the dx command.

```
0:000> dx @$myScript = Debugger.State.Scripts.FirstSampleFunction.Contents
```

Use the dx expression evaluator to call the addTwoValues function.

```
0:000> dx @$myScript.addTwoValues(10, 41),d
@$myScript.addTwoValues(10, 41),d : 51
```

You can also use the *@\$scriptContents* built in alias to work with the scripts. The *@\$scriptContents* alias merges all of the .Content of all of the scripts that are loaded.

```
0:001> dx @$scriptContents.addTwoValues(10, 40),d
@$scriptContents.addTwoValues(10, 40),d : 50
```

When you are done working with the script use the .scriptunload command to unload the script.

```
0:000> .scriptunload c:\WinDbg\Scripts\FirstSampleFunction.js
JavaScript script successfully unloaded from 'c:\WinDbg\Scripts\FirstSampleFunction.js'
```

Debugger Command Automation

This section describes how to create and execute a simple JavaScript debugger script that automates the sending of the **u (Unassemble)** command. The sample also shows how to gather and display command output in a loop.

This script provides a single function, RunCommands().

```

// WinDbg JavaScript sample
// Shows how to call a debugger command and display results
"use strict";

function RunCommands()
{
    var ctl = host.namespace.Debugger.Utility.Control;
    var output = ctl.ExecuteCommand("u");
    host.diagnostics.debugLog("****> Displaying command ouput \n");

    for (var line of output)
    {
        host.diagnostics.debugLog("  ", line, "\n");
    }

    host.diagnostics.debugLog("****> Exiting RunCommands Function \n");
}

```

Use a text editor such as Notepad to create a text file named *RunCommands.js*

Use the [.load \(Load Extension DLL\)](#) command to load the JavaScript provider.

```
0:000> .load jsprovider.dll
```

Use the *.scriptload* command to load the *RunCommands* script.

```
0:000> .scriptload c:\WinDbg\Scripts\RunCommands.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\RunCommands.js'
```

After the script is loaded the additional functionality is available in the debugger. Use the [dx \(Display NatVis Expression\)](#) command to display *Debugger.State.Scripts.RunCommands* to see that our script is now resident.

```

0:000>dx -r3 Debugger.State.Scripts.RunCommands
Debugger.State.Scripts.RunCommands
  Contents      : [object Object]
  host          : [object Object]
  diagnostics   : [object Object]
  namespace     :
  currentSession: Live user mode: <Local>
  currentProcess: notepad.exe
  currentThread : ntdll!DbgUiRemoteBreakin (00007ffd`87f2f440)
  memory        : [object Object]

```

Use the *dx* command to call the *RunCommands* function in the *RunCommands* script.

```

0:000> dx Debugger.State.Scripts.RunCommands.Contents.RunCommands()
****> Displaying command ouput
ntdll!ExpInterlockedPopEntrySListEnd+0x17 [d:\rs1\minkernel\ntos\rtl\amd64\slist.asm @ 196]:
00007ffd`87f06e67 cc          int     3
00007ffd`87f06e68 cc          int     3
00007ffd`87f06e69 0f1f8000000000  nop     dword ptr [rax]
ntdll!RtlpInterlockedPushEntrySList [d:\rs1\minkernel\ntos\rtl\amd64\slist.asm @ 229]:
00007ffd`87f06e70 0f0d09      prefetchw [rcx]
00007ffd`87f06e73 53          push    rbx
00007ffd`87f06e74 4c8bd1      mov     r10,rcx
00007ffd`87f06e77 488bca      mov     rcx,rdx
00007ffd`87f06e7a 4c8bda      mov     r11,rdx
****> Exiting RunCommands Function

```

Special JavaScript Debugger Functions

There are several special functions in a JavaScript script called by the script provider itself.

initializeScript

When a JavaScript script loads and is executed, it goes through a series of steps before the variables, functions, and other objects in the script affect the object model of the debugger.

- The script is loaded into memory and parsed.
- The root code in the script is executed.
- If the script has a method called `initializeScript`, that method is called.
- The return value from `initializeScript` is used to determine how to automatically modify the object model of the debugger.
- The names in the script are bridged to the debugger's namespace.

As mentioned, `initializeScript` will be called immediately after the root code of the script is executed. Its job is to return a JavaScript array of registration objects to the provider indicating how to modify the object model of the debugger.

```
function initializeScript()
{
    // Add code here that you want to run everytime the script is loaded.
    // We will just send a message to indicate that function was called.
    host.diagnostics.debugLog("****> initializeScript was called\n");
}
```

invokeScript

The `invokeScript` method is the primary script method and is called when `.scriptload` and `.scriptrun` are run.

```
function invokeScript()
{
    // Add code here that you want to run everytime the script is executed.
    // We will just send a message to indicate that function was called.
    host.diagnostics.debugLog("****> invokeScript was called\n");
}
```

uninitializeScript

The `uninitializeScript` method is the behavioral opposite of `initializeScript`. It is called when a script is unlinked and is getting ready to unload. Its job is to undo any changes to the object model which the script made imperatively during execution and/or to destroy any objects which the script cached.

If a script neither makes imperative manipulations to the object model nor caches results, it does not need to have an `uninitializeScript` method. Any changes to the object model performed as indicated by the return value of `initializeScript` are undone automatically by the provider. Such changes do not require an explicit `uninitializeScript` method.

```
function uninitializeScript()
{
    // Add code here that you want to run everytime the script is unloaded.
    // We will just send a message to indicate that function was called.
    host.diagnostics.debugLog("****> uninitialize was called\n");
}
```

Summary of Functions Called by Script Commands

This table summarizes which functions are called by the script commands

	.scriptload	.scriptrun (Run Script)	.scriptunload (Unload Script)
root	yes	yes	
initializeScript	yes	yes	
invokeScript		yes	
uninitializeScript			yes

Use this sample code to see when each function is called as the script is loaded, executed and unloaded.

```
// Root of Script
host.diagnostics.debugLog("****> Code at the very top (root) of the script is always run \n");

function initializeScript()
{
    // Add code here that you want to run everytime the script is loaded.
    // We will just send a message to indicate that function was called.
    host.diagnostics.debugLog("****> initializeScript was called \n");
}

function invokeScript()
{
    // Add code here that you want to run everytime the script is executed.
    // We will just send a message to indicate that function was called.
    host.diagnostics.debugLog("****> invokeScript was called \n");
}

function uninitializeScript()
{
    // Add code here that you want to run everytime the script is unloaded.
    // We will just send a message to indicate that function was called.
    host.diagnostics.debugLog("****> uninitialize was called\n");

}

function main()
{
    // main is just another function name in JavaScript
    // main is not called by .scriptload or .scriptrun
    host.diagnostics.debugLog("****> main was called \n");
}
```

Creating a Debugger Visualizer in JavaScript

Custom visualization files allow you to group and organize data in a visualization structure that better reflects the data relationships and content. You can use the JavaScript debugger extensions to write debugger visualizers which act in a way very similar to NatVis. This is accomplished via authoring a JavaScript prototype object (or an ES6 class) which acts as the visualizer for a given data type. For more information about NatVis and the debugger see [dx \(Display NatVis Expression\)](#).

Example class - Simple1DArray

Consider an example of a C++ class which represents a single dimensional array. This class has two members,

`m_size` which is the overall size of the array, and `m_pValues` which is a pointer to a number of ints in memory equal to the `m_size` field.

```
class Simple1DArray
{
private:

    ULONG64 m_size;
    int *m_pValues;
};
```

We can use the `dx` command to look at the default data structure rendering.

```
0:000> dx g_array1D
g_array1D           [Type: Simple1DArray]
[+0x000] m_size      : 0x5 [Type: unsigned __int64]
[+0x008] m_pValues    : 0x8be32449e0 : 0 [Type: int *]
```

JavaScript Visualizer

In order to visualize this type, we need to author a prototype (or ES6) class which has all the fields and properties we want the debugger to show. We also need to have the `initializeScript` method return an object which tells the JavaScript provider to link our prototype as a visualizer for the given type.

```
function initializeScript()
{
    //
    // Define a visualizer class for the object.
    //
    class myVisualizer
    {
        //
        // Create an ES6 generator function which yields back all the values in the array.
        //
        *[Symbol.iterator]()
        {
            var size = this.m_size;
            var ptr = this.m_pValues;
            for (var i = 0; i < size; ++i)
            {
                yield ptr.dereference();

                //
                // Note that the .add(1) method here is effectively doing pointer arithmetic on
                // the underlying pointer. It is moving forward by the size of 1 object.
                //
                ptr = ptr.add(1);
            }
        }
    }

    return [new host.typeSignatureRegistration(myVisualizer, "Simple1DArray")];
}
```

Save the script in a file named `arrayVisualizer.js`.

Use the [.load \(Load Extension DLL\)](#) command to load the JavaScript provider.

```
0:000> .load C:\ScriptProviders\jsprovider.dll
```

Use .scriptload to load the array visualizer script.

```
0:000> .scriptload c:\WinDbg\Scripts\arrayVisualizer.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\arrayVisualizer.js'
```

Now, when the dx command is used the script visualizer will display rows of array content.

```
0:000> dx g_array1D
g_array1D : [object Object] [Type: Simple1DArray]
  [<Raw View>]  [Type: Simple1DArray]
  [0x0] : 0x0
  [0x1] : 0x1
  [0x2] : 0x2
  [0x3] : 0x3
  [0x4] : 0x4
```

In addition, this JavaScript visualization provides LINQ functionality, such as Select.

```
0:000> dx g_array1D.Select(n => n * 3),d
g_array1D.Select(n => n * 3),d
  [0] : 0
  [1] : 3
  [2] : 6
  [3] : 9
  [4] : 12
```

What Affects the Visualization

A prototype or class which is made the visualizer for a native type through a return of a host.typeSignatureRegistration object from initializeScript will have all of the properties and methods within JavaScript added to the native type. In addition, the following semantics apply:

- Any name which does not start with two underscores (_) will be available in the visualization.
- Names which are part of standard JavaScript objects or are part of protocols which the JavaScript provider creates will not show up in the visualization.
- An object can be made iterable via the support of [Symbol.iterator].
- An object can be made indexable via the support of a custom protocol consisting of several functions: getDimensionality, getValueAt, and optionally setValueAt.

Native and JavaScript Object Bridge

The bridge between JavaScript and the object model of the debugger is two-way. Native objects can be passed into JavaScript and JavaScript objects can be passed into the Debugger's expression evaluator. As an example of this, consider the addition of the following method in our script:

```
function multiplyBySeven(val)
{
    return val * 7;
}
```

This method can now be utilized in the example LINQ query above. First we load the JavaScript visualization.

```
0:000> .scriptload c:\WinDbg\Scripts\arrayVisualizer2.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\arrayVisualizer2.js'

0:000> dx @$myScript = Debugger.State.Scripts.arrayVisualizer2.Contents
```

Then we can use the multiplyBySeven function inline as shown below.

```
0:000> dx g_array1D.Select(@$myScript.multiplyBySeven),d
g_array1D.Select(@$myScript.multiplyBySeven),d
[0] : 0
[1] : 7
[2] : 14
[3] : 21
[4] : 28
```

Conditional Breakpoints with JavaScript

You can use JavaScript to do supplemental processing after a breakpoint is hit. For example, script can be used to examine other run time values and then determine if you want to automatically continue code execution or stop and do additional manual debugging.

For general information on working with breakpoints, see [Methods of Controlling Breakpoints](#).

DebugHandler.js Example Breakpoint Processing Script

This example will evaluate notepad's open and save dialog: *notepad!ShowOpenSaveDialog*. This script will evaluate the *pszCaption* variable to determine if the current dialog is an "Open" dialog or if it is a "Save As" dialog. If it's an open dialog, code execution will continue. If it's a save as dialog, code execution will stop, and the debugger will break in.

```
// Use JavaScript strict mode
"use strict";

// Define the invokeScript method to handle breakpoints

function invokeScript()
{
    var ctl = host.namespace.Debugger.Utility.Control;

    //Get the address of my string
    var address = host.evaluateExpression("pszCaption");

    //The open and save dialogs use the same function
    //When we hit the open dialog, continue.
    //When we hit the save dialog, break.
    if(host.memory.readWideString(address)=="Open"){
        //host.diagnostics.debugLog("We're opening, let's continue!\n");
        ctl.ExecuteCommand("gc");
    }else{
        //host.diagnostics.debugLog("We're saving, let's break!\n");
    }
}
```

Use the [.load \(Load Extension DLL\)](#) command to load the JavaScript provider.

```
0:000> .load jsprovider.dll
```

This command sets a breakpoint on notepad!ShowOpenSaveDialog, and will run the script above whenever that breakpoint is hit.

```
bp notepad!ShowOpenSaveDialog ".scriptrun C:\\WinDbg\\Scripts\\DebugHandler.js"
```

Then when the File > Save option is selected in notepad, the script is run, the g command is not sent, and a break in code execution occurs.

```
JavaScript script successfully loaded from 'C:\\WinDbg\\Scripts\\DebugHandler.js'
notepad!ShowOpenSaveDialog:
00007ff6`f9761884 48895c2408      mov     qword ptr [rsp+8],rbx ss:000000db`d2a9f2f0=0000021985fe2060
```

Work With 64-Bit Values in JavaScript Extensions

This section describes how 64-bit values passed into a JavaScript debugger extension behave. This issue arises as JavaScript only has the ability to store numbers using 53-bits.

64-Bit and JavaScript 53-Bit Storage

Ordinal values passed into JavaScript are normally marshaled as JavaScript numbers. The problem with this is that JavaScript numbers are 64-bit double precision floating point values. Any ordinal over 53-bits would lose precision on entry into JavaScript. This presents an issue for 64-bit pointers and other 64-bit ordinal values which may have flags in the highest bytes. In order to deal with this, any 64-bit native value (whether from native code or the data model) which enters JavaScript enters as a library type -- not as a JavaScript number. This library type will round trip back to native code without losing numeric precision.

Auto-Conversion

The library type for 64-bit ordinal values supports the standard JavaScript valueOf conversion. If the object is used in a math operation or other construct which requires value conversion, it will automatically convert to a JavaScript number. If loss of precision were to occur (the value utilizes more than 53-bits of ordinal precision), the JavaScript provider will throw an exception.

Note that if you use bitwise operators in JavaScript, you are further limited to 32-bits of ordinal precision.

This sample code sums two numbers and will be used to test the conversion of 64 bit values.

```

function playWith64BitValues(a64, b64)
{
    // Sum two numbers to demonstrate 64-bit behavior.
    //
    // Imagine a64==100, b64==100
    // The below would result in sum==1100 as a JavaScript number. No exception is thrown. The values
    auto-convert.
    //
    // Imagine a64==2^56, b64=1
    // The below will **Throw an Exception**. Conversion to numeric results in loss of precision!
    //
    var sum = a64 + b64;
    host.diagnostics.debugLog("Sum    >> ", sum, "\n");

}

function performOp64BitValues(a64, b64, op)
{
    //
    // Call a data model method passing 64-bit value. There is no loss of precision here. This round trips
    perfectly.
    // For example:
    // 0:000> dx @$myScript.playWith64BitValues(0x4444444444444444ull, 0x3333333333333333ull, (x, y) => x +
    y)
    // @$myScript.playWith64BitValues(0x4444444444444444ull, 0x3333333333333333ull, (x, y) => x + y) :
    0x7777777777777777
    //
    return op(a64, b64);
}

```

Use a text editor such as Notepad to create a text file named *PlayWith64BitValues.js*

Use the [.load \(Load Extension DLL\)](#) command to load the JavaScript provider.

```
0:000> .load jsprovider.dll
```

Use the [.scriptload](#) command to load the script.

```
0:000> .scriptload c:\WinDbg\Scripts\PlayWith64BitValues.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\PlayWith64BitValues.js'
```

To make the script a bit more convenient to work with, assign a variable in the debugger to hold the contents of the script using the [dx](#) command.

```
0:000> dx @$myScript = Debugger.State.Scripts.PlayWith64BitValues.Contents
```

Use the [dx](#) expression evaluator to call the [addTwoValues](#) function.

First we will calculate the value of $2^{53} = 9007199254740992$ (Hex 0x2000000000000000).

First to test, we will use $(2^{53}) - 2$ and see that it returns the correct value for the sum.

```
0:000> dx @$myScript.playWith64BitValues(9007199254740990, 9007199254740990)
Sum    >> 18014398509481980
```

Then we will calculate $(2^{53}) - 1 = 9007199254740991$. This returns the error indicating that the conversion process will lose precision, so this is the largest value that can be used with the sum method in JavaScript code.

```
0:000> dx @$myScript.playWith64BitValues(9007199254740990, 9007199254740991)
Error: 64 bit value loses precision on conversion to number
```

Call a data model method passing 64-bit values. There is no loss of precision here.

```
0:001> dx @$myScript.performOp64BitValues( 0x7FFFFFFFFFFFFFFF, 0x7FFFFFFFFFFFFFFF, (x, y) => x + y)
@$myScript.performOp64BitValues( 0x7FFFFFFFFFFFFFFF, 0x7FFFFFFFFFFFFFFF, (x, y) => x + y) :
0xfffffffffffffffffe
```

Comparison

The 64-bit library type is a JavaScript object and not a value type such as a JavaScript number. This has some implications for comparison operations. Normally, equality (==) on an object would indicate that operands refer to the same object and not the same value. The JavaScript provider mitigates this by tracking live references to 64-bit values and returning the same "immutable" object for non-collected 64-bit value. This means that for comparison, the following would occur.

```
// Comparison with 64 Bit Values

function comparisonWith64BitValues(a64, b64)
{
    //
    // No auto-conversion occurs here. This is an *EFFECTIVE* value comparison. This works with ordinals
    with above 53-bits of precision.
    //
    var areEqual = (a64 == b64);
    host.diagnostics.debugLog("areEqual    >> ", areEqual, "\n");
    var areNotEqual = (a64 != b64);
    host.diagnostics.debugLog("areNotEqual    >> ", areNotEqual, "\n");

    //
    // Auto-conversion occurs here. This will throw if a64 does not pack into a JavaScript number with no
    loss of precision.
    //
    var isEqualTo42 = (a64 == 42);
    host.diagnostics.debugLog("isEqualTo42    >> ", isEqualTo42, "\n");
    var isLess = (a64 < b64);
    host.diagnostics.debugLog("isLess    >> ", isLess, "\n");
```

Use a text editor such as Notepad to create a text file named *ComparisonWith64BitValues.js*

Use the [.load \(Load Extension DLL\)](#) command to load the JavaScript provider.

```
0:000> .load jsprovider.dll
```

Use the .scriptload command to load the script.

```
0:000> .scriptload c:\WinDbg\Scripts\ComparisonWith64BitValues.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\ComparisonWith64BitValues.js'
```

To make the script a bit more convenient to work with, assign a variable in the debugger to hold the contents of the script using the dx command.

```
0:000> dx @$myScript = Debugger.State.Scripts.comparisonWith64BitValues.Contents
```

First to test, we will use $(2^{53}) - 2$ and see that it returns the expected values.

```
0:001> dx @$myScript.comparisonWith64BitValues(9007199254740990, 9007199254740990)
areEqual    >> true
areNotEqual  >> false
isEqualTo42  >> false
isLess      >> false
```

We will also try the number 42 as the first value to validate the comparison operator is working as it should.

```
0:001> dx @$myScript.comparisonWith64BitValues(42, 9007199254740990)
areEqual    >> false
areNotEqual  >> true
isEqualTo42  >> true
isLess      >> true
```

Then we will calculate $(2^{53}) - 1 = 9007199254740991$. This value returns the error indicating that the conversion process will lose precision, so this is the largest value that can be used with the comparison operators in JavaScript code.

```
0:000> dx @$myScript.playWith64BitValues(9007199254740990, 9007199254740991)
Error: 64 bit value loses precision on conversion to number
```

Maintaining Precision in Operations

In order to allow a debugger extension to maintain precision, a set of math functions are projected on top of the 64-bit library type. If the extension needs (or may possibly) need precision above 53-bits for incoming 64-bit values, the following methods should be utilized instead of relying on standard operators:

Method Name	Signature	Description
asNumber	.asNumber()	Converts the 64-bit value to a JavaScript number. If loss of precision occurs, AN EXCEPTION IS THROWN
convertToNumber	.convertToNumber()	Converts the 64-bit value to a JavaScript number. If loss of precision occurs, NO EXCEPTION IS THROWN
getLowPart	.getLowPart()	Converts the lower 32-bits of the 64-bit value to a JavaScript number
getHighPart	.getHighPart()	Converts the high 32-bits of the 64-bit value to a JavaScript number
add	.add(value)	Adds a value to the 64-bit value and returns the result
subtract	.subtract(value)	Subtracts a value from the 64-bit value and returns the result
multiply	.multiply(value)	Multiplies the 64-bit value by the supplied value and returns the result

divide	.divide(value)	Divides the 64-bit value by the supplied value and returns the result
bitwiseAnd	.bitwiseAnd(value)	Computes the bitwise and of the 64-bit value with the supplied value and returns the result
bitwiseOr	.bitwiseOr(value)	Computes the bitwise or of the 64-bit value with the supplied value and returns the result
bitwiseXor	.bitwiseXor(value)	Computes the bitwise xor of the 64-bit value with the supplied value and returns the result
bitwiseShiftLeft	.bitwiseShiftLeft(value)	Shifts the 64-bit value left by the given amount and returns the result
bitwiseShiftRight	.bitwiseShiftRight(value)	Shifts the 64-bit value right by the given amount and returns the result
toString	.toString([radix])	Converts the 64-bit value to a display string in the default radix (or the optionally supplied radix)

JavaScript Debugger Example Scripts

5/31/2017 • 12 min to read • [Edit Online](#)

This topic provides the following user and kernel mode JavaScript code samples.

- [Data Filtering: Plug and Play Device Tree in KD \(Kernel Mode\)](#)
- [Extend Devices Specific To Multimedia \(Kernel Mode\)](#)
- [Adding Bus Information to _DEVICE_OBJECT \(Kernel Mode\)](#)
- [Find an Application Title \(User Mode\)](#)

Working with Samples

Use the general process to test any of the samples.

1. Determine if the sample JavaScript is intended for kernel or user mode debugging. Then either load an appropriate dump file or establish a live connection to a target system.
2. Use a text editor such as Notepad to create a text file named and save it with a .js file extension, such as *HelloWorld.js*

```
// WinDbg JavaScript sample
// Says Hello World!

// Code at root will be run with .scriptrun and .scriptload
host.diagnostics.debugLog("****> Hello World! \n");

function sayHi()
{
    //Say Hi
    host.diagnostics.debugLog("Hi from JavaScript! \n");
}
```

1. Use the **.load (Load Extension DLL)** command to load the JavaScript provider.

```
0:000> .load jsprovider.dll
```

1. Use the **.scriptrun (Run Script)** command to load and execute the script. The .scriptrun command will run code at the root/top and the code under the function names *initializeScript* and *invokeScript*.

```
0:000> .scriptrun c:\WinDbg\Scripts\HelloWorld.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\HelloWorld.js'
****> Hello World!
```

1. If the script contains a uniquely named function, use the dx command to execute that function, that is located in `Debugger.State.Scripts.ScriptName.Contents.FunctionName`.

```
0:001> dx Debugger.State.Scripts.HelloWorld.Contents.sayHi()
Hi from JavaScript!
Debugger.State.Scripts.HelloWorld.Contents.sayHi()
```

Refer to [JavaScript Debugger Scripting](#) for additional information about working with JavaScript.

Data Filtering: Plug and Play Device Tree in KD (Kernel Mode)

This sample code filters the device node tree to display just devices that contain a path of PCI that are started.

This script is intended to support kernel mode debugging.

You can use the !devnode 0 1 command to display information about the device tree. For more information, see [!devnode](#).

```
// PlugAndPlayDeviceTree.js
// An ES6 generator function which recursively filters the device tree looking for PCI devices in the started
// state.
//
function *filterDevices(deviceNode)
{
    //
    // If the device instance path has "PCI" in it and is started (state == 776), yield it from the generator.
    //
    if (deviceNode.InstancePath.indexOf("PCI") != -1 && deviceNode.State == 776)
    {
        yield deviceNode;
    }

    //
    // Recursively invoke the generator for all children of the device node.
    //
    for (var childNode of deviceNode.Children)
    {
        yield* filterDevices(childNode);
    }
}

//
// A function which finds the device tree of the first session in the debugger and passes it to our filter
// function.
//
function filterAllDevices()
{
    return filterDevices(host.namespace.Debugger.Sessions.First().Devices.DeviceTree.First());
}
```

Either load a kernel dump file or establish a kernel mode connection to a target system.

```
0: kd> !load jsprovider.dll
```

```
0: kd> .scriptload c:\WinDbg\Scripts\deviceFilter.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\deviceFilter.js'
```

Call the filterAllDevices() function.

```
0: kd> dx Debugger.State.Scripts.PlugAndPlayDeviceTree.Contents.filterAllDevices()
Debugger.State.Scripts.PlugAndPlayDeviceTree.Contents.filterAllDevices() : [object Generator]
[0x0]      : PCI\VEN_8086&DEV_D131&SUBSYS_304A103C&REV_11\3&21436425&0&00
[0x1]      : PCI\VEN_8086&DEV_D138&SUBSYS_304A103C&REV_11\3&21436425&0&18 (pci)
[0x2]      : PCI\VEN_10DE&DEV_06FD&SUBSYS_062E10DE&REV_A1\4&324c21a&0&0018 (nvlddmkm)
[0x3]      : PCI\VEN_8086&DEV_3B64&SUBSYS_304A103C&REV_06\3&21436425&0&B0 (HECIx64)
[0x4]      : PCI\VEN_8086&DEV_3B3C&SUBSYS_304A103C&REV_05\3&21436425&0&D0 (usbehci)
[0x5]      : PCI\VEN_8086&DEV_3B56&SUBSYS_304A103C&REV_05\3&21436425&0&D8 (HDAudBus)
...
```

Each of these objects presented above, automatically supports DML, and can be clicked through just as with any other dx query.

Alternatively to using this script, it is possible to use a LINQ query to accomplish a similar result.

```
0: kd> dx @$cursession.Devices.DeviceTree.Flatten(n => n.Children).Where(n => n.InstancePath.Contains("PCI") && n.State == 776)
@$cursession.Devices.DeviceTree.Flatten(n => n.Children).Where(n => n.InstancePath.Contains("PCI") && n.State == 776)
[0x0]      : PCI\VEN_8086&DEV_D131&SUBSYS_304A103C&REV_11\3&21436425&0&00
[0x1]      : PCI\VEN_8086&DEV_D138&SUBSYS_304A103C&REV_11\3&21436425&0&018 (pci)
[0x2]      : PCI\VEN_10DE&DEV_06FD&SUBSYS_062E10DE&REV_A1\4&324c21a&0&0018 (nvlddmkm)
[0x3]      : PCI\VEN_8086&DEV_3B64&SUBSYS_304A103C&REV_06\3&21436425&0&B0 (HECIx64)
[0x4]      : PCI\VEN_8086&DEV_3B3C&SUBSYS_304A103C&REV_05\3&21436425&0&D0 (usbehci)
[0x5]      : PCI\VEN_8086&DEV_3B56&SUBSYS_304A103C&REV_05\3&21436425&0&D8 (HDAudBus)
...
...
```

Extend Devices Specific To Multimedia (Kernel Mode)

This larger JavaScript example extends a kernel _DEVICE_OBJECT for information specific to multimedia and adds StreamingDevices to a debugger session.

This script is intended to support kernel mode debugging.

Note that the choice to extend Session with StreamingDevices is done for example purposes only. This should be either left to _DEVICE_OBJECT only or deeper inside a namespace under the existing .Devices.* hierarchy.

```
// StreamingFinder.js
// Extends a kernel _DEVICE_OBJECT for information specific to multimedia
// and adds StreamingDevices to a debugger session.
//

"use strict";

function initializeScript()
{
    // isStreamingDeviceObject:
    //
    // Returns whether devObj (as a _DEVICE_OBJECT -- not a pointer) looks like it is a device
    // object for a streaming device.
    //
    function isStreamingDeviceObject(devObj)
    {
        try
        {
            var devExt = devObj.DeviceExtension;
            var possibleStreamingExtPtrPtr = host.createPointerObject(devExt.address, "ks.sys",
"__KSIDevice_Header **", devObj);
            var possibleStreamingExt = possibleStreamingExtPtrPtr.dereference().dereference();
            var baseDevice = possibleStreamingExt.BaseDevice;

            if (devObj.targetLocation == baseDevice.dereference().targetLocation)
            {
                return true;
            }
        }
        //
        // The above code expects to fail (walking into invalid or paged out memory) often. A failure to read
        // the memory
        // of the target process will result in an exception. Catch such exception and indicate that the
        // object does not
        // match the profile of a "streaming device object".
        //
        catch(exc)
```

```

        }

        return false;
    }

    // findStreamingFDO(pdo):
    //
    // From a physical device object, walks up the device stack and attempts to find a device which
    // looks like a streaming device (and is thus assumed to be the FDO).  pdo is a pointer to
    // the _DEVICE_OBJECT for the pdo.
    //
    function findStreamingFDO(pdo)
    {
        for (var device of pdo.UpperDevices)
        {
            if (isStreamingDeviceObject(device.dereference()))
            {
                return device;
            }
        }

        return null;
    }

    // streamingDeviceList:
    //
    // A class which enumerates all streaming devices on the system.
    //
    class streamingDeviceList
    {
        constructor(session)
        {
            this.__session = session;
        }

        *[Symbol.iterator]()
        {
            //
            // Get the list of all PDOs from PNP using LINQ:
            //
            var allPDOs = this.__session.Devices.DeviceTree.Flatten(function(dev) { return dev.Children; })
                .Select (function(dev) { return
                    dev.PhysicalDeviceObject; });

            //
            // Walk the stack up each PDO to find the functional device which looks like a KS device.  This is
            // a very simple heuristic test: the back pointer to the device in the KS device extension is
            // accurate.  Make sure this is wrapped in a try/catch to avoid invalid memory reads causing
            // us to bail out.
            //
            // Don't even bother checking the PDO.
            //
            for (var pdo of allPDOs)
            {
                var fdo = findStreamingFDO(pdo);
                if (fdo != null)
                {
                    yield fdo;
                }
            }
        }
    }

    // streamingDeviceExtension:
    //
    // An object which will extend "session" and include the list of streaming devices.
    //
    class streamingDeviceExtension

```

```

class StreamingDeviceExtension
{
    get StreamingDevices()
    {
        return new streamingDeviceList(this);
    }
};

// createEntryList:
//
// An abstraction over the create entry list within a streaming device.
//
class createEntryList
{
    constructor(ksHeader)
    {
        this.__ksHeader = ksHeader;
    }

    *[Symbol.iterator]()
    {
        for (var entry of
host.namespace.Debugger.Utility.Collections.FromListEntry(this.__ksHeader.ChildCreateHandlerList,
"ks!KSICREATE_ENTRY", "ListEntry"))
        {
            if (!entry.CreateItem.Create.isNull)
            {
                yield entry;
            }
        }
    }
}

// streamingInformation:
//
// Represents the streaming state of a device.
//
class streamingInformation
{
    constructor(fdo)
    {
        this.__fdo = fdo;

        var devExt = fdo.DeviceExtension;
        var streamingExtPtrPtr = host.createPointerObject(devExt.address, "ks.sys", "_KSIDevice_HEADER
**", fdo);
        this.__ksHeader = streamingExtPtrPtr.dereference().dereference();
    }

    get CreateEntries()
    {
        return new createEntryList(this.__ksHeader);
    }
}

// createEntryVisualizer:
//
// A visualizer for KSICREATE_ENTRY
//
class createEntryVisualizer
{
    toString()
    {
        return this.CreateItem.ObjectClass.toString();
    }

    get CreateContext()
    {
        //
        // This is probably not entirely accurate. The context is not *REQUIRED* to be an Unknown
    }
}

```

```

// This is probably not entirely accurate. The context is not "REQUIRED" to be an IUnknown.
// More analysis should probably be performed.
//
return host.createTypedObject(this.CreateItem.Context.address, "ks.sys", "IUnknown", this);
}

}

// deviceExtension:
//
// Extends our notion of a device in the device tree to place streaming information on
// top of it.
//
class deviceExtension
{
    get StreamingState()
    {
        if (isStreamingDeviceObject(this))
        {
            return new streamingInformation(this);
        }

        //
        // If we cannot find a streaming FDO, returning undefined will indicate that there is no value
        // to the property.
        //
        return undefined;
    }
}

return [new host.namedModelParent(streamingDeviceExtension, "Debugger.Models.Session"),
        new host.typeSignatureExtension(deviceExtension, "_DEVICE_OBJECT"),
        new host.typeSignatureRegistration(createEntryVisualizer, "KSICREATE_ENTRY")]
}

```

First load the script provider as described previously. Then load the script.

```

0: kd> .scriptload c:\WinDbg\Scripts\StreamingFinder.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\StreamingFinder.js'

```

Then use the dx command to access the new StreamingDevices capabilities that the script provides.

```

0: kd> dx -r3 @$cursession.StreamingDevices.Select(d => d->StreamingState.CreateEntries)
@$cursession.StreamingDevices.Select(d => d->StreamingState.CreateEntries)

Adding Bus Information to _DEVICE_OBJECT (Kernel Mode)

This script extends the visualization of _DEVICE_OBJECT to add a BusInformation field which has PCI specific information underneath it. The manner and namespacing of this sample are still being discussed. It should be considered a sample of the capabilities of the JavaScript provider.

This script is intended to support kernel mode debugging.

```

"use strict";

*****
DeviceExtensionInformation.js:

An example which extends _DEVICE_OBJECT to add bus specific information
to each device object.

NOTE: The means of conditionally adding and the style of namespacing this
are still being discussed. This currently serves as an example of the capability
of JavaScript extensions.

*****

function initializeScript()

Find an Application Title (User Mode)

This example iterates through all the threads in the debugger's current process, finds a frame which includes `__mainCRTStartup` and then returns the string from the `StartupInfo.lpTitle` within the CRT's startup. This script shows examples of iteration, string manipulation, and LINQ queries within JavaScript.

This script is intended to support user mode debugging.

```
// TitleFinder.js
// A function which uses just JavaScript concepts to find the title of an application
//
function findTitle()
{
    var curProcess = host.currentProcess;
    for (var thread of curProcess.Threads)
    {
        for (var frame of thread.Stack.Frames)
        {
            if (frame.toString().includes("__mainCRTStartup"))
            {
                var locals = frame.LocalVariables;

                //
                // locals.StartupInfo.lpTitle is just an unsigned short *. We need to actually call an API to
                // read the UTF-16 string in the target address space. This would be true even if this were
                // a char* or wchar_t*.
                //
                return host.memory.readWideString(locals.StartupInfo.lpTitle);
            }
        }
    }
}

//
// A function which uses both JavaScript and integrated LINQ concepts to do the same.
//
function findTitleWithLINQ()
{
    var isMainFrame = function(frame) { return frame.toString().includes("__mainCRTStartup"); };
    var isMainThread = function(thread) { return thread.Stack.Frames.Any(isMainFrame); };

    var curProcess = host.currentProcess;
    var mainThread = curProcess.Threads.Where(isMainThread).First();
    var mainFrame = mainThread.Stack.Frames.Where(isMainFrame).First();

    var locals = mainFrame.LocalVariables;

    //
    // locals.StartupInfo.lpTitle is just an unsigned short *. We need to actually call an API to
    // read the UTF-16 string in the target address space. This would be true even if this were
    // a char* or wchar_t*.
    //
    return host.memory.readWideString(locals.StartupInfo.lpTitle);
}
```

```
0: kd> .scriptload c:\WinDbg\Scripts\TitleFinder.js
JavaScript script successfully loaded from 'c:\WinDbg\Scripts\TitleFinder.js'
```

Calling the `findTitle()` function returns `notepad.exe`

```
0:000> dx Debugger.State.Scripts.TitleFinder.Contents.findTitle()
Debugger.State.Scripts.TitleFinder.Contents.findTitle() : C:\Windows\System32\notepad.exe
```

Calling the LINQ version, `findTitleWithLINQ()` also returns `notepad.exe`

```
0:000> dx Debugger.State.Scripts.TitleFinder.Contents.findTitleWithLINQ()
Debugger.State.Scripts.titleFinder.Contents.findTitleWithLINQ() : C:\Windows\System32\notepad.exe
```

Native Debugger Objects in JavaScript Extensions

5/31/2017 • 33 min to read • [Edit Online](#)

Native debugger objects represent various constructs and behaviors of the debugger environment. The objects can be passed into (or acquired in) JavaScript extensions to manipulate the state of the debugger.

Example debugger objects include the following.

- Session
- Threads / Thread
- Processes / Process
- Stack Frames / Stack Frame
- Local Variables
- Modules / Module
- Utility
- State
- Settings

For example the `host.namespace.Debugger.Utility.Control.ExecuteCommand` object can be used to send the `u` command to the debugger with following two lines of JavaScript code.

```
var ctl = host.namespace.Debugger.Utility.Control;
var output = ctl.ExecuteCommand("u");
```

This topic describes how to work with common objects and provides reference information on their attributes and behaviors.

[Extending the Debugger via the Data Model](#) [Extending a Debugger Object in JavaScript](#) [Debugger Objects in JavaScript Extensions](#) [Host APIs for JavaScript Extensions](#) [Data Model Concepts in JavaScript](#) [Debugger Data Model Design Considerations](#) For general information about working with JavaScript, see [JavaScript Debugger Scripting](#). For JavaScript examples that use the debugger objects, see [JavaScript Debugger Example Scripts](#). For information about working with the settings objects, see [.settings \(Set Debug Settings\)](#).

To explore the objects available in a debugger session, use the [dx \(Display NatVis Expression\)](#) command. For example, you can display some of the top level debugger objects with this dx command.

```

0: kd> dx -r2 Debugger
Debugger
  Sessions      : [object Object]
    [0x0]        : Remote KD: KdSrv:Server=@{<Local>},Trans=@{NET:Port=50000,Key=1.2.3.4,Target}
  Settings
    Debug
    Display
    EngineInitialization
    Extensions
    Input
    Sources
    Symbols
    AutoSaveSettings : false
  State
    DebuggerVariables
    PseudoRegisters
    Scripts
    UserVariables
  Utility
    Collections
    Control
    Objects

```

All of the items listed above are clickable DML and can be recursed further down to view the debugger object structure.

Extending the Debugger via the Data Model

The debugger data model allows for the creation of an interface to information about applications and drivers in Windows that has the following attributes.

- Is discoverable and organized- a logically structured name space can be queried using the dx command.
- Can be queried using LINQ- This allows for extraction and sorting of data using a standard query language.
- Can be logically and consistently extended - Extensible using techniques described in this topic with debugger scripting providers such as Natvis and JavaScript.

Extending a Debugger Object in JavaScript

In addition to being able to create a visualizer in JavaScript, script extensions can also modify the core concepts of the debugger - sessions, processes, threads, stacks, stack frames, local variables - and even publish themselves as extension points that other extensions can consume.

This section describes how to extend a core concept within the debugger. Extensions which are built to be shared should conform to the guidelines presented in [Debugger Data Model Design Considerations](#).

Registering an Extension

A script can register the fact that it provides an extension through an entry in the array returned from the initializeScript method.

```

function initializeScript()
{
    return [new host.namedModelParent(comProcessExtension, "Debugger.Models.Process")];
}

```

The presence of a host.namedModelParent object within the returned array indicates to the debugger that a given prototype object or ES6 class (comProcessExtension in this case) is going to be a parent data model to the model which is registered under the name Debugger.Models.Process.

Debugger Object Extension Points

The following debugger extension points are integral to the debugger and available to be used by script providers such as JavaScript.

Debugger.Models.Sessions	The list of sessions (targets) that the debugger is attached to
Debugger.Models.Session	An individual session (target) that the debugger is attached to (live user mode, KD, etc...)
Debugger.Models.Processes	The list of processes within a session
Debugger.Models.Threads	The list of threads within a process
Debugger.Models.Thread	An individual thread within a process (regardless of whether user or kernel mode)
Debugger.Models.Stack	The stack of a thread
Debugger.Models.StackFrames	The collection of frames which make up a stack
Debugger.Models.StackFrame	An individual stack frame within a stack
Debugger.Models.LocalVariables	The local variables within a stack frame
Debugger.Models.Parameters	The parameters for a call within a stack frame
Debugger.Models.Module	An individual module within the address space of a process

Additional Data Model Objects

In addition, there are some additional data model objects that are defined by the core data model.

DataModel.Models.Intrinsic	An intrinsic value (ordinals, floats, etc...)
DataModel.Models.String	A string
DataModel.Models.Array	A native array
DataModel.Models.Guid	A GUID
DataModel.Models.Error	An error object
DataModel.Models.Concepts.Iterable	Applied to every object which is iterable
DataModel.Models.Concepts.StringDisplayable	Applied to every object which has a display string conversion

Example COM Debugger Object Extension Overview

Let's consider an example. Imagine that you want to create a debugger extension to display information specific to COM, such as the global interface table (GIT).

In the past, there might be an existing debugger extension with a number of commands which provide a means to access things about COM. One command might display process centric information (the global interface table for instance). Another command might provide thread centric information such as what apartment code is executing within. You might need to know about and load a second debugger extension to explore other aspects of COM.

Instead of having a set of hard to discover commands, a JavaScript extension can modify the debugger's concept of what a process and a thread is, to add this information in a way that's natural, explorable, and composable with other debugger extensions.

User or Kernel Mode Debugger Object Extension

The debugger and the debugger objects have different behavior in user and kernel mode. When you create your debugger model objects you need to decide which environments you will be working in. Because we will be working with COM in user mode, we will create and test this com extension in user mode. In other situations, you may be able to create a debugger JavaScript that will work in both user and kernel mode debugging.

Creating a Sub-Namespace

Going back to our example, we can define a prototype or ES6 class, *comProcessExtension* which contains the set of things we want to add to a process object.

Important The intent with the sub-namespace is to create a logically structured and naturally explorable paradigm. For example, avoid dumping unrelated items into the same sub-namespace. Carefully review the information discussed in [Debugger Data Model Design Considerations](#) before creating a sub-namespace.

In this code snippet, we create add a sub-namespace called 'COM' on to the existing process debugger object.

```
var comProcessExtension =
{
    //
    // Add a sub-namespace called 'COM' on process.
    //
    get COM()
    {
        //
        // What is 'this' below...?  It's the debugger's process object.  Yes -- this means that there is a
        // cross-language
        // object hierarchy here.  A C++ object implemented in the debugger has a parent model (prototype)
        which is
        // implemented in JavaScript.
        //
        return new comNamespace(this);
    }
}
```

Namespace Implementation

Next, create the object which implements the sub-namespace COM on a process.

Important

There can be multiple processes (whether attached to such in user mode or under KD). This extension cannot assume that the present state of the debugger is the what the user intended. Someone can capture <someProcess>.COM in a variable and modify it, which can lead to presenting information from the wrong process context. The solution is to add code in the extension so that each instantiation will keep track of what process it is attached to. For this code sample, this information is passed via the 'this' pointer of the property.

```
this.__process = process;
```

```

class comNamespace
{
    constructor(process)
    {
        //
        // This is an entirely JavaScript object. Each instantiation of a comNamespace will keep track
        // of what process it is attached to (passed via the 'this' pointer of the property getter
        // we authored above.
        //
        this.__process = process;
    }

    get GlobalObjects()
    {
        return new globalObjects(this.__process);
    }
}

```

Implementation logic for the COM global interface table

To separate this out the implementation logic for the COM global interface table more clearly, we'll define one ES6 class, *gipTable* which abstracts away the COM GIP table and another, *globalObjects*, which is what will get returned from the GlobalObjects() getter defined in the Namespace Implementation code snip shown above. All of these details can be hidden inside the closure of initializeScript to avoid publishing any of these internal details out into the debugger namespace.

```

// gipTable:
//
// Internal class which abstracts away the GIP Table. It iterates objects of the form
// {entry : GIPEntry, cookie : GIT cookie}
//
class gipTable
{
    constructor(gipProcess)
    {
        //
        // Windows 8 through certain builds of Windows 10, it's in CGIPTable::_palloc. In certain builds
        // of Windows 10 and later, this has been moved to GIPEntry::_palloc. We need to check which.
        //
        var gipAllocator = undefined;
        try
        {
            gipAllocator = host.getModuleSymbol("combase.dll", "CGIPTable::_palloc", "CPageAllocator",
gipProcess)._palloc;
        }
        catch(err)
        {
        }

        if (gipAllocator == undefined)
        {
            gipAllocator = host.getModuleSymbol("combase.dll", "GIPEntry::_palloc", "CPageAllocator",
gipProcess)._palloc;
        }

        this.__data = {
            process : gipProcess,
            allocator : gipAllocator,
            pageList : gipAllocator._pPageListStart,
            pageCount : gipAllocator._cPages,
            entriesPerPage : gipAllocator._cEntriesPerPage,
            bytesPerEntry : gipAllocator._cbPerEntry,
            PAGESHIFT : 16,
            PAGEMASK : 0x0000FFFF,
            SEONOMASK : 0xFF00
        }
    }
}

```

```

        );
    }

 *[Symbol.iterator]()
{
    for (var pageNum = 0; pageNum < this.__data.pageCount; ++pageNum)
    {
        var page = this.__data.pageList[pageNum];
        for (var entryNum = 0; entryNum < this.__data.entriesPerPage; ++entryNum)
        {
            var entryAddress = page.address.add(this.__data.bytesPerEntry * entryNum);
            var gipEntry = host.createPointerObject(entryAddress, "combase.dll", "GIPEntry *",
this.__data.process);
            if (gipEntry.cUsage != -1 && gipEntry.dwType != 0)
            {
                yield {entry : gipEntry, cookie : (gipEntry.dwSeqNo | (pageNum << this.__data.PAGESHIFT) |
entryNum)};
            }
        }
    }
}

entryFromCookie(cookie)
{
    var sequenceNo = (cookie & this.__data.SEQNOMASK);
    cookie = cookie & ~sequenceNo;
    var pageNum = (cookie >> this.__data.PAGESHIFT);
    if (pageNum < this.__data.pageCount)
    {
        var page = this.__data.pageList[pageNum];
        var entryNum = (cookie & this.__data.PAGEMASK);
        if (entryNum < this.__data.entriesPerPage)
        {
            var entryAddress = page.address.add(this.__data.bytesPerEntry * entryNum);
            var gipEntry = host.createPointerObject(entryAddress, "combase.dll", "GIPEntry *",
this.__data.process);
            if (gipEntry.cUsage != -1 && gipEntry.dwType != 0 && gipEntry.dwSeqNo == sequenceNo)
            {
                return {entry : gipEntry, cookie : (gipEntry.dwSeqNo | (pageNum << this.__data.PAGESHIFT) |
entryNum)};
            }
        }
    }
}

//  

// If this exception flows back to C/C++, it will be a failed HRESULT (according to the type of error  

-- here E_BOUNDS)  

// with the message being encapsulated by an error object.  

//  

// throw new RangeError("Unable to find specified value");
}

}

// globalObjects:  

//  

// The class which presents how we want the GIP table to look to the data model. It iterates the actual  

// objects  

// in the GIP table indexed by their cookie.  

//  

class globalObjects
{
    constructor(process)
    {
        this.__gipTable = new gipTable(process);
    }
}

```

```

        }

        *[Symbol.iterator]()
        {
            for (var gipCombo of this.__gipTable)
            {
                yield new host.indexedValue(gipCombo.entry.pUnk, [gipCombo.cookie]);
            }
        }

        getDimensionality()
        {
            return 1;
        }

        getValueAt(cookie)
        {
            return this.__gipTable.entryFromCookie(cookie).entry.pUnk;
        }
    }
}

```

Lastly, use `host.namedModelRegistration` to register the new COM functionality.

```

function initializeScript()
{
    return [new host.namedModelParent(comProcessExtension, "Debugger.Models.Process"),
            new host.namedModelRegistration(comNamespace, "Debugger.Models.ComProcess")];
}

```

Save the code to `GipTableAbstractor.js` using an application such as notepad.

Here is the process information available in user mode before loading this extension.

```

0:000:x86> dx @$curprocess
@$curprocess          : DataBinding.exe
Name      : DataBinding.exe
Id        : 0x1b9c
Threads
Modules

```

Load the JavaScript scripting provider and the extension.

```

0:000:x86> !load jsprovider.dll
0:000:x86> .scriptload C:\JSExtensions\GipTableAbstractor.js
JavaScript script successfully loaded from 'C:\JSExtensions\GipTableAbstractor.js'

```

Then use the `dx` command to display information about the process using the predefined `@$curprocess`.

```

0:000:x86> dx @$curprocess
@$curprocess          : DataBinding.exe
Name      : DataBinding.exe
Id        : 0x1b9c
Threads
Modules
COM      : [object Object]

```

```

0:000:x86> dx @$curprocess.COM
@$curprocess.COM : [object Object]
  GlobalObjects : [object Object]
0:000:x86> dx @$curprocess.COM.GlobalObjects
@$curprocess.COM.GlobalObjects : [object Object]
  [0x100] : 0x12f4fb0 [Type: IUnknown *]

  [0x302] : 0x37ea910 [Type: IUnknown *]
  [0x403] : 0x37fcfe0 [Type: IUnknown *]
  [0x504] : 0x12fe1d0 [Type: IUnknown *]
  [0x605] : 0x59f04e8 [Type: IUnknown *]
  [0x706] : 0x59f0eb8 [Type: IUnknown *]
  [0x807] : 0x59f5550 [Type: IUnknown *]
  [0x908] : 0x12fe340 [Type: IUnknown *]
  [0xa09] : 0x5afcb58 [Type: IUnknown *]

```

This table is also programmatically accessible via GIT cookie.

```

0:000:x86> dx @$curprocess.COM.GlobalObjects[0xa09]
@$curprocess.COM.GlobalObjects[0xa09] : 0x5afcb58 [Type: IUnknown *]
  [+0x00c] __abi_reference_count [Type: __abi_FTMWeakRefData]
  [+0x014] __capture [Type: Platform::Details::__abi_CapturePtr]

```

Extending Debugger Object Concepts with LINQ

In addition to being able to extend objects like process and thread, JavaScript can extend concepts associated with the data model as well. For example, it is possible to add a new LINQ method to every iterable. Consider an example extension, "DuplicateDataModel" which duplicates every entry in an iterable N times. The following code shows how this could be implemented.

```

function initializeScript()
{
  var newLinqMethod =
  {
    Duplicate : function *(n)
    {
      for (var val of this)
      {
        for (var i = 0; i < n; ++i)
        {
          yield val;
        }
      };
    }
  };

  return [new host.namedModelParent(newLinqMethod, "DataModel.Models.Concepts.Iterable")];
}

```

Save the code to DuplicateDataModel.js using an application such as notepad.

Load the JavaScript scripting provider if necessary and then load the DuplicateDataModel.js extension.

```

0:000:x86> !load jsprovider.dll
0:000:x86> .scriptload C:\JSExtensions\DuplicateDataModel.js
JavaScript script successfully loaded from 'C:\JSExtensions\DuplicateDataModel.js'

```

Use the dx command to test the new Duplicate function.

```

0: kd> dx -r1 Debugger.Sessions.First().Processes.First().Threads.Duplicate(2),d
Debugger.Sessions.First().Processes.First().Threads.Duplicate(2),d : [object Generator]
[0] : nt!DbgBreakPointWithStatus (fffff800`9696ca60)
[1] : nt!DbgBreakPointWithStatus (fffff800`9696ca60)
[2] : intelppm!MWaitIdle+0x18 (fffff805`0e351348)
[3] : intelppm!MWaitIdle+0x18 (fffff805`0e351348)
...

```

Debugger Objects in JavaScript Extensions

Passing Native Objects

Debugger objects can be passed into or acquired in JavaScript extensions in a variety of ways.

- They can be passed to JavaScript functions or methods
- They can be the instance object for a JavaScript prototype (as a visualizer, for instance)
- They can be returned from host methods designed to create native debugger objects
- They can be returned from host methods designed to create debugger native objects

Debugger objects that are passed to a JavaScript extension have a set of functionality that is described in this section.

- Property Access
- Projected Names
- Special Types Pertaining to Native Debugger Objects
- Additional Attributes

Property Access

While there are some properties on objects which are placed there by the JavaScript provider itself, the majority of properties on a native object which enters JavaScript are provided by the data model. This means that for a property access --- `object.propertyName` or `object[propertyName]`, the following will occur.

- If `propertyName` is the name of a property projected onto the object by the JavaScript provider itself, it will resolve to this first; otherwise
- If `propertyName` is the name of a key projected onto the object by the data model (another Visualizer), it will resolve to this name second; otherwise
- If `propertyName` is the name of a field of the native object, it will resolve to this name third; otherwise
- If `object` is a pointer, the pointer will be dereferenced, and the cycle above will continue (a projected property of the dereferenced object followed by a key followed by a native field)

The normal means of property access in JavaScript -- `object.propertyName` and `object[propertyName]` -- will access the underlying native fields of an object, much as the 'dx' command would within the debugger.

Projected Names

The following properties (and methods) are projected onto native objects which enter JavaScript.

METHOD	SIGNATURE	DESCRIPTION
hostContext	Property	Returns an object which represents the context the object is within (the address space, debug target, etc...)

METHOD	SIGNATURE	DESCRIPTION
targetLocation	Property	Returns an object which is an abstraction of where the object is within an address space (virtual address, register, sub-register, etc...)
targetSize	Property	Returns the size of the object (effectively: sizeof(<TYPE OF OBJECT>)
addParentModel	.addParentModel(object)	Adds a new parent model (akin to a JavaScript prototype but on the data model side) to the object
removeParentModel	.removeParentModel(object)	Removes a given parent model from the object
runtimeTypedObject	Property	Performs analysis on the object and tries to convert it to the runtime (most derived) type

If the object is a pointer, the following properties (and methods) are projected onto the pointer which enters JavaScript:

PROPERTY NAME	SIGNATURE	DESCRIPTION
add	.add(value)	Performs pointer math addition between the pointer and the specified value
address Property	Returns the address of the pointer as a 64-bit ordinal object (a library type)	Returns the address of the pointer as a 64-bit ordinal object (a library type)
dereference	.dereference()	Dereferences the pointer and returns the underlying object
isNull	Property	Returns whether or not the pointer value is nullptr (0)

Special Types Pertaining to Native Debugger Objects

Location Objects

The location object which is returned from the targetLocation property of a native object contains the following properties (and methods).

PROPERTY NAME	SIGNATURE	DESCRIPTION
add	.add(value)	Adds an absolute byte offset to the location.
subtract	.subtract(value)	Subtracts an absolute byte offset from the location.

Additional Attributes

Iterability

Any object which is understood as iterable by the data model (it is a native array or it has a visualizer (NatVis or otherwise) which makes it iterable) will have an iterator function (indexed via the ES6 standard `Symbol.iterator`) placed upon it. This means that you can iterate a native object in JavaScript as follows.

```
function iterateNative(nativeObject)
{
    for (var val of nativeObject)
    {
        //
        // val will contain each element iterated from the native object.  This would be each element of an
        array,
        // each element of an STL structure which is made iterable through NatVis, each element of a data
        structure
        // which has a JavaScript iterator accessible via [Symbol.iterator], or each element of something
        // which is made iterable via support of IIterableConcept in C/C++.
        //
    }
}
```

Indexability

Objects which are understood as indexable in one dimension via ordinals (e.g.: native arrays) will be indexable in JavaScript via the standard property access operator -- `object[index]`. If an object is indexable by name or is indexable in more than one dimension, the `getValueAt` and `setValueAt` methods will be projected onto the object so that JavaScript code can utilize the indexer.

```
function indexNative(nativeArray)
{
    var first = nativeArray[0];
}
```

String Conversion

Any native object which has a display string conversion via support of `IStringDisplayableConcept` or a `NatVis` `DisplayString` element will have that string conversion accessible via the standard JavaScript `toString` method.

```
function stringifyNative(nativeObject)
{
    var myString = nativeObject.toString();
}
```

Creating Native Debugger Objects

As mentioned, a JavaScript script can get access to native objects by having them passed into JavaScript in one of several ways or it can create them through calls to the host library. Use the following functions to create native debugger objects.

METHOD	SIGNATURE	DESCRIPTION
--------	-----------	-------------

METHOD	SIGNATURE	DESCRIPTION
host.getModuleSymbol	<pre>getModuleSymbol(moduleName, symbolName, [contextInheritor]) getModuleSymbol(moduleName, symbolName, [typeName], [contextInheritor])</pre>	<p>Returns an object for a global symbol within a particular module. The module name and symbol name are strings.</p> <p>If the optional <i>contextInheritor</i> argument is supplied, the module and symbol will be looked up within the same context (address space, debug target) as the passed object. If the argument is not supplied, the module and symbol will be looked up in the debugger's current context. A JavaScript extension which is not a one-off test script should always supply an explicit context.</p> <p>If the optional <i>typeName</i> argument is supplied, the symbol will be assumed to be of the passed type and the type indicated in symbol(s) will be ignored. Note that any caller which expects to operate on public symbols for a module should always supply an explicit type name.</p>
host.createPointerObject	<pre>createPointerObject(address, moduleName, typeName, [contextInheritor])</pre>	<p>Creates a pointer object at the specified address or location. The module name and type name are strings.</p> <p>If the optional <i>contextInheritor</i> argument is supplied, the module and symbol will be looked up within the same context (address space, debug target) as the passed object. If the argument is not supplied, the module and symbol will be looked up in the debugger's current context. A JavaScript extension which is not a one-off test script should always supply an explicit context.</p>

METHOD	SIGNATURE	DESCRIPTION
host.createTypedObject	createTypedObject(location, moduleName, typeName, [contextInheritor])	<p>Creates a object which represents a native typed object within the address space of a debug target at the specified location. The module name and type name are strings.</p> <p>If the optional <i>contextInheritor</i> argument is supplied, the module and symbol will be looked up within the same context (address space, debug target) as the passed object. If the argument is not supplied, the module and symbol will be looked up in the debugger's current context. A JavaScript extension which is not a one-off test script should always supply an explicit context.</p>

Host APIs for JavaScript Extensions

The JavaScript provider inserts an object called host into the global namespace of every script which it loads. This object provides access to critical functionality for the script as well as access to the namespace of the debugger. It is set up in two phases.

- **Phase 1:** Before any script executes, the host object only contains the minimal set of functionality necessary for a script to initialize itself and register its extensibility points (both as producer and consumer). The root and initialization code is not intended to manipulate the state of a debug target or perform complex operations and, as such, the host is not fully populated until after the initializeScript method returns.
- **Phase 2:** After initializeScript returns, the host object is populated with everything necessary to manipulate the state of debug targets.

Host Object Level

A few key pieces of functionality are directly under the host object. The remainder are sub-namespaced. Namespaces include the following.

NAMESPACE	DESCRIPTION
diagnostics	Functionality to assist in the diagnosis and debugging of script code
memory	Functionality to enable memory reading and writing within a debug target

Root Level

Directly within the host object, the following properties, methods, and constructors can be found.

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
createPointerObject	createPointerObject(address, moduleName, typeName, [contextInheritor])	2	Creates a pointer object at the specified address or location. The module name and type name are strings. The optional contextInheritor argument works as with <code>getModuleSymbol</code> .
createTypedObject	createTypedObject(location, moduleName, typeName, [contextInheritor])	2	Creates a object which represents a native typed object within the address space of a debug target at the specified location. The module name and type name are strings. The optional <code>contextInheritor</code> argument works as with <code>getModuleSymbol</code> .
currentProcess	Property	2	Returns the object representing the current process of the debugger
currentSession	Property	2	Returns the object representing the current session of the debugger (which target, dump, etc...) is being debugged
currentThread	Property	2	Returns the object representing the current thread of the debugger
evaluateExpression	evaluateExpression(expression, [contextInheritor])	2	This calls into the debug host to evaluate an expression using the language of the debug target only. If the optional <code>contextInheritor</code> argument is supplied, the expression will be evaluated in the context (e.g.: address space and debug target) of the argument; otherwise, it will be evaluated in the current context of the debugger

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
evaluateExpressionInContext	evaluateExpressionInContext(context, expression)	2	This calls into the debug host to evaluate an expression using the language of the debug target only. The context argument indicates the implicit this pointer to utilize for the evaluation. The expression will be evaluated in the context (e.g.: address space and debug target) indicated by the <i>context</i> argument.
getModuleSymbol	getModuleSymbol(moduleName, symbolName, [contextInheritor])	2	Returns an object for a global symbol within a particular module. The module name and symbol name are strings. If the optional <i>contextInheritor</i> argument is supplied, the module and symbol will be looked up within the same context (address space, debug target) as the passed object. If the argument is not supplied, the module and symbol will be looked up in the debugger's current context. A JavaScript extension which is not a one-off script should always supply an explicit context
getNamedModel	getNamedModel(modelName)	2	Returns the data model which was registered against a given name. Note that it is perfectly legal to call this against a name which is not yet registered. Doing so will create a stub for that name and manipulations of the stub will be made to the actual object upon registration
indexedValue	new indexedValue(value, indicies)	2	A constructor for an object which can be returned from a JavaScript iterator in order to assign a default set of indicies to the iterated value. The set of indicies must be expressed as a JavaScript array.

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
Int64	new Int64(value, [highValue])	1	This constructs a library Int64 type. The single argument version will take any value which can pack into an Int64 (without conversion) and place it into such. If an optional second argument is supplied, a conversion of the first argument is packed into the lower 32-bits and a conversion of the second argument is packed into the upper 32 bits.
namedModelParent	new namedModelParent(object, name)	1	A constructor for an object intended to be placed in the array returned from initializeScript , this represents using a JavaScript prototype or ES6 class as a data model parent extension of a data model with the given name
namedModelRegistration	new namedModelRegistration(object, name)	1	A constructor for an object intended to be placed in the array returned from initializeScript , this represents the registration of a JavaScript prototype or ES6 class as a data model via a known name so that other extensions can find and extend
namespace	Property	2	Gives direct access to the root namespace of the debugger. One could, for example, access the process list of the first debug target via <code>host.namespace.Debugger.Sessions.First().Processes</code> using this property

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
registerNamedModel	registerNamedModel(object, modelName)	2	<p>This registers a JavaScript prototype or ES6 class as a data model under the given name. Such a registration allows the prototype or class to be located and extended by other scripts or other debugger extensions. Note that a script should prefer to return a namedModelRegistration object from its initializeScript method rather than doing this imperatively. Any script which makes changes imperatively is required to have an initializeScript method in order to clean up.</p>
registerExtensionForTypeSignature	registerExtensionForTypeSignature(object, typeSignature)	2	<p>This registers a JavaScript prototype or ES6 class as an extension data model for a native type as given by the supplied type signature. Note that a script should prefer to return a typeSignatureExtension object from its initializeScript method rather than doing this imperatively. Any script which makes changes imperatively is required to have an initializeScript method in order to clean up.</p>
registerPrototypeForTypeSignature	registerPrototypeForTypeSignature(object, typeSignature)	2	<p>This registers a JavaScript prototype or ES6 class as the canonical data model (e.g.: visualizer) for a native type as given by the supplied type signature. Note that a script should prefer to return a typeSignatureExtension object from its initializeScript method rather than doing this imperatively. Any script which makes changes imperatively is required to have an uninitializeScript method in order to clean up.</p>

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
parseInt64	parseInt64(string, [radix])	1	This method acts similarly to the standard JavaScript parseInt method except that it returns a library Int64 type instead. If a radix is supplied, the parse will occur in either base 2, 8, 10, or 16 as indicated.
typeSignatureExtension	new typeSignatureExtension(object, typeSignature, [moduleName], [minVersion], [maxVersion])	1	A constructor for an object intended to be placed in the array returned from initializeScript , this represents an extension of a native type described via a type signature by a JavaScript prototype or ES6 class. Such a registration "adds fields" to the debugger's visualization of any type which matches the signature rather than taking it over entirely. An optional module name and version can restrict the registration. Versions are specified as "1.2.3.4" style strings.
typeSignatureRegistration	new typeSignatureRegistration(object, typeSignature, [moduleName], [minVersion], [maxVersion])	1	A constructor for an object intended to be placed in the array returned from initializeScript , this represents a canonical registration of a JavaScript prototype or ES6 class against a native type signature. Such a registration "takes over" the debugger's visualization of any type which matches the signature rather than merely extending it. An optional module name and version can restrict the registration. Versions are specified as "1.2.3.4" style strings.
unregisterNamedModel	unregisterNamedModel(modelName)	2	This unregisters a data model from lookup by the given name undoing any operation performed by registerNamedModel

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
unregisterExtensionForTypeSignature	unregisterExtensionForTypeSignature(object, typeSignature, [moduleName], [minVersion], [maxVersion])	2	<p>This unregisters a JavaScript prototype or ES6 class from being an extension data model for a native type as given by the supplied type signature. It is the logical undo of <code>registerExtensionForTypeSignature</code>. Note that a script should prefer to return a typeSignatureExtension object from its initializeScript method rather than doing this imperatively. Any script which makes changes imperatively is required to have an initializeScript method in order to clean up. An optional module name and version can restrict the registration. Versions are specified as "1.2.3.4" style strings.</p>
unregisterPrototypeForTypeSignature	unregisterPrototypeForTypeSignature(object, typeSignature, [moduleName], [minVersion], [maxVersion])	2	<p>This unregisters a JavaScript prototype or ES6 class from being the canonical data model (e.g.: visualizer) for a native type as given by the supplied type signature. It is the logical undo of <code>registerPrototypeForTypeSignature</code>. Note that a script should prefer to return a typeSignatureRegistration object from its initializeScript method rather than doing this imperatively. Any script which makes changes imperatively is required to have an uninitializeScript method in order to clean up. An optional module name and version can restrict the registration. Versions are specified as "1.2.3.4" style strings.</p>

Diagnostics Functionality

The diagnostics sub-namespace of the host object contains the following.

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
------	-----------	---------------	-------------

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
debugLog	debugLog(object...)	1	This provides printf style debugging to a script extension. At present, output from debugLog is routed to the output console of the debugger. At a later point in time, there are plans to provide flexibility on routing this output. NOTE: This should not be used as a means of printing user output to console. It may not be routed there in the future.

Memory Functionality

The memory sub-namespace of the host object contains the following.

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
readMemoryValues	readMemoryValues(location, numElements, [elementSize], [isSigned], [contextInheritor])	2	This reads a raw array of values from the address space of the debug target and places a typed array on top of the view of this memory. The supplied location can be an address (a 64-bit value), a location object, or a native pointer. The size of the array is indicated by the <i>numElements</i> argument. The size (and type) of each element of the array is given by the optional <i>elementSize</i> and <i>isSigned</i> arguments. If no such arguments are supplied, the default is byte (unsigned / 1 byte). If the optional <i>contextInheritor</i> argument is supplied, memory will be read in the context (e.g.: address space and debug target) indicated by the argument; otherwise, it will be read from the debugger's current context. Note that using this method on 8, 16, and 32-bit values results in a fast typed view being placed over the read memory. Using this method on 64-bit values results in an array of 64-bit library types being constructed which is significantly more expensive!

NAME	SIGNATURE	PHASE PRESENT	DESCRIPTION
readString	readString(location, [contextInheritor]) readString(location, [length], [contextInheritor])	2	This reads a narrow (current code page) string from the address space of a debug target, converts it to UTF-16, and returns the result as a JavaScript string. It may throw an exception if the memory could not be read. The supplied location can be an address (a 64-bit value), a location object, or a native char. <i>If the optional contextInheritor argument is supplied, memory will be read in the context (e.g.: address space and debug target) indicated by the argument; otherwise, it will be read from the debugger's current context.</i> <i>If the optional length argument is supplied, the read string will be of the specified length.</i>
readWideString	readWideString(location, [contextInheritor]) readWideString(location, [length], [contextInheritor])	2	This reads a wide(UTF-16) string from the address space of a debug target and returns the result as a JavaScript string. It may throw an exception if the memory could not be read. The supplied location can be an address (a 64-bit value), a location object, or a native wchar_t. If the optional contextInheritor argument is supplied, memory will be read in the context (e.g.: address space and debug target) indicated by the argument; otherwise, it will be read from the debugger's current context. If the optional length argument is supplied, the read string will be of the specified length.

Data Model Concepts in JavaScript

Data Model Mapping

The following data model concepts map to JavaScript.

CONCEPT	NATIVE INTERFACE	JAVASCRIPT EQUIVALENT
String Conversion	IStringDisplayableConcept	standard: <code>toString(...){...}</code>

CONCEPT	NATIVE INTERFACE	JAVASCRIPT EQUIVALENT
Iterability	IIterableConcept	standard: [Symbol.iterator]0{...}
Indexability	IIndexableConcept	protocol: getDimensionality(...) / getValueAt(...) / setValueAt(...)
Runtime Type Conversion	IPreferredRuntimeTypeConcept	protocol: getPreferredRuntimeTypedObject(...)

String Conversion

The string conversion concept (IStringDisplayableConcept) directly translates to the standard JavaScript **toString** method. As all JavaScript objects have a string conversion (provided by Object.prototype if not provided elsewhere), every JavaScript object returned to the data model can be converted to a display string. Overriding the string conversion simply requires implementing your own `toString`.

```
class myObject
{
    //
    // This method will be called whenever any native code calls
    IStringDisplayableConcept::ToDisplayString(...)
    //
    toString()
    {
        return "This is my own string conversion!";
    }
}
```

Iterability

The data model's concept of whether an object is iterable or not maps directly to the ES6 protocol of whether an object is iterable. Any object which has a [Symbol.iterator] method is considered iterable. Implementation of such will make the object iterable.

An object which is only iterable can have an implementation such as follows.

```
class myObject
{
    //
    // This method will be called whenever any native code calls IIterableConcept::GetIterator
    //
    *[Symbol.iterator]()
    {
        yield "First Value";
        yield "Second Value";
        yield "Third Value";
    }
}
```

Special consideration must be given for objects which are both iterable and indexable as the objects returned from the iterator must include the index as well as the value via a special return type.

Iterable and Indexable

An object which is iterable and indexable requires a special return value from the iterator. Instead of yielding the values, the iterator yields instances of `indexedValue`. The indices are passed as an array in the second argument to the `indexedValue` constructor. They can be multi-dimensional but must match the dimensionality returned in the indexer protocol.

This code shows an example implementation.

```
class myObject
{
    //
    // This method will be called whenever any native code calls IIterableConcept::GetIterator
    //
    *[Symbol.iterator]()
    {
        //
        // Consider this a map which mapped 42->"First Value", 99->"Second Value", and 107->"Third Value"
        //
        yield new host.indexedValue("First Value", [42]);
        yield new host.indexedValue("Second Value", [99]);
        yield new host.indexedValue("Third Value", [107]);
    }
}
```

Indexability

Unlike JavaScript, the data model makes a very explicit differentiation between property access and indexing. Any JavaScript object which wishes to present itself as indexable in the data model must implement a protocol consisting of a `getDimensionality` method which returns the dimensionality of the indexer and an optional pair of `getValueAt` and `setValueAt` methods which perform reads and writes of the object at supplied indices. It is acceptable to omit either the `getValueAt` or `setValueAt` methods if the object is read-only or write-only

```
class myObject
{
    //
    // This method will be called whenever any native code calls IIndexableConcept::GetDimensionality or
    IIterableConcept::GetDefaultIndexDimensionality
    //
    getDimensionality()
    {
        //
        // Pretend we are a two dimensional array.
        //
        return 2;
    }

    //
    // This method will be called whenever any native code calls IIndexableConcept::GetAt
    //
    getValueAt(row, column)
    {
        return this.__values[row * this.__columnCount + column];
    }

    //
    // This method will be called whenever any native code calls IIndexableConcept::SetAt
    //
    setValueAt(value, row, column)
    {
        this.__values[row * this.__columnCount + column] = value;
    }
}
```

Runtime Type Conversion

This is only relevant for JavaScript prototypes/classes which are registered against type system (native) types. The debugger is often capable of performing analysis (e.g. Run-Time Type Information (RTTI) / v-table analysis) to determine the true runtime type of an object from a static type expressed in code. A data model registered against

a native type can override this behavior via an implementation of the `IPREFERREDRUNTIMECONCEPT`. Likewise, a JavaScript class or prototype registered against a native object can provide its own implementation via implementation of a protocol consisting of the `getPreferredRuntimeTypedObject` method.

Note that while this method can technically return anything, it is considered bad form for it to return something which isn't really the runtime type or a derived type. Such can result in significant confusion for users of the debugger. Overriding this method can, however, be valuable for things such as C-style header+object styles of implementation, etc...

```
class myNativeModel
{
    //
    // This method will be called whenever the data model calls
    IPREFERREDRUNTIMECONCEPT::CastToPreferredRuntimeType
    //
    getPreferredRuntimeTypedObject()
    {
        var loc = this.targetLocation;

        //
        // Perform analysis...
        //
        var runtimeLoc = loc.Add(runtimeObjectOffset);

        return host.createTypedObject(runtimeLoc, runtimeModule, runtimeTypeName);
    }
}
```

Debugger Data Model Design Considerations

Design Principles

Consider the following principles to make your debugger extensions present information that is discoverable, queryable, and scriptable.

- Information is close to where it is needed. For example, information on a registry key should be displayed as part of a local variable that contains a registry key handle.
- Information is structured. For example, information about a registry key is presented in separate fields such as key type, key ACL, key name, and value. This means that the individual fields can be accessed without parsing text.
- Information is consistent. Information about registry key handles is presented in as similar a way as possible to information about file handles.

Avoid these approaches that do not support these principles.

- Do not structure your items into a single flat "Kitchen sink". An organized hierarchy allows users to browse for the information they are looking for without prior knowledge of what they are looking for and supports discoverability.
- Do not convert a classic `dbgeng` extension by simply moving it to the model while still outputting screens of raw text. This is not composable with other extensions and cannot be queried with LINQ expressions. Instead break the data into separate, queryable fields.

Naming Guidelines

- Capitalization of fields should be `PascalCase`. An exception could be considered for names that are widely known in another casing, such as `jQuery`.
- Avoid using special characters that would not normally be used in a C++ identifier. For example, avoid using names such as "Total Length" (that contains a space), or "[size]" (that contains square brackets). This convention

allows for easier consumption from scripting languages where these characters are not allowed as part of identifiers, and also allows easier consumption from the command window.

Organization and Hierarchy Guidelines

- Do not extend the top level of the debugger namespace. Instead, you should extend an existing node in the debugger so that the information is displayed where it is most relevant.
- Do not duplicate concepts. If you are creating a data model extension that lists additional information about a concept that already exists in the debugger, extend the existing information rather than trying to replace it with new information. In other words, an extension that displays details about a module should extend the existing *Module* object rather than creating a new list of modules.
- Free floating utility commands must be part of the *Debugger.Utility* namespace. They should also be sub-namespaced appropriately (e.g. *Debugger.Utility.Collections.FromListEntry*)

Backwards Compatibility and Breaking Changes

A script that is published should not break compatibility with other scripts that depend on it. For example, if a function is published to the model, it should remain in the same location and with the same parameters, whenever possible.

No Use of Outside Resources

- Extensions must not spawn external processes. External processes can interfere with the behavior of the debugger, and will misbehave in various remote debugger scenarios (e.g. dbgsrv remotes, ntsd remotes, and "ntsd -d remotes")
- Extensions must not display any user interface. Displaying user interface elements will behave incorrectly on remote debugging scenarios, and can break console debugging scenarios.
- Extensions must not manipulate the debugger engine or debugger UI through undocumented methods. This causes compatibility problems and will behave incorrectly on debugger clients with different UI.
- Extensions must access target information only through the documented debugger APIs. Trying to access information about a target through win32 APIs will fail for many remote scenarios, and even some local debugging scenarios across security boundaries.

No Use of Dbgeng Specific Features

Scripts that are intended to be used as extensions must not rely on dbgeng-specific features whenever possible (such as executing "classic" debugger extensions). Scripts should be usable on top of any debugger that hosts the data model.

Testing Debugger Extensions

Extensions are expected to work in a wide range of scenarios. While some extensions may be specific to a scenario (such as a kernel debugging scenario), most extensions should be expected to work in all scenarios, or have metadata indicating the supported scenarios.

Kernel Mode

- Live kernel debugging
- Kernel dump debugging

User Mode

- Live user mode debugging
- User mode dump debugging

In addition, consider these debugger usage scenarios

- Multi-process debugging
- Multi-session debugging (e.g. dump + live user within a single session)

Remote Debugger Usage

Test for proper operation with the remote debugger usage scenarios.

- dbgsrv remotes
- ntsd remotes
- ntsd -d remotes

For more information, see [Debugging Using CDB and NTSD](#) and [Activating a Process Server](#).

Regression testing

Investigate the use of test automation that can verify the functionality of your extensions, as new versions of the debugger are released.

Glossary

5/26/2017 • 1 min to read • [Edit Online](#)

This glossary contains terms and acronyms related to the Microsoft Debugging Tools for Windows.

[Send comments about this topic to Microsoft](#)

A

5/26/2017 • 1 min to read • [Edit Online](#)

accessible

A debugging session is *accessible* if the current target is suspended.

actual processor type

The type of the physical processor in the target computer.

See also [effective processor type](#), [executing processor type](#).

For more information, see [Target Information](#).

arbitrary exception filter

An exception filter that has been manually added to the engine's list of event filters.

See also [specific exception filter](#).

For more information, see [Event Filters](#).

[Send comments about this topic to Microsoft](#)

B

5/26/2017 • 1 min to read • [Edit Online](#)

blue screen

The blue character-mode screen displayed after a bug check occurs.

breakpoint

A location in the target or a target operation which will cause an event when triggered.

For more information, see [Using Breakpoints](#).

breakpoint ID

The unique identifier for a breakpoint.

For more information, see [Using Breakpoints](#).

breakpoint type

The method used to implement the breakpoint. There are two types of breakpoints: processor breakpoints and software breakpoints.

break status

A setting that influences how the debugger engine proceeds after an event. The break status indicates whether the event should break into the debugger, have a notification printed to the debugger console, or be ignored. The break status is part of an event filter.

See also [handling status](#).

For more information, see the topics [Controlling Exceptions and Events](#) and [Event Filters](#).

bug check

When Windows encounters hardware problems, inconsistencies within data necessary for its operation, or other severe errors, it shuts down and displays error information on a blue character-mode screen.

This shutdown is known variously as a bug check, kernel error, system crash, stop error, or, occasionally, trap. The screen display itself is referred to as a blue screen or stop screen. The most important information shown on the screen is a message code which gives information about the crash; this is known as a bug check code or stop code.

WinDbg or KD can configure the system so that a debugger is automatically contacted when such an error occurs. Alternatively, the system can be instructed to automatically reboot in case of such an error.

For more information, see [Bug Checks \(Blue Screens\)](#).

bug check code

The hexadecimal code indicating a specific type of bug check .

[Send comments about this topic to Microsoft](#)

C

5/26/2017 • 2 min to read • [Edit Online](#)

C++ expression

An expression that can be evaluated by the C++ expression evaluator.

C call stack

See call stack.

call stack

The set of stack frames for each thread containing representing the function calls made by the thread. Each time a function call is made a new stack frame is pushed onto the top of the stack. When that function returns, the stack frame is popped off the stack.

Sometimes referred to as the or simply the .

callback object

See event callbacks, input callbacks, and output callbacks.

checked build

Two different builds of each NT-based operating system exist:

- The (or) of Windows is the end-user version of the operating system. For details, see free build.
- The (or) of Windows serves as a testing and debugging aid in the developing of the operating system and kernel-mode drivers. The checked build contains extra error checking, argument verification, and debugging information that is not available in the free build. , making it easier to trace the cause of problems in system software. A checked system or driver can help isolate and track down driver problems that can cause unpredictable behavior, result in memory leaks, or result in improper device configuration.

Although the checked build provides extra protection, it consumes more memory and disk space than the free build. System and driver performance is slower, because additional code paths are executed due to parameter checking and output of diagnostic messages, and some alternate implementations of kernel functions are used.

The checked build of Windows should not be confused with a driver that has been built in one of the Checked Build Environments of the Windows Driver Kit (WDK).

child symbol

A symbol that is contained in another symbol. For example, the symbol for a member in a structure is a child of the symbol for that structure.

client

See client object.

client object

A client object is used for interaction with the debugger engine. It holds per-client state, and provides implementations for the top-level interfaces in the debugger engine API.

client thread

The thread in which the client object was created. In general, a client's methods may be called only from this thread. The debugger engine uses this thread to make all calls to the callback object registered with the client.

code breakpoint

See software breakpoint.

crash dump file

A file that contains a snapshot of certain memory regions and other data related to an application or operating system. A crash dump file can be stored and then used to debug the application or operating system at a later time.

A user-mode crash dump file can be created by Windows when an application crashes, and a kernel-mode crash dump file can be created by special Windows routines when Windows itself crashes. There are several different types of crash dump files.

current process

The process that the debugger engine is currently controlling. When an event occurs, the current process is set to the event process.

current target

The target that the debugger engine is currently controlling. When an event occurs, the current target is set to the event target.

current thread

The thread that the debugger engine is currently controlling. When an event occurs, the current thread is set to the event thread.

D

5/26/2017 • 2 min to read • [Edit Online](#)

data breakpoint

See processor breakpoint.

DbgEng extension

A debugger extension based on the prototypes in the dbgeng.h header file. These extensions use the debugger engine API to communicate with the debugger engine.

debug build

See Checked Build.

debuggee

See target.

debugger

A debugger engine application that uses the full functionality of the debugger engine. For example, WinDbg, CDB, NTSD, and KD are debuggers.

debugger console

A fictional entity representing the source of the debugger engine input and the destination of its output. In reality, the debugger engine only uses input and output callbacks and has no notion of what is being used to implement them.

Typically, input is received from the Debugger Command window and output is sent to the same window. However, the input and output callbacks can provide many other sources of input and destinations for output, for example, remote connections, script files, and log files.

debugger engine

A library for manipulating debugging targets. Its interface is based on the prototypes in the dbgeng.h file. It is used by debuggers, extensions, and debugger engine applications.

debugger engine API

A powerful interface to control the behavior of the debugger engine. It may be used by debuggers, DbgEng extensions, and debugger engine applications. The prototypes for this interface are found in the dbgeng.h header file.

debugger engine application

A stand-alone application that uses the debugger engine API to control the debugger engine.

debugger extension

An external function that can run inside the debugger. Each extension is exported from a module known as an debugger extension DLL. The debugger engine invokes the debugger extension by calling its code within the DLL. Some debugger extensions ship with Debugging Tools for Windows. You can write your own extensions to automate any number of debugger features or to customize the output of the information accessible to the debugger.

Also referred to as an , or simply .

debugger extension DLL

A DLL containing debugger extensions. When the debugger engine loads the DLL these extensions become available for use within the debugger.

debugger extension library

See debugger extension DLL.

debugging client

An instance of the debugger engine acting as a proxy, sending debugger commands and I/O to the debugging server.

debugging server

An instance of the debugger engine acting as a host, listening for connections from debugging clients.

debugging session

The debugging session is the actual act of running a software debugging program, such as WinDbg, KD, or CDB, to debug a software component, system service, application, or operating system. The debugging session can also be run against a memory dump file for analysis.

A debugging session starts when a target is acquired and lasts until all targets have been discarded.

default exception filter

The event filter which applies to exception events that do not match any other exception filters. The default exception filter is a specific exception filter.

dormant mode

A state in which a debugger program is running, but without a target or active session.

downstream store

A cache of symbols created by a symbol server. Typically this cache is on your local machine, while the symbol store is located remotely. If you have a chain of symbol servers, the downstream store can be located on any computer downstream from the symbol store.

dump file

See crash dump file.

dump target

A crash dump file that is being debugged.

[Send comments about this topic to Microsoft](#)

E

5/26/2017 • 1 min to read • [Edit Online](#)

effective processor type

The processor type the debugger uses when dealing with the target computer. The effective processor type affects how the debugger sets breakpoints, accesses registers, gets stack traces, and performs other processor-specific actions.

engine

See debugger engine.

event

The debugger engine monitors some of the events that occur in its targets. These include a breakpoint being triggered, an exception, thread and process creation, module loading, and internal debugger engine changes.

event filter

A collection of rules that influence how the debugger engine proceeds after an event has occurred in a target. There are three types of event filters: specific event filters, specific exception filters, and arbitrary exception filters.

event callback objects

Instances of the [IDebugEventCallbacks](#) interface which have been registered with a client. The engine notifies the event callbacks whenever an event occurs.

event callbacks

See event callback objects.

event process

The process for which the last event occurred.

event target

The target for which the last event occurred.

event thread

The thread for which the last event occurred.

executing processor type

The type of the processor in the current processor context.

exception

An error condition resulting from the execution of a particular machine instruction or from the target indicating that it has encountered an error. Exceptions can be hardware or software-related errors.

An exception is an and is identified by its .

exception code

An identifier which determines the type of an exception event.

exception filter

An event filter for an exception event specified by exception code.

extension

See debugger extension.

extension command

See debugger extension.

F

5/26/2017 • 1 min to read • [Edit Online](#)

free build

Two different builds of each NT-based operating system exist:

- The (or) of Windows is the end-user version of the operating system. The system and drivers are built with full optimization, debugging asserts are disabled, and debugging information is stripped from the binaries. A free system and driver are smaller and faster, and it uses less memory.
- The (or) of Windows serves as a testing and debugging aid. For details, see checked build.

Distribution media containing the free build of the operating system do not have any special labels -- in other words, the CD containing the free build will just be labeled with the Windows version name, and no reference to the type of build.

first-chance exception

The first opportunity to handle an exception. If an exception is not handled by any handler on the first opportunity, the handlers are given a second chance.

[Send comments about this topic to Microsoft](#)

H

5/26/2017 • 1 min to read • [Edit Online](#)

host

See host computer.

handling status

The handling status specifies whether the debugger engine should flag an exception event as handled or not. The handling status is part of an exception filter.

See also break status. For more information, see [Controlling Exceptions and Events](#) and [Event Filters](#)

host computer

The host computer is the computer that runs the debugging session. All debugger operations--such as executing commands and extensions, and symbol loading--are performed on the host computer.

In a typical two-system kernel debugging session, the debugger is running on the host computer, which is connected to the target computer being debugged.

[Send comments about this topic to Microsoft](#)

I/O Request Packet (IRP)

A data structure used to represent an I/O request and control its processing. An IRP structure consists of a header and one or more stack locations.

image

An executable, DLL, or driver that Windows has loaded as part of a user-mode process or the Windows kernel.

See also image file.

image file

The file from which an image was loaded.

implicit process

In kernel-mode debugging, the process used to determine which virtual address space to use when performing virtual to physical address translation. When an event occurs, the implicit process is set to the event process.

See also implicit thread.

For more information, see [Threads and Processes](#).

implicit thread

In kernel-mode debugging, the thread used to determine some of the target's registers, including frame offset and instruction offset. When an event occurs, the implicit thread is set to the event thread.

inaccessible

A debugging session is *inaccessible* when all the targets are executing.

initial breakpoint

A breakpoint that automatically occurs near the beginning of a debugging session, after a reboot, or after a target application is restarted.

For more information, see [Using Breakpoints](#).

input callback objects

Instances of the [IDebugInputCallbacks](#) interface which have been registered with a client. Whenever the debugger engine requires input it asks the input callbacks to provide it.

See also output callbacks.

For more information, see [Using AMLI Debugger Commands](#).

input callbacks

See input callback objects.

interrupt

A condition that disrupts normal command execution and transfers control to an interrupt handler. I/O devices requiring service from the processor usually initiate interrupts.

Interrupt Request Level (IRQL)

The priority ranking of an interrupt. Each processor has an IRQL setting that threads can raise or lower. Interrupts that occur at or below the processor's IRQL setting are masked and will not interfere with the current operation. Interrupts that occur above the processor's IRQL setting take precedence over the current operation.

[Send comments about this topic to Microsoft](#)

K

5/26/2017 • 1 min to read • [Edit Online](#)

KD connection server

A proxy used during some forms of kernel-mode remote debugging. It listens for connections from smart client and performs memory, processor, or Windows operations as requested by these remote clients.

See also debugging server.

For more information, see [KD Connection Servers \(Kernel Mode\)](#).

kernel

The kernel is the portion of the Windows operating system that manages and controls access to hardware resources. It performs thread scheduling and dispatching, interrupt and exception handling, and multiprocessor synchronization.

kernel error

See bug check.

kernel mode

Kernel-mode code has permission to access any part of the system, and is not restricted like user-mode code. It can gain access to any part of any other process running in either user mode or kernel mode.

Performance-sensitive operating system components run in kernel mode. In this way they can interact with the hardware and with each other without the overhead of context switch. All the kernel-mode components are fully protected from applications running in user mode. They can be grouped as follows:

- Executive.

This contains the base operating system components such as memory management, process and thread management, security, I/O, interprocess communication.

- Kernel.

This performs low-level functions such as thread scheduling, interrupt and exception dispatching, and multiprocessor synchronization. It also provides a set of routines and basic objects used by the Executive to implement higher-level semantics.

- Hardware Abstraction Layer (HAL).

This handles all direct interface to hardware. It thus isolates the Windows Kernel, device drivers, and Windows Executive from platform-specific hardware differences.

- Window and Graphics Subsystem.

This implements the graphical user interface (GUI) functions.

When a process erroneously accesses a portion of memory that is in use by another application or by the system, the lack of restrictions on kernel-mode processes forces Windows to stop the entire system. This is referred to as a bug check.

Malfunctioning hardware devices or device drivers, which reside in kernel mode, are often the culprits in bug checks.

kernel-mode target

See target computer.

kernel-mode debugging

A debugger session in which the target is running in kernel mode.

[Send comments about this topic to Microsoft](#)

live kernel-mode debugging

Kernel-mode debugging using live targets.

See also live user-mode debugging.

live target

A target application or target computer that is currently operational (as opposed to a dump target).

live user-mode debugging

User-mode debugging using live targets.

See also live user-mode debugging.

local context

See scope.

local debugging

This refers to a debugging session in which the debugger and the application to be debugged reside on the same computer.

O

5/26/2017 • 1 min to read • [Edit Online](#)

output callback objects

Instances of the [IDebugOutputCallbacks](#) interface which have been registered with a client object. All output from the debugger engine is sent to the output callbacks.

output callbacks

See output callback objects.

[Send comments about this topic to Microsoft](#)

P

5/26/2017 • 1 min to read • [Edit Online](#)

page table

A process-specific table that maps virtual memory addresses to physical memory addresses.

Page Table Entry (PTE)

An item in the page table.

paged pool

A portion of system memory that can be paged to disk.

Note that this term does not only refer to memory that actually has actually been paged out to the disk - it includes any memory that the operating system is permitted to page.

paging

A virtual memory operation in which the memory manager transfers pages from memory to disk when physical memory becomes full. A *page fault* occurs when a thread accesses a page that is not in memory.

parent symbol

A *symbol* that is contains in other symbols, for example, a structure contains its member.

See also *child symbol*.

For more information, see [Scopes and Symbol Groups](#).

primary client

A client object that has joined the current debugging session

For more information, see [Client Objects](#).

process server

An instance of the debugger engine acting as a proxy, listening for connections from smart client and performing memory, processor, or Windows operations as requested by these remote clients.

See also *debugging server*.

For more information, see [Process Servers \(User Mode\)](#) and Process Server and Smart Client.

processor breakpoint

A breakpoint that is implemented by the processor. The debugger engine instructs the target's processor to insert this breakpoint.

See also software breakpoint. See also *software breakpoint*.

For more information, see [Using Breakpoints](#).

[Send comments about this topic to Microsoft](#)

remote debugging

Remote debugging is the practice of using a remote connection to perform debugging.

Since user-mode debugging is usually done on one machine, remote user-mode debugging typically uses two machines. In this scenario, one computer contains the target application and a debugging server, while the other computer contains the debugging client. An alternate method is to have the target application and a process server on one computer, and a smart client on the other.

Since kernel-mode debugging is usually done on two machines, remote kernel-mode debugging requires three machines. The target computer is the computer being debugged. The server is attached to the target; it contains the kernel-mode debugger. The client is the computer which is controlling the session remotely. Typically, one computer is the being debugged, another contains the debugging server, and the third contains the debugging client.

In addition, there are other methods of remote debugging: using the Remote tool, using a KD connection server, or using a repeater. The method you should choose depends on the configuration of the machines in question and the available connections.

For more information, see [Remote Debugging](#).

register

A very fast temporary memory location in the CPU.

register context

The full processor state which includes all the processor's registers.

For more information, see [Register Context](#).

retail build

See free build.

[Send comments about this topic to Microsoft](#)

S

5/26/2017 • 2 min to read • [Edit Online](#)

scope

The context that defines the local variables. The scope has three components: a stack frame, a current instruction, and a register context.

Sometimes referred to as *local context* or *lexical scope*.

second-chance exception

The second opportunity to handle an exception. This opportunity is only provided if the exception was not handled on the first chance.

smart client

An instance of the debugger engine acting as a host. The smart client is connected to a process server, or a KD connection server.

specific exception filter

An event filter for an exception for which the engine has a built-in filter. Most specific exception filters refer to specific types of exceptions (identified by exception code), but the default exception filter also qualifies as a specific exception filter.

specific event filter

An event filter for an event which is not an exception. The specific event filters are listed in [DEBUG_FILTER_XXX](#).

specific filter

An event filter for an event for which the engine has a built-in filter.

software breakpoint

A breakpoint that is implemented by the debugger engine temporarily modifying the target's executable code. The breakpoint is triggered when the code is executed. The code modification is invisible to users of the debugger or the debugger engine API.

stack

See call stack.

stack frame

The memory in the call stack containing the data for a single function call. This includes the return address, parameters passed to the function, and local variables.

stop code

See bug check code.

stop error

See bug check.

stop screen

See blue screen.

subregister

A register that is contained within another register. When the subregister changes, the portion of the register that contains the subregister also changes.

suspended

A target, process, or thread is suspended if it has been blocked from executing.

symbol

A unit of debugging information which provides interpretive information about the target in a debugging session. Examples of symbols include variables (local and global), functions, types and function entries. Information about symbols can include the name, type (if applicable), and the address or register where it is stored, as well as any parent or child symbols. This information is stored in symbol files and is typically not available in the module itself.

The debugger engine can synthesize certain symbols when symbol files are not available (for example, exported symbols), but these symbols generally provide only minimal information.

symbol file

A supplemental file created when an application, library, driver, or operating system is built. A symbol file contains data which is not actually needed when running the binaries, but which is very useful in the debugging process.

symbol group

A group of symbols, typically representing all the local variables in a scope.

symbol type

Descriptive information about a symbol's representation, such as its layout in memory. This is part of the information a compiler uses to generate code to manipulate the symbol. It is also used by the debugger engine to manipulate symbols. The symbol type is distributed in symbol files.

synthetic module

A region of memory that the engine treats like a module. A synthetic module may contain synthetic symbols.

synthetic symbol

A memory address that the engine treats like a symbol.

system crash

See bug check.

[Send comments about this topic to Microsoft](#)

T

5/26/2017 • 1 min to read • [Edit Online](#)

target

A target application, target computer, or dump target.

Sometimes referred to as the *debuggee*.

target application

An application that is being debugged in user-mode.

target computer

A computer that is being debugged in kernel-mode.

target ID

The unique identifier for a target.

target process

In user-mode debugging, an operating system process that is part of the target application.

In kernel-mode debugging, the virtual process representing the kernel.

target thread

In user-mode debugging, an operating system thread in the target application.

In kernel-mode debugging, a virtual thread representing a processor.

thread context

The state preserved by Windows when switching threads. This is similar to the register context, except that there is some extra kernel-only processor state that is part of the register context but not the thread context. This extra state is available as registers during kernel-mode debugging.

For more information, see [Scopes and Symbol Groups](#).

transport layer

This controls communication between the host and target computers during remote debugging.

trap

See [bug check](#).

type

See [symbol type](#).

user mode

Applications and subsystems run within Windows in *user mode*. Processes that run in user mode do so within their own virtual address spaces. They are restricted from gaining direct access to many parts of the system, including system hardware, memory that was not allocated for their use, and other portions of the system that might compromise system integrity. Because processes that run in user mode are effectively isolated from the system and other user-mode processes, they cannot interfere with these resources.

User-mode processes can be grouped in the following categories:

- **System Processes**

These perform important functions and are integral part of the operating system. System processes include such items as the logon process and the session manager process.

- **Server Processes**

These are operating system services such as the Event Log and the Scheduler. They can be configured to start automatically at boot time.

- **Environment Subsystems**

These are used to create a complete operating system environment for the applications. Windows provides the following three environments: Win32, POSIX, and OS/2.

- **User Applications**

There are five types: Win32, Windows 3.1, Microsoft MS-DOS, POSIX, and OS/2.

user-mode debugging

A debugger session in which the target is running in user mode.

user-mode target

See target application.

[Send comments about this topic to Microsoft](#)

V

5/26/2017 • 1 min to read • [Edit Online](#)

virtual process

In kernel-mode debugging the debugger engine creates a single *virtual process* to represent the target's kernel.

virtual thread

In kernel-mode debugging the debugger engine creates a *virtual thread* for each processor in the target computer.

[Send comments about this topic to Microsoft](#)

WdbgExts API

An interface exposed by the debugger engine for extensions. It contains a subset of the functionality of the debugger engine API and can only be used by extensions.

WdbgExts extension

An extension based on the prototypes in the wdbgexts.h header file. These extensions use the WdbgExts API.

WOW64

An emulation layer in 64-bit Windows that can run 32-bit Windows applications. When debugging a 32-bit application running on 64-bit Windows, it is important to distinguish between the application itself and the WOW64 subsystem.

Debugging a User-Mode Process Using WinDbg

5/26/2017 • 5 min to read • [Edit Online](#)

You can use WinDbg to attach to a running process or to spawn and attach to a new process.

Attaching to a Running Process

There are several ways you can use WinDbg to attach to a running process. Regardless of the method you choose, you will need the process ID or the process name. The process ID is a number assigned by the operating system. For more information about how to determine the process ID and the process name, see [Finding the Process ID](#).

WinDbg Menu

When WinDbg is in dormant mode, you can attach to a running process by choosing **Attach to a Process** from the **File** menu or by pressing **F6**.

In the **Attach to Process** dialog box, select the process you want to debug, and click **OK**.

Command Prompt

In a Command Prompt window, you can attach to a running process when you launch WinDbg. Use one of the following commands:

- **windbg -p ProcessID**
- **windbg -pn ProcessName**

where *ProcessID* is the Process ID of a running process or *ProcessName* is the name of a running process.

For more information about the command-line syntax, see [WinDbg Command-Line Options](#).

Debugger Command Window

If WinDbg is already debugging one or more processes, you can attach to a running process by using the [.attach \(Attach to Process\)](#) command in the **Debugger Command window**.

The debugger always starts multiple target processes simultaneously, unless some of their threads are frozen or suspended.

If the [.attach](#) command is successful, the debugger attaches to the specified process the next time the debugger issues an execution command. If you use this command several times in a row, execution has to be requested by the debugger as many times as you use this command.

Attaching to a Running Process Noninvasively

If you want to debug a running process and interfere only minimally in its execution, you should debug the process [noninvasively](#).

WinDbg Menu

When WinDbg is in dormant mode, you can noninvasively debug a running process by choosing **Attach to a Process** from the **File** menu or by pressing **F6**.

When the **Attach to Process** dialog box appears, select the **Noninvasive** check box. Then, select the line that contains the process ID and name that you want. (You can also enter the process ID in the **Process ID** box.) Finally, click **OK**.

Command Prompt

In a Command Prompt window, you can attach to a running process noninvasively when you launch WinDbg. Use one of the following commands:

windbg -pv -p ProcessID **windbg -pv -pn ProcessName** There are several other useful command-line options. For more information about the command-line syntax, see [WinDbg Command-Line Options](#).

Debugger Command Window

If the debugger is already active, you can noninvasively debug a running process by using the [.attach -v \(Attach to Process\)](#) command in the [Debugger Command window](#).

You can use the **.attach** command if the debugger is already debugging one or more processes invasively. You cannot use this command if WinDbg is dormant.

If the **.attach -v** command is successful, the debugger debugs the specified process the next time that the debugger issues an execution command. Because execution is not permitted during noninvasive debugging, the debugger cannot noninvasively debug more than one process at a time. This restriction also means that using the **.attach -v** command might make an existing invasive debugging session less useful.

Spawning a New Process

WinDbg can start a user-mode application and then debug the application. The application is specified by name. The debugger can also automatically attach to child processes (additional processes that the original target process started).

Processes that the debugger creates (also known as spawned processes) behave slightly differently than processes that the debugger does not create.

Instead of using the standard heap API, processes that the debugger creates use a special debug heap. You can force a spawned process to use the standard heap instead of the debug heap by using the [_NO_DEBUG_HEAP environment variable](#) or the **-hd** command-line option.

Also, because the target application is a child process of the debugger, it inherits the debugger's permissions. This permission might enable the target application to perform certain actions that it could not perform otherwise. For example, the target application might be able to affect protected processes.

WinDbg Menu

When WinDbg is in dormant mode, you can spawn a new process by choosing **Open Executable** from the **File** menu or by pressing **CTRL+E**.

When the Open Executable dialog box appears, enter the full path of the executable file in the **File name** box, or use the **Look in** list to select the path and file name that you want.

If you want to use any command-line parameters with the user-mode application, enter them in the **Arguments** box. If you want to change the starting directory from the default directory, enter the directory path in the **Start** directory box. If you want WinDbg to attach to child processes, select the **Debug child processes also** check box.

After you make your selections, click **Open**.

Command Prompt

In a Command Prompt window, you can spawn a new process when you launch WinDbg. Use the following command:

windbg [-o] ProgramName [Arguments]

The **-o** option causes the debugger to attach to child processes. There are several other useful command-line options. For more information about the command-line syntax, see [WinDbg Command-Line Options](#).

Debugger Command Window

If WinDbg is already debugging one or more processes, you can create a new process by using the [.create \(Create Process\)](#) command in the [Debugger Command window](#).

The debugger will always start multiple target processes simultaneously, unless some of their threads are frozen or suspended.

If the [.create](#) command is successful, the debugger creates the specified process the next time that the debugger issues an execution command. If you use this command several times in a row, execution has to be requested by the debugger as many times as you use this command.

You can control the application's starting directory by using the [.createdir \(Set Created Process Directory\)](#) command before [.create](#). You can use the [.createdir -I](#) command or the [-noinh](#) command-line option to control whether the target application inherits the debugger's handles.

You can activate or deactivate the debugging of child processes by using the [.childdbg \(Debug Child Processes\)](#) command.

Reattaching to a Process

If the debugger stops responding or freezes, you can attach a new debugger to the target process. For more information about how to attach a debugger in this situation, see [Reattaching to the Target Application](#).

[Send comments about this topic to Microsoft](#)

Debugging a UWP app using WinDbg

5/26/2017 • 8 min to read • [Edit Online](#)

You can debug Universal Windows Platform (UWP) app using WinDbg. This approach would typically be used for advanced scenarios, where it is not possible to complete the debugging task using the built in Visual Studio debugger. For more information about debugging in Visual Studio, see [Debugging in Visual Studio](#).

Attaching to a UWP app

Attaching to UWP process is the same as attaching to a user mode process. For example, in WinDbg you can attach to a running process by choosing **Attach to a Process from the File** menu or by pressing F6. For more information, see [Debugging a User-Mode Process Using WinDbg](#).

A UWP app will not be suspended in the same ways that it does when not being debugged. To explicitly suspend/resume a UWP app, you can use the .suspendpackage and .resumepackage commands (details below). For general information on Process Lifecycle Management (PLM) used by UWP apps, see [App lifecycle](#) and [Launching, resuming, and background tasks](#).

Launching and debugging a UWP app

The -plmPackage and -plmApp command line parameters instruct the debugger to launch an app under the debugger.

```
windbg.exe -plmPackage <PLMPackageName> -plmApp <ApplicationId> [<parameters>]
```

Since multiple apps can be contained within a single package, both <PLMPackageName> and <ApplicationId> parameters are required. This is a summary of the parameters.

Parameter	Description
<PLMPackageName>	The name of the application package. Use the .querypackages command to lists all UWP applications. Do not provide a path to the location of the package, provide just the package name.
<ApplicationId>	The ApplicationId is located in the application manifest file and can be viewed using the .querypackage or .querypackages command as discussed in this topic. For more information about the application manifest file, see App package manifest .
[<parameters>]	Optional parameters passed to the App. Not all apps use or require parameters.

HelloWorld Sample

To demonstrate UWP debugging, this topic uses the HelloWorld example described in [Create a "Hello, world" app \(XAML\)](#).

To create a workable test app, it is only necessary to complete up to step three of the lab.

Locating the Full Package Name and AppId

Use the .querypackages command to locate the full package name and the AppId. Type .querypackages and then user CRTL+F to search up in the output for the application name, such as HelloWorld. When the entry is located using CTRL+F, it will show the package full name, for example `e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8` and the AppId of `App`.

Example:

```
0:000> .querypackages
...
Package Full Name: e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
Package Display Name: HelloWorld
Version: 1.0.0.0
Processor Architecture: x86
Publisher: CN=domars
Publisher Display Name: domars
Install Folder: c:\users\domars\documents\visual studio
2015\Projects\HelloWorld\HelloWorld\bin\x86\Release\AppX
Package State: Unknown
AppId: App
...
```

Viewing the Base Package Name in the in the Manifest

For troubleshooting, you may want to view the base package name in Visual Studio.

To locate the base package name in Visual Studio, click on the ApplicationManifest.xml file in project explorer. The base package name will be displayed under the packaging tab as "Package name". By default, the package name will be a GUID, for example `e24caf14-8483-4743-b80c-ca46c28c75df`.

To use notepad to locate the base package name, open the ApplicationManifest.xml file and locate the **Identity Name** tag.

```
<Identity
  Name="e24caf14-8483-4743-b80c-ca46c28c75df"
  Publisher="CN= User1"
  Version="1.0.0.0" />
```

Locating the Application Id in the Manifest

To locate the Application Id in the manifest file for an installed UWP app, look for the *Application Id* entry.

For example, for the hello world app the Application ID is `App`.

```
<Application Id="App"
  Executable="$targetnametoken$.exe"
  EntryPoint="HelloWorld.App">
```

Example WinDbg Command Line

This is an example command line loading the HelloWorld app under the debugger using the full package name and AppId.

```
windbg.exe -plmPackage e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8 -plmApp App
```

Launching a background task under the debugger

A background task can be explicitly launched under the debugger from the command line using the TaskId. To do this, use the -plmPackage and -plmBgTaskId command line parameters:

```
windbg.exe -plmPackage <PLMPackageName> -plmBgTaskId <BackgroundTaskId>
```

Parameter	Description
<PLMPackageName>	The name of the application package. Use the .querypackages command to lists all UWP applications. Do not provide a path to the location of the package, provide just the package name.
<BackgroundTaskId>	The BackgroundTaskId can be located using the .querypackages command as described below. For more information about the application manifest file, see App package manifest .

This is an example of loading the SDKSamples.BackgroundTask code under the debugger.

```
windbg.exe -plmPackage Microsoft.SDKSamples.BackgroundTask.CPP_1.0.0.0_x64_8wekyb3d8bbwe -plmBgTaskId {ee4438ee-22db-4cdd-85e4-8ad8a1063523}
```

You can experiment with the Background task sample code to become familiar with UWP debugging. It can be downloaded at [Background task sample](#).

Use the .querypackages command to locate the BackgroundTaskId. Use CTRL-F to locate the app and then locate the *Background Task Id* field. The background task must be running to display the associated background task name and task id.

```
0:000> .querypackages
...
Package Full Name: Microsoft.SDKSamples.BackgroundTask.CPP_1.0.0.0_x86_8wekyb3d8bbwe
Package Display Name: BackgroundTask C++ sample
Version: 1.0.0.0
Processor Architecture: x86
Publisher: CN=Microsoft Corporation, O=Microsoft Corporation, L=Redmond, S=Washington, C=US
Publisher Display Name: Microsoft Corporation
Install Folder: C:\Users\DOMARS\Documents\Visual Studio
2015\Projects\Background_task_sample\C++\Debug\BackgroundTask.Windows\AppX
Package State: Running
AppId: BackgroundTask.App
Background Task Name: SampleBackgroundTask
Background Task Id: {ee4438ee-22db-4cdd-85e4-8ad8a1063523}
...
```

If you know the full package name you can use .querypackage to display the *Background Task Id* field.

You can also locate the BackgroundTaskId by using the enumerateBgTasks option of the PLMDebug. For more information about the PLMDebug utility, see [PLMDebug](#).

```
C:\Program Files\Debugging Tools for Windows (x64)>PLMDebug /enumerateBgTasks
Microsoft.SDKSamples.BackgroundTask.CPP_1.0.0.0_x64_8wekyb3d8bbwe
Package full name is Microsoft.SDKSamples.BackgroundTask.CPP_1.0.0.0_x64_8wekyb3d8bbwe.
Background Tasks:
SampleBackgroundTask : {C05806B1-9647-4765-9A0F-97182CEA5AAD}

SUCCEEDED
```

Debugging a UWP process remotely using a Process Server (DbgSrv)

All of the -plm* commands work correctly with dbgsrv. To debug using dbgsrv, use the -premove switch with the connection string for dbgsrv:

```
windbg.exe -premove npipe:pipe=fdsa,server=localhost -plmPackage e24caf14-8483-4743-b80c-
ca46c28c75df_1.0.0.0_x86_97ghe447vaan8 -plmApp App
```

For more information about the -premove options, see [Process Servers \(User Mode\)](#) and [Process Server Examples](#).

Summary of UWP app commands

This section provides a summary of UWP app debugger commands

Gathering Package Information

.querypackage

The .querypackage displays the state of a UWP application. For example, if the app is running, it can be in the *Active* state.

```
.querypackage <PLMPackageName>
```

Example:

```
0:000> .querypackage e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
Package Full Name: e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
Package Display Name: HelloWorld
Version: 1.0.0.0
Processor Architecture: x86
Publisher: CN=domars
Publisher Display Name: domars
Install Folder: c:\users\domars\documents\visual studio
2015\Projects\HelloWorld\HelloWorld\bin\x86\Release\AppX
Package State: Running
AppId: App
Executable: HelloWorld.exe
```

.querypackages

The .querypackages command lists all the installed UWP applications and their current state.

```
.querypackages
```

Example:

```

0:000> .querypackages
...
Package Full Name: Microsoft.MicrosoftSolitaireCollection_3.9.5250.0_x64_8wekyb3d8bbwe
Package Display Name: Microsoft Solitaire Collection
Version: 3.9.5250.0
Processor Architecture: x64
Publisher: CN=Microsoft Corporation, O=Microsoft Corporation, L=Redmond, S=Washington, C=US
Publisher Display Name: Microsoft Studios
Install Folder: C:\Program
Files\WindowsApps\Microsoft.MicrosoftSolitaireCollection_3.9.5250.0_x64_8wekyb3d8bbwe
Package State: Unknown
AppId: App

Package Full Name: e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
Package Display Name: HelloWorld
Version: 1.0.0.0
Processor Architecture: x86
Publisher: CN=domars
Publisher Display Name: domars
Install Folder: c:\users\domars\documents\visual studio
2015\Projects\HelloWorld\HelloWorld\bin\x86\Release\AppX
Package State: Running
AppId: App
Executable: HelloWorld.exe

Package Full Name: Microsoft.SDKSamples.BackgroundTask.CPP_1.0.0.0_x86_8wekyb3d8bbwe
Package Display Name: BackgroundTask C++ sample
Version: 1.0.0.0
Processor Architecture: x86
Publisher: CN=Microsoft Corporation, O=Microsoft Corporation, L=Redmond, S=Washington, C=US
Publisher Display Name: Microsoft Corporation
Install Folder: C:\Users\DOMARS\Documents\Visual Studio
2015\Projects\Background_task_sample\C++\Debug\BackgroundTask.Windows\AppX
Package State: Unknown
AppId: BackgroundTask.App

...

```

Launching an app for Debugging

.createpackageapp

The .createpackageapp command enables debugging and launches a UWP application.

```
.createpackageapp <PLMPackageName> <ApplicationId> [<parameters>]
```

This table lists the parameters for .createpackageapp.

Parameter	Description
<PLMPackageName>	The name of the application package. Use the .querypackages command to lists all UWP applications. Do not provide a path to the location of the package, provide just the package name.
<ApplicationId>	The ApplicationId can be located using .querypackage or .querypackages as discussed earlier in this topic. For more information about the application manifest file, see App package manifest .

[<parameters>]

Optional parameters that are passed to the application. Not all applications require or use these optional parameters.

Example:

```
.createpackageapp e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8 App
```

Enabling and Disabling Use of Debug Commands

.enablepackagedebug

The .enablepackagedebug command enables debugging for UWP application. You must use .enablepackagedebug before you call any of the suspend, resume, or terminate functions.

Note that the .createpackageapp command also enables debugging of the app.

```
.enablepackagedebug <PLMPackageName>
```

Example:

```
.enablepackagedebug e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

.disablepackagedebug

The .disablepackagedebug command disables debugging for UWP application.

```
.disablepackagedebug <PLMPackageName>
```

Example:

```
.disablepackagedebug e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

Starting and Stopping apps

Note that suspend, resume, and terminate affect all currently running apps in the package.

.suspendpackage

The .suspendpackage command, suspends a UWP application.

```
.suspendpackage <PLMPackageName>
```

Example:

```
0:024> .suspendpackage e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

.resumepackage

The .resumepackage command resumes a UWP application.

```
.resumepackage <PLMPackageName>
```

Example:

```
.resumepackage e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

.terminatepackageapp

The .terminatepackageapp command terminates the all of the UWP applications in the package.

```
.terminatepackageapp <PLMPackageName>
```

Example:

```
.terminatepackageapp e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

Background Tasks

.activatepackagebgtask

The .activatepackagebgtask command enables debugging and launches a UWP background task.

```
.activatepackagebgtask <PLMPackageName> <bgTaskId>
```

Example:

```
.activatepackagebgtask Microsoft.SDKSamples.BackgroundTask.CPP_1.0.0.0_x64_8wekyb3d8bbwe {C05806B1-9647-4765-9A0F-97182CEA5AAD}
```

Usage Examples

Attach a debugger when your app is launched

Suppose you have an app named HelloWorld that is in a package named e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8. Verify that your package is installed by displaying the full names and running states all installed packages. In a Command Prompt window, enter the following command. You can use CTRL+F to search the command output for the app name of HelloWorld.

```
.querypackages
...
Package Full Name: e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
Package Display Name: HelloWorld
Version: 1.0.0.0
Processor Architecture: x86
Publisher: CN=domars
Publisher Display Name: user1
Install Folder: c:\users\user1\documents\visual studio
2015\Projects\HelloWorld\HelloWorld\bin\x86\Release\AppX
Package State: Unknown
AppId: App
...
...
```

Use .createpackageapp to launch and attach to the app. The .createpackageapp command also enables debugging of the app.

```
.createpackageapp e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8 App
```

When you have finished debugging, decrement the debug reference count for the package using the `.disablepackagedebug` command.

```
.disablepackagedebug e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

Attach a debugger to an app that is already running

Suppose you want to attach WinDbg to MyApp, which is already running. In WinDbg, on the **File** menu, choose **Attach to a Process**. Note the process ID for MyApp. Let's say the process ID is 4816. Increment the debug reference count for the package that contains MyApp.

```
.enablepackagedebug e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

In WinDbg, in the **Attach to Process** dialog box, select process 4816, and click OK. WinDbg will attach to MyApp.

When you have finished debugging, decrement the debug reference count for the package using the `.disablepackagedebug` command.

```
.disablepackagedebug e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

Manually suspend and resume your app

Follow these steps to manually suspend and resume your app. First, increment the debug reference count for the package that contains your app.

```
.enablepackagedebug e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

Suspend the package. Your app's suspend handler is called, which can be helpful for debugging.

```
.suspendpackage e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

When you have finished debugging, resume the package.

```
.resumepackage e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

Finally, decrement the debug reference count for the package.

```
.disablepackagedebug e24caf14-8483-4743-b80c-ca46c28c75df_1.0.0.0_x86_97ghe447vaan8
```

Opening a Dump File Using WinDbg

5/26/2017 • 1 min to read • [Edit Online](#)

There are several ways you can use WinDbg to open a dump file.

WinDbg Menu

If WinDbg is already running and is in dormant mode, you can open a dump by choosing **Open Crash Dump** from the **File** menu or by pressing CTRL+D. When the Open Crash Dump dialog box appears, enter the full path and name of the crash dump file in the **File name** box, or use the dialog box to select the proper path and file name. When the proper file has been chosen, click **Open**.

Command Prompt

In a Command Prompt window, you can open a dump file when you launch WinDbg. Use the following command:

windbg -y SymbolPath -i ImagePath -z DumpFileName

The **-v** option (verbose mode) is also useful. For more information about the command-line syntax, see [WinDbg Command-Line Options](#).

Debugger Command Window

If WinDbg is already in a kernel-mode debugging session, you can open a dump file by using the [.opendump \(Open Dump File\)](#) command, followed by **g (Go)**.

[Send comments about this topic to Microsoft](#)

Live Kernel-Mode Debugging Using WinDbg

5/31/2017 • 4 min to read • [Edit Online](#)

There are two ways you can use WinDbg to initiate a live kernel-mode debugging session.

WinDbg Menu

When WinDbg is in dormant mode, you can begin a kernel debugging session by choosing **Kernel Debug** from the **File** menu or by pressing CTRL+K. When the **Kernel Debugging** dialog box appears, click the appropriate tab: **NET, 1394, USB, COM, or Local**. Each tab specifies a different connection method. For more information about the dialog box and its entries, see [File | Kernel Debug](#).

Command Prompt

In a Command Prompt window, you can initiate a kernel-mode debugging session when you launch WinDbg. Enter one of the following commands:

```
windbg [-y SymbolPath] -k net:port=PortNumber, key=Key windbg [-y SymbolPath] -k  
1394:channel=1394Channel[,symlink=1394Protocol] windbg [-y SymbolPath] -k  
usb:targetname=USBString windbg [-y SymbolPath] -k com:port=ComPort,baud=BaudRate windbg [-y  
SymbolPath] -k com:pipe,port=\\VMHost\\pipe\\PipeName[, resets=0][,reconnect] windbg [-y SymbolPath] -  
k com:modem windbg [-y SymbolPath] -kl windbg [-y SymbolPath] -k For more information, see WinDbg  
Command-Line Options.
```

Environment Variables

For debugging over a serial (COM port) or 1394 connection, you can use environment variables to specify the connection settings.

Use the following variables to specify a serial connection.

set _NT_DEBUG_PORT = ComPort **set _NT_DEBUG_BAUD_RATE = BaudRate** Use the following variables to specify a 1394 connection.

```
set _NT_DEBUG_BUS = 1394 set _NT_DEBUG_1394_CHANNEL = 1394Channel **** set  
_NT_DEBUG_1394_SYMLINK = 1394Protocol **** For more information, see Kernel-Mode Environment  
Variables.
```

Parameters

SymbolPath

A list of directories where symbol files are located. Directories in the list are separated by semicolons. For more information, see [Symbol Path](#).

PortNumber

A port number to use for network debugging. You can choose any number from 49152 through 65535. For more information, see [Setting Up a Network Connection Manually](#).

Key

The encryption key to use for network debugging. We recommend that you use an automatically generated key, which is provided by bcdedit when you configure the target computer. For more information, see [Setting Up a Network Connection Manually](#).

1394Channel

The 1394 channel number. Valid channel numbers are any integer between 0 and 62, inclusive. *1394Channel* must match the number used by the target computer, but does not depend on the physical 1394 port chosen on the adapter. For more information, see [Setting Up a 1394 Connection Manually](#).

1394Protocol

The connection protocol to be used for the 1394 kernel connection. This can almost always be omitted, because the debugger will automatically choose the correct protocol. If you wish to set this manually, and the target computer is running Windows XP, *1394Protocol* should be set equal to "channel". If the target computer is running Windows Server 2003 or later, *1394Protocol* should be set equal to "instance". If it is omitted, the debugger will default to the protocol appropriate for the current target computer. This can only be specified through the command line or the environment variables, not through the WinDbg graphical interface.

USBString

A USB connection string. This must match the string specified with the /targetname boot option. For more information, see [Setting Up a USB 3.0 Connection Manually](#) and [Setting Up a USB 2.0 Connection Manually](#).

ComPort

The name of the COM port. This can be in the format "com2" or in the format "\\.\com2", but should not simply be a number. For more information, see [Setting Up a Serial Connection Manually](#).

BaudRate

The baud rate. This can be 9600, 19200, 38400, 57600, or 115200.

VMHost

When debugging a virtual machine, *VMHost* specifies the name of the physical computer on which the virtual machine is running. If the virtual machine is running on the same computer as the kernel debugger itself, use a single period (.) for *VMHost*. For more information, see [Setting Up a Connection to a Virtual Machine](#).

PipeName

The name of the pipe created by the virtual machine for the debugging connection.

resets=0

Specifies that an unlimited number of reset packets can be sent to the target when the host and target are synchronizing. This parameter is only needed when debugging certain kinds of virtual machines.

reconnect

Causes the debugger to automatically disconnect and reconnect the pipe if a read/write failure occurs. Additionally, if the named pipe is not found when the debugger is started, the reconnect parameter will cause it to wait for a pipe of this name to appear. This parameter is only needed when debugging certain kinds of virtual machines.

-kl

Causes the debugger to perform local kernel-mode debugging. For more information, see [Local Kernel-Mode Debugging](#).

Examples

The following batch file could be used to set up and start a debugging session over a COM port connection.

```
set _NT_SYMBOL_PATH=d:\mysymbols
set _NT_DEBUG_PORT=com1
set _NT_DEBUG_BAUD_RATE=115200
set _NT_DEBUG_LOG_FILE_OPEN=d:\debuggers\logfile1.log
windbg -k
```

The following batch file could be used to set up and start a debugging session over a 1394 connection.

```
set _NT_SYMBOL_PATH=d:\mysymbols
set _NT_DEBUG_BUS=1394
set _NT_DEBUG_1394_CHANNEL=44
set _NT_DEBUG_LOG_FILE_OPEN=d:\debuggers\logfile1.log
windbg -k
```

The following command lines could be used to start WinDbg without any environment variables.

```
windbg -y d:\mysymbols -k com:port=com2,baud=57600 windbg -y d:\mysymbols -k
com:port=\.\com2,baud=115200 windbg -y d:\mysymbols -k 1394:channel=20,symlink=instance
windbg -y d:\mysymbols -k net:port=50000,key=AutoGeneratedKey
```

Ending a Debugging Session in WinDbg

5/26/2017 • 2 min to read • [Edit Online](#)

Exiting WinDbg

You can exit WinDbg by choosing **Exit** from the **File** menu or by pressing ALT+F4.

If you are performing user-mode debugging, these commands close the application that you are debugging, unless you used the **-pd** command-line option when you started the debugger.

If you are performing kernel-mode debugging, the target computer remains in its current state. This situation enables you to leave the target running or frozen. (If you leave the target frozen, any future connection from a kernel debugger can resume debugging where you left it.)

Ending a User-Mode Session Without Exiting

To end a user-mode debugging session, return the debugger to dormant mode, and close the target application, you can use the following methods:

- Enter the **.kill (Kill Process)** command.
- Enter the **q (Quit)** command (unless you started the debugger with the **-pd** option).
- Choose **Stop Debugging** from the **Debug** menu.
- Press SHIFT+F5.
- Click the **Stop Debugging** button () on the toolbar

To end a user-mode debugging session, return the debugger to dormant mode, and set the target application running again, you can use the following methods:

- Enter the **.detach (Detach from Process)** command. If you are debugging multiple targets, this command detaches from the current target and continues the debugging session with the remaining targets.
- Choose **Detach Debuggee** from the **Debug** menu. If you are debugging multiple targets, this command detaches from all current targets.
- Enter the **qd (Quit and Detach)** command.
- Enter the **q (Quit)** command, if you started the debugger with the **-pd** option.

To end a user-mode debugging session, return the debugger to dormant mode, but leave the target application in the debugging state, you can use the following method:

- Enter the **.abandon (Abandon Process)** command.

For information about reattaching to the target, see [Reattaching to the Target Application](#).

Ending a Kernel-Mode Session Without Exiting

To end a kernel-mode debugging session, return the debugger to dormant mode, and leave the target computer frozen, you can use the following methods:

- Enter the **q (Quit)** command (unless you started the debugger with the **-pd** option)

- Choose **Stop Debugging** from the **Debug** menu.
- Press SHIFT+F5.
- Click the **Stop debugging (Shift+F5)** button (

When a WinDbg session ends, you are prompted to save the workspace for the current session, and then WinDbg returns to dormant mode. At this point, you can use all starting options. That is, you can start to debug a running process, spawn a new process, attach to a target computer, open a crash dump, or connect to a remote debugging session.

Setting Symbol and Executable Image Paths in WinDbg

5/26/2017 • 3 min to read • [Edit Online](#)

Symbol Path

The symbol path specifies the directories where the symbol files are located. For more information about symbols and symbol files, see [Symbols](#).

Note If you are connected to the Internet or a corporate network, the most efficient way to access symbols is to use a symbol server. You can use a symbol server by using the `srv*` or `symsrv*` string within your symbol path. For more information about symbol servers, see [Symbol Stores and Symbol Servers](#).

To control the symbol path in WinDbg, do one of the following:

- Choose **Symbol File Path** from the **File** menu or press **CTRL+S**.
- Use the **.sympath (Set Symbol Path)** command. If you are using a symbol server, the **.symfix (Set Symbol Store Path)** command is similar to **.sympath** but saves you typing.
- When you start the debugger, use the **-y** command-line option. See [WinDbg Command-Line Options](#).
- Before you start the debugger, use the `_NT_SYMBOL_PATH` and `_NT_ALT_SYMBOL_PATH` [environment variables](#) to set the path. The symbol path is created by appending `_NT_SYMBOL_PATH` after `_NT_ALT_SYMBOL_PATH`. (Typically, the path is set through the `_NT_SYMBOL_PATH`. However, you might want to use `_NT_ALT_SYMBOL_PATH` to override these settings in special cases, such as when you have private versions of shared symbol files.) If you try to add an invalid directory through these environment variables, the debugger ignores this directory.

Note If you use the **-sins** command-line option, the debugger ignores the symbol path environment variable.

Executable Image Path

An executable file is a binary file that the processor can run. These files typically have the `.exe`, `.dll`, or `.sys` file name extension. Executable files are also known as modules, especially when executable files are described as units of a larger application. Before the Windows operating system runs an executable file, it loads it into memory. The copy of the executable file in memory is called the executable image or the image.

Note These terms are sometimes used imprecisely. For example, some documents might use "image" for the actual file on the disk. Also, the Windows kernel and HAL have special module names. For example, the `nt` module corresponds to the `Ntoskrnl.exe` file.

The executable image path specifies the directories that the binary executable files are located in.

In most situations, the debugger knows the location of the executable files, so you do not have to set the path for this file.

However, there are situations when this path is required. For example, kernel-mode [small memory dump](#) files do not contain all of the executable files that exist in memory at the time of a stop error (that is, a crash). Similarly, user-mode minidump files do not contain the application binaries. If you set the path of the executable files, the debugger can find these binary files.

The debugger's executable image path is a string that consists of multiple directory paths, separated by semicolons. Relative paths are supported. However, unless you always start the debugger from the same directory, you should add a drive letter or a network share before each path. Network shares are also supported. The debugger searches the executable image path recursively. That is, the debugger searches the subdirectories of each directory that is listed in this path.

To control the executable image path in WinDbg, do one of the following:

- Choose **Image File Path** from the **File** menu, or press CTRL+I.
- Use the [.exepath \(Set Executable Path\)](#) command.
- When you start the debugger, use the **-i** command-line option. See [WinDbg Command-Line Options](#).
- Before you start the debugger, use the **_NT_EXECUTABLE_IMAGE_PATH** [environment variable](#) to set the path.

Note If you use the **-sins** command-line option, the debugger ignores the executable image path environment variable.

Remote Debugging Using WinDbg

5/31/2017 • 2 min to read • [Edit Online](#)

Remote debugging involves two debuggers running at two different locations. The debugger that performs the debugging is called the *debugging server*. The second debugger, called the *debugging client*, controls the debugging session from a remote location. To establish a remote session, you must set up the debugging server first and then activate the debugging client.

The code that is being debugged could be running on the same computer that is running the debugging server, or it could be running on a separate computer. If the debugging server is performing user-mode debugging, then the process that is being debugged can run on the same computer as the debugging server. If the debugging server is performing kernel-mode debugging, then the code being debugged would typically run on a separate target computer.

The following diagram illustrates a remote session where the debugging server, running on a host computer, is performing kernel-mode debugging of code that is running on a separate target computer.

There are several transport protocols you can use for a remote debugging connection: TCP, NPIPE, SPIPE, SSL, and COM Port. Suppose you have chosen to use TCP as the protocol and you have chosen to use WinDbg as both the debugging client and the debugging server. You can use the following procedure to establish a remote kernel-mode debugging session:

1. On the host computer, open WinDbg and establish a kernel-mode debugging session with a target computer. (See [Live Kernel-Mode Debugging Using WinDbg](#).)
2. Break in by choosing **Break** from the **Debug** menu or by pressing CRTL-Break.
3. In the [Debugger Command Window](#), enter the following command.

.server tcp:port=5005

Note The port number 5005 is arbitrary. The port number is your choice.

4. WinDbg will respond with output similar to the following.

```
Server started. Client can connect with any of these command lines
0: <debugger> -remote tcp:Port=5005,Server=YourHostComputer
```

5. On the remote computer, open WinDbg, and choose **Connect to Remote Session** from the **File** menu.
6. Under **Connection String**, enter the following string.

tcp:Port=5005,Server=YourHostComputer

where *YourHostComputer* is the name of your host computer, which is running the debugging server.

Click **OK**.

Using the Command Line

As an alternative to the procedure given in the preceding section, you can set up a remote debugging session at the command line. Suppose you are set up to establish a kernel-mode debugging session, between a host computer and a target computer, over a 1394 cable on channel 32. You can use the following procedure to establish a remote debugging session:

1. On the host computer, enter the following command in a Command Prompt window.

```
windbg -server tcp:port=5005 -k 1394:channel=32
```

2. On the remote computer, enter the following command in a Command Prompt window.

```
windbg -remote tcp:Port=5005,Server=YourHostComputer
```

where *YourHostComputer* is the name of your host computer, which is running the debugging server.

Additional Information

There are many ways to establish remote debugging other than the ones shown in this topic. For complete information about setting up a debugging server in the WinDbg [Debugger Command Window](#), see [.server \(Create Debugging Server\)](#). For complete information about launching WinDbg (and establishing remote debugging) at the command line, see [WinDbg Command-Line Options](#).

[Send comments about this topic to Microsoft](#)

Entering Debugger Commands in WinDbg

5/31/2017 • 2 min to read • [Edit Online](#)

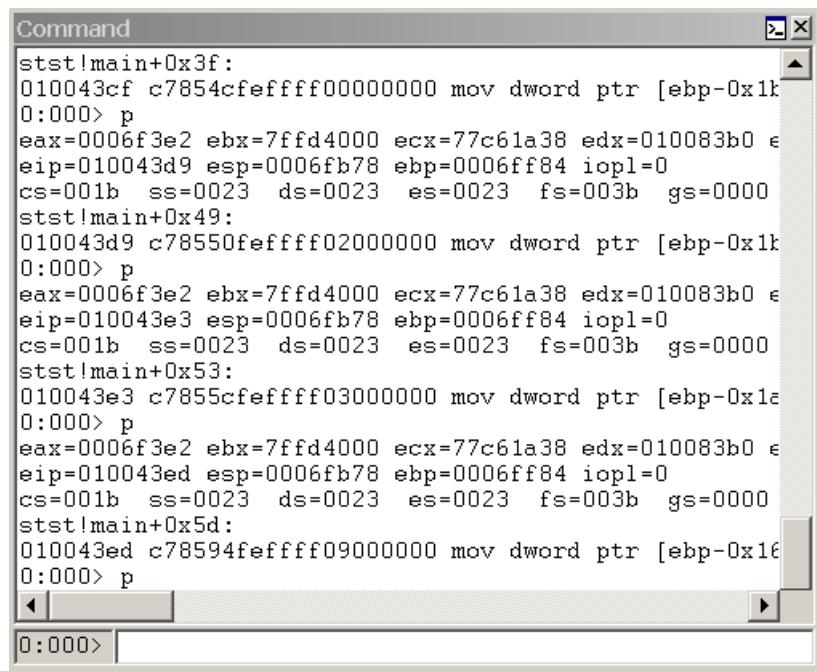

The Debugger Command window is the primary debugging information window in WinDbg. You can enter debugger commands and view the command output in this window.

Note This window displays "Command" in the title bar. However, this documentation always refers to this window as "the Debugger Command window" to avoid confusing it with the Command Prompt windows that are used to issue Microsoft MS-DOS commands.

Opening the Debugger Command Window

To open the Debugger Command window, choose **Command** from the **View** menu. (You can also press ALT+1 or click the **Command** button () on the toolbar. ALT+SHIFT+1 closes the Debugger Command window.)

The following screen shot shows an example of a Debugger Command window.

```
Command
stst!main+0x3f:
010043cf c7854cfefffff00000000 mov dword ptr [ebp-0x1k
0:000> p
eax=0006f3e2 ebx=7ffd4000 ecx=77c61a38 edx=010083b0 e
eip=010043d9 esp=0006fb78 ebp=0006ff84 iopl=0
cs=001b ss=0023 ds=0023 es=0023 fs=003b gs=0000
stst!main+0x49:
010043d9 c78550cfefffff02000000 mov dword ptr [ebp-0x1k
0:000> p
eax=0006f3e2 ebx=7ffd4000 ecx=77c61a38 edx=010083b0 e
eip=010043e3 esp=0006fb78 ebp=0006ff84 iopl=0
cs=001b ss=0023 ds=0023 es=0023 fs=003b gs=0000
stst!main+0x53:
010043e3 c78555cfefffff03000000 mov dword ptr [ebp-0x1e
0:000> p
eax=0006f3e2 ebx=7ffd4000 ecx=77c61a38 edx=010083b0 e
eip=010043ed esp=0006fb78 ebp=0006ff84 iopl=0
cs=001b ss=0023 ds=0023 es=0023 fs=003b gs=0000
stst!main+0x5d:
010043ed c78594cfefffff09000000 mov dword ptr [ebp-0x1e
0:000> p
```

Using the Debugger Command Window

The Debugger Command window is split into two panes. You type commands in the smaller pane (the command entry pane) at the bottom of the window and view the output in the larger pane at the top of the window.

In the command entry pane, use the UP ARROW and DOWN ARROW keys to scroll through the command history. When a command appears, you can edit it or press ENTER to run the command.

The Debugger Command window contains a shortcut menu with additional commands. To access this menu, right-click the title bar of the window or click the icon near the upper-right corner of the window (). The following list describes some of the menu commands:

- **Add to command output** adds a comment to the command output, similar to the [Edit | Add to Command Output](#) command.
- **Clear command output** deletes all of the text in the window.

- **Choose text color and recolor selection...** opens a dialog box that enables you to choose the text color in which to display the text that is selected in the Debugger Command window.
- **Word wrap** turns the word wrap status on and off. This command affects the whole window, not only commands that you use after this state is selected. Because many commands and extensions produce formatted displays, it is not recommended that you use word wrap.
- **Mark current location** sets a marker at the current cursor location in the command window. The name of the mark is the contents of the line to the right of the cursor.
- **Go to mark** causes the window to scroll so that the line that contains the chosen mark is positioned at the top of the window.
- **Always floating** causes the window to remain undocked, even if it is dragged to a docking location.
- **Move with frame** causes the window to move when the WinDbg frame is moved, even if the window is undocked. For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#).

[Send comments about this topic to Microsoft](#)

Using the Command Browser Window in WinDbg

5/26/2017 • 2 min to read • [Edit Online](#)

A Command Browser window displays and stores the text results of a debugger command. This window creates a command reference that enables you to view the results of a specific command without re-entering the command. A Command Browser window also provides navigation through the stored commands, so you can more quickly access commands than with the [Debugger Command window](#).

Opening the Command Browser Window

You can open multiple Command Browser windows at one time. To open a Command Browser window, choose **Command Browser** from the **View** menu. (You can also press CTRL+N or click the **Command Browser** button () on the toolbar. ALT+SHIFT+N closes the Command Browser window.)

You can also open a Command Browser window by entering [.browse \(Display Command in Browser\)](#) in the regular Debugger Command window.

The following screen shot shows an example of a Command Browser window.

Using the Command Browser Window

In the Command Browser window, you can do the following:

- To enter a command, type it in the **Command** box.
- To view the results of a previously entered command, use the **Start**, **Prev**, and **Next** buttons to scroll through the command list, or select one of the preceding 20 commands from the **Command** menu. To find a command that is not one of the preceding 20 commands, use the **Next** button.

The Command Browser window has a shortcut menu with additional commands. To access the menu, right-click the title bar or click the icon near the upper-right corner of the window (). The following list describes some of the menu commands:

- **Start**, **Prev**, and **Next** move the cursor to the start of the command history or to the previous or next command, respectively.
- **Add to Recent Commands** puts the current command into the **Recent Commands** menu of the **View** menu in the WinDbg window. Recent commands are saved in the workspace.
- **Toolbar** turns the toolbar on and off.

- **Move to new dock** closes the Command Browser window and opens it in a new dock.
- **Always floating** causes the window to remain undocked even if it is dragged to a docking location.
- **Move with frame** causes the window to move when the WinDbg frame is moved, even if the window is undocked. For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#).

Commands that you enter in a Command Browser window are executed by the debugger engine, not by the WinDbg user interface. This means that you cannot enter user interface commands like `.cls` in a Command Browser window. If the user interface is a remote client, the server (not the client) executes the command.

A command that you enter in a Command Browser window executes synchronously, so it does not display output until it has completed.

Command Browser windows are saved in the WinDbg workspace, but the command histories are not saved. Only the current command for each Command Browser window is saved in the workspace.

[Send comments about this topic to Microsoft](#)

Setting Breakpoints in WinDbg

5/26/2017 • 1 min to read • [Edit Online](#)

There are several ways you can set, view, and manipulate breakpoints using WinDbg.

Debugger Command Window

You can set, view, and manipulate breakpoints by entering commands in the Debugger Command Window. For a list of commands, see [Methods of Controlling Breakpoints](#).

WinDbg Menu

You can open the **Breakpoints** dialog box by choosing **Breakpoints** from the **Edit** menu or by pressing ALT+F9. This dialog box lists all breakpoints, and you can use it to disable, enable, or clear existing breakpoints or to set new breakpoints.

Code Windows

The Disassembly window and the Source windows highlight lines that have breakpoints set. Enabled breakpoints are red, and disabled breakpoints are yellow.

If you set the cursor on a specific line in the Disassembly window or in a Source window, you can press F9 to set a breakpoint at that line.

[Send comments about this topic to Microsoft](#)

Viewing the Call Stack in WinDbg

5/26/2017 • 2 min to read • [Edit Online](#)

The call stack is the chain of function calls that have led to the current location of the program counter. The top function on the call stack is the current function, the next function is the function that called the current function, and so on. The call stack that is displayed is based on the current program counter, unless you change the register context. For more information about how to change the register context, see [Changing Contexts](#).

In WinDbg, you can view the call stack by entering commands or by using the Calls window.

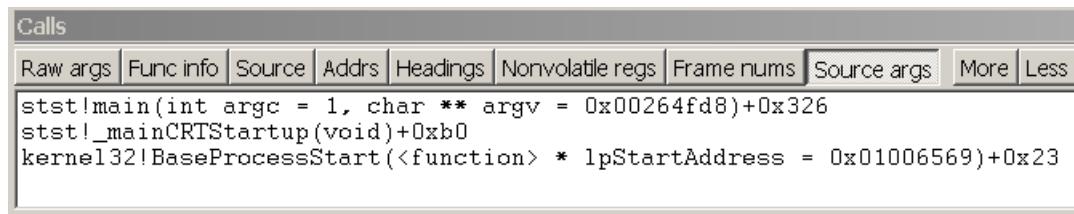

Debugger Command Window

You can view the call stack by entering one of the **k (Display Stack Backtrace)** commands in the Debugger Command window.

Calls Window

As an alternative to the **k** command, you can view the call stack in the Calls window. To open the Calls window, choose **Call Stack** from the **View** menu.

The following screen shot shows an example of a Calls window.

Buttons in the Calls window enable you to customize the view of the call stack. To move to the corresponding call location in the [Source window](#) or [Disassembly window](#), double-click a line of the call stack, or select a line and press ENTER. This action also changes the [local context](#) to the selected stack frame. For more information about running to or from this point, see [Controlling the Target](#).

In user mode, the stack trace is based on the stack of the current thread. For more information about the stack of the current thread, see [Controlling Processes and Threads](#).

In kernel mode, the stack trace is based on the current register context. You can set the register context to match a specific thread, context record, or trap frame. For more information about setting the register context, see [Register Context](#).

The Calls window has a toolbar that contains several buttons and has a shortcut menu with additional commands. To access this menu, right-click the title bar or click the icon near the upper-right corner of the window (grid icon). The toolbar and menu contain the following buttons and commands:

- **Raw args** displays the first three parameters that are passed to the function. On an x86-based processor, this display includes the first three parameters that are passed to the function ("Args to Child").
- **Func info** displays Frame Pointer Omission (FPO) data and other internal information about the function. This command is available only on an x86-based processor.
- **Source** displays source module names and line numbers after the function names (if the debugger has this information).

- **Addr**s displays various frame-related addresses. On an x86-based processor, this display includes the base pointer for the stack frame ("ChildEBP") and the return address ("RetAddr").
- **Nonvolatile regs** displays the nonvolatile portion of the register context. This command is available only on an Itanium-based processor.
- **Frame nums** displays frame numbers. Frames are always numbered consecutively, beginning with zero.
- **Arg types** displays detailed information about the arguments that are expected and received by the functions in the stack.
- **Always floating** causes the window to remain undocked even if it is dragged to a docking location.
- **Move with frame** causes the window to move when the WinDbg frame is moved, even if the window is undocked. For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#).

Additional Information

For more information about the register context and the local context, see [Changing Contexts](#).

[Send comments about this topic to Microsoft](#)

Assembly Code Debugging in WinDbg

5/26/2017 • 2 min to read • [Edit Online](#)

In WinDbg, you can view assembly code by entering commands or by using the Disassembly window.

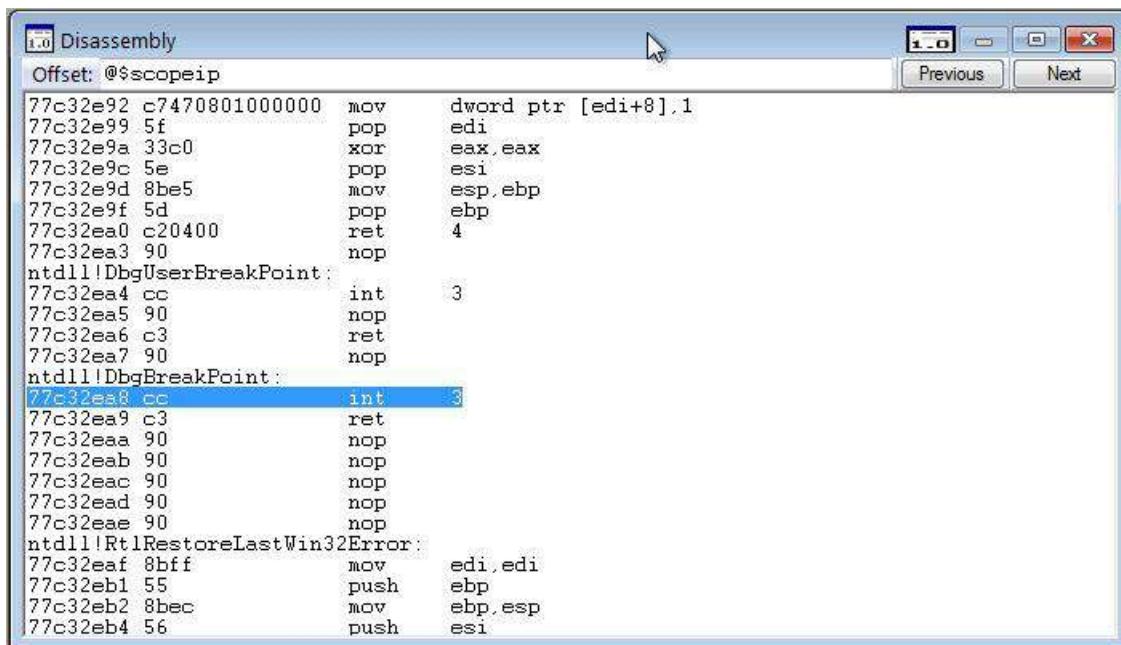

Debugger Command Window

You can view assembly code by entering the one of the **u**, **ub**, **uu (Unassemble)** commands in the Debugger Command window.

Disassembly Window

To open or switch to the Disassembly window, choose **Disassembly** from the **View** menu. (You can also press ALT+7 or click the **Disassembly** button () on the toolbar. ALT+SHIFT+7 will close the Disassembly Window.)

The following screen shot shows an example of a Disassembly window.

The debugger takes a section of memory, interprets it as binary machine instructions, and then disassembles it to produce an assembly-language version of the machine instructions. The resulting code is displayed in the Disassembly window.

In the Disassembly window, you can do the following:

- To disassemble a different section of memory, in the **Offset** box, type the address of the memory you want to disassemble. (You can press ENTER after typing the address, but you do not have to.) The Disassembly window displays code before you have completed the address; you can disregard this code.
- To see other sections of memory, click the **Previous** or **Next** buttons or press the PAGE UP or PAGE DOWN keys. These commands display disassembled code from the preceding or following sections of memory, respectively. By pressing the RIGHT ARROW, LEFT ARROW, UP ARROW, and DOWN ARROW keys, you can navigate within the window. If you use these keys to move off of the page, a new page will appear.

The Disassembly window has a toolbar that contains two buttons and a shortcut menu with additional commands. To access the menu, right-click the title bar or click the icon that appears near the upper-right corner of the window (). The following list describes some of the menu commands:

- **Go to current address** opens the Source window with the source file that corresponds to the selected line in the Disassembly window and highlights this line.
- **Disassemble before current instruction** causes the current line to be placed in the middle of the Disassembly window. This command is the default option. If this command is cleared, the current line will appear at the top of the Disassembly window, which saves time because reverse-direction disassembly can be time-consuming.
- **Highlight instructions from the current source line** causes all of the instructions that correspond to the current source line to be highlighted. Often, a single source line will correspond to multiple assembly instructions. If code has been optimized, these assembly instructions might not be consecutive. This command enables you to find all of the instructions that were assembled from the current source line.
- **Show source line for each instruction** displays the source line number that corresponds to each assembly instruction.
- **Show source file for each instruction** displays the source file name that corresponds to each assembly instruction.

Additional Information

For more information about assembly debugging and related commands and a full explanation of the assembly display, see [Debugging in Assembly Mode](#).

[Send comments about this topic to Microsoft](#)

Source Code Debugging in WinDbg

5/26/2017 • 5 min to read • [Edit Online](#)

Source Path

The source path specifies the directories where the C and C++ source files are located. For more information about viewing source code in the debugger, see [Source Code](#).

Note If you are connected to a corporate network, the most efficient way to access source files is to use a source server. You can use a source server by using the `srv*` string within your source path. For more information about source servers, see [Using a Source Server](#).

To control the source path in WinDbg, do one of the following:

- Choose **Source File Path** from the **File** menu or press CTRL+P.
- Use the [.srcpath \(Set Source Path\)](#) command. If you are using a source server, [.srcfix \(Use Source Server\)](#) is slightly easier.
- Use the [.lsrcpath \(Set Local Source Path\)](#) command. If you are using a source server, [.lsrcfix \(Use Local Source Server\)](#) is slightly easier.
- When you start the debugger, use the `-srcpath` or `-lsrcpath` command-line option. See [WinDbg Command-Line Options](#).
- Before you start the debugger, set the `_NT_SOURCE_PATH` [environment variable](#).

Opening and Closing Source Files

To open or close a source file directly, do one of the following:

- Choose **Open Source File** from the **File** menu, or press CTRL+O. You can also use the **Open source file** button (

Note When you use the menu or the toolbar button to open a source file, the path of that file is automatically appended to the source path.

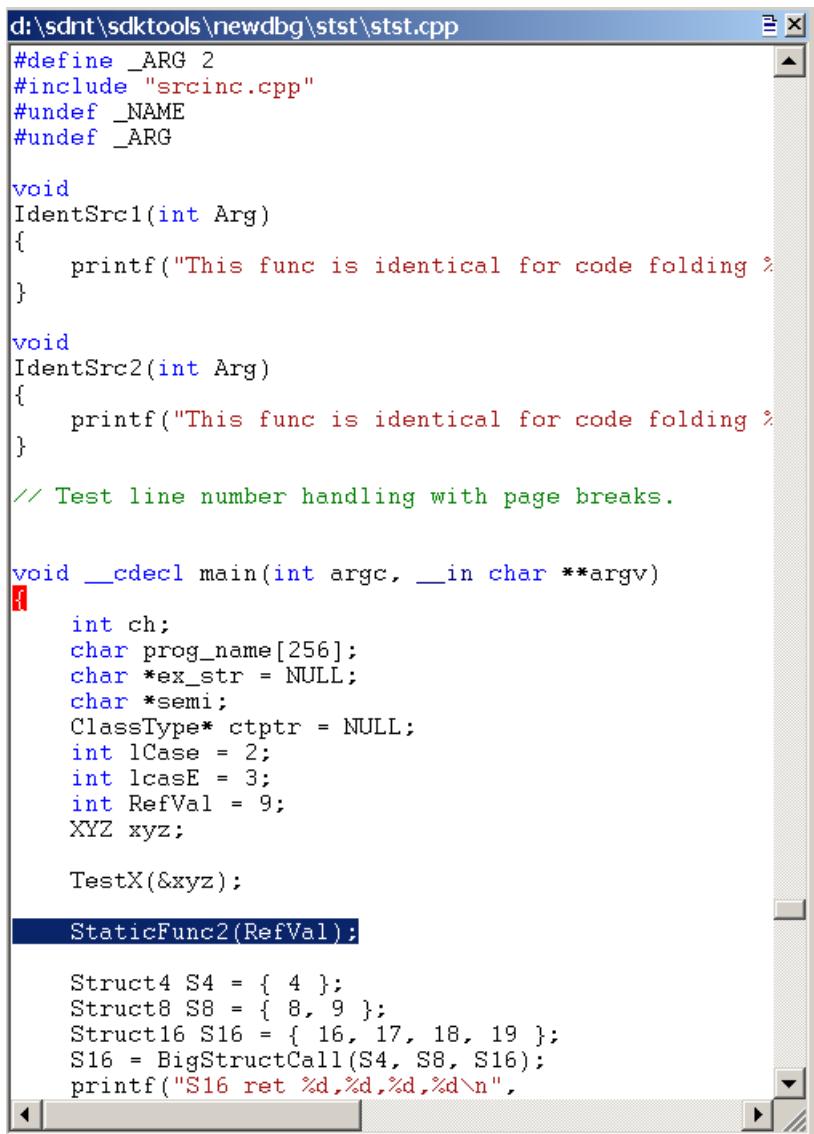

- Choose **Close Current Window** from the **File** menu.
- Click the **Close** button in the corner of the Source window.
- Choose **Recent Files** from the **File** menu to open one of the four source files that you most recently opened in WinDbg.
- Enter the [.open \(Open Source File\)](#) command.
- Enter the [.lsf \(Load or Unload Source File\)](#) command.

In WinDbg, the Source window displays source files that have been loaded into the debugger.

Opening the Source Window

The debugger opens a source window when it loads a new source file. To restore or switch to an open Source window, go to the **Window** menu and choose from the list of windows at the bottom of the menu.

The following screen shot shows an example of a Source window.

```
d:\sdnt\sdktools\newdbg\stst\stst.cpp
#define _ARG 2
#include "srcinc.cpp"
#undef _NAME
#undef _ARG

void
IdentSrc1(int Arg)
{
    printf("This func is identical for code folding %d\n", Arg);

void
IdentSrc2(int Arg)
{
    printf("This func is identical for code folding %d\n", Arg);

// Test line number handling with page breaks.

void __cdecl main(int argc, __in char **argv)
{
    int ch;
    char prog_name[256];
    char *ex_str = NULL;
    char *semi;
    ClassType* ctptr = NULL;
    int lCase = 2;
    int lcasE = 3;
    int RefVal = 9;
    XYZ xyz;

    TestX(&xyz);

    StaticFunc2(RefVal);

    Struct4 S4 = { 4 };
    Struct8 S8 = { 8, 9 };
    Struct16 S16 = { 16, 17, 18, 19 };
    S16 = BigStructCall(S4, S8, S16);
    printf("S16 ret %d,%d,%d,%d\n",
```

Each source file resides in its own Source window. The title of each Source window is the full path of the source file.

Using the Source Window

Each Source window displays the text of one source file. You cannot edit a source file in the debugger. For more information about changing the font and tab settings, see [Changing Text Properties](#).

Each Source window has a shortcut menu with additional commands. To access the menu, right-click the title bar or click the icon that appears near the upper-right corner of the window (📋). The following list describes some of the menu commands:

- **Set instruction pointer to current line** changes the value of the instruction pointer to the instruction that corresponds to the current line. This command is equivalent to using the [Edit | Set Current Instruction](#) command or pressing **CTRL+SHIFT+I**.
- **Edit this file** opens the source file in a text editor. The editor is determined by the WinDiff editor registry information or by the value of the **WINDBG_INVOKE_EDITOR** environment variable. For example, consider the case when the value of **WINDBG_INVOKE_EDITOR** is the following.

```
c:\my\path\myeditor.exe -file %f -line %l
```

In this case, Myeditor.exe will open to the one-based line number of the current source file. The **%l** option indicates that line numbers should be read as one-based, while **%f** indicates that the current source file should be used. Other substitution possibilities include **%L**, which indicates that line

numbers are zero-based, and %p, which can also indicate that the current source file should be used.

- **Evaluate selection** evaluates the currently selected text by using the C++ expression evaluator. The result appears in the [Debugger Command window](#). If the selected text includes more than one line, a syntax error results. This command is equivalent to using the [Edit | Evaluate Selection](#) command, pressing CTRL+SHIFT+V, or using the [?? \(Evaluate C++ Expression\)](#) command with the selected text as its argument.
- **Display selected type** displays the data type of the selected object. This display appears in the Debugger Command window. If the selected text includes more than a single object, a syntax error or other irregular results might be displayed. This command is equivalent to using the [Edit | Display Selected Type](#) command or pressing CTRL+SHIFT+Y.
- **Open memory window for selection** opens a new docked Memory window that displays memory starting at the address of the selected expression.
- **Add selection to Watch window** appends the selected source token to the Watch window.
- **Disassemble at current line** causes the instruction that corresponds to the current line to appear in the [Disassembly window](#). The selected line is highlighted in the Source window and in the Disassembly window, but this command affects only the display—the instruction pointer is not changed. If the Disassembly window is closed when this command is clicked, it is opened.
- **Select source language** displays a list of programming languages. Select the programming language that you used to generate the source file, and then click **OK** to enable basic syntax highlighting for the current Source window. Select **<None>** to disable syntax highlighting for the current Source window.

Source Window Colors and Hover Evaluation

If the debugger recognizes the source file name extension, the Source window displays certain syntax elements in color. To turn off or change the colors, do the following:

- To turn the syntax colors off in a single window, open the Source window's shortcut menu, click **Select source language**, and then click **<None>**.
- To turn the syntax colors off for all Source windows, choose **Options** from the **View** menu. Then clear the **Parse Source Languages** check box.
- To change the syntax colors, choose **Options** from the **View** menu. Then, in the **Colors** area, select a syntax element and click the **Change** button to change the color.
- The parsing method that is used for the highlighting is determined by the programming language that is associated with the file extension for the source file. To change the programming language that is associated with a specific file extension, use the [File Extensions for Source Languages dialog box](#). To open this dialog box, choose **Source language file extensions** from the **View** menu.

The line that represents the current program counter is highlighted. Lines at which breakpoints are set are highlighted as well.

If you select a Source window and then use the mouse to hover over a symbol in that window, the symbol will be evaluated. The evaluation is the same as that produced by the [dt \(Display Type\)](#) command. To deactivate this evaluation, choose **Options** from the **View** menu. Then clear the **Evaluate on hover** check box.

Additional Information

For more information about source debugging and related commands, see [Debugging in Source Mode](#).

[Send comments about this topic to Microsoft](#)

Viewing and Editing Memory in WinDbg

5/26/2017 • 6 min to read • [Edit Online](#)

In WinDbg, you can view and edit memory by entering commands or by using a Memory window.

Debugger Command Window

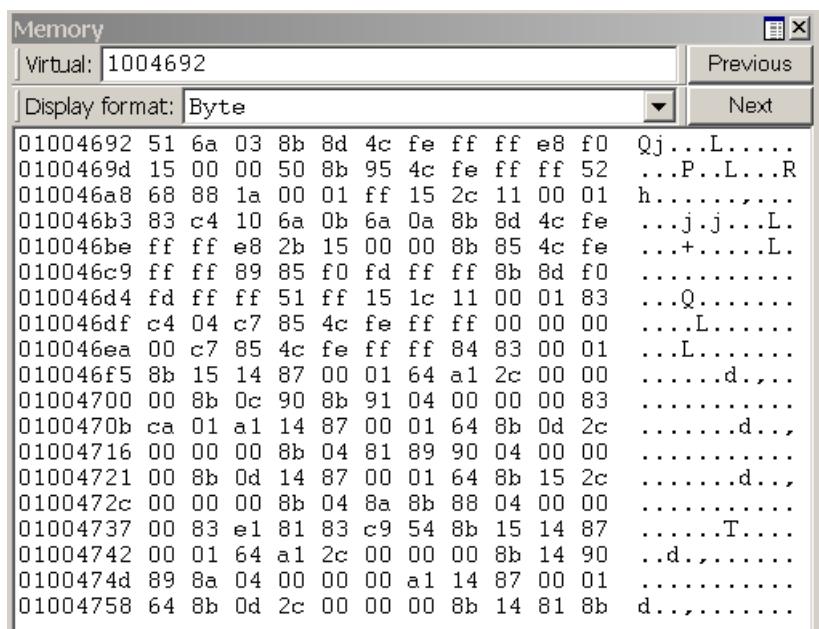

You can view memory by entering one of the **Display Memory** commands in the Debugger Command window.

You can edit memory by entering one of the **Enter Values** commands in the Debugger Command window. For more information, see [Accessing Memory by Virtual Address](#) and [Accessing Memory by Physical Address](#).

Opening a Memory Window

To open a Memory window, choose **Memory** from the **View** menu. (You can also press ALT+5 or click the **Memory** button () on the toolbar. ALT+SHIFT+5 closes the active Memory window.)

The following screen shot shows an example of a Memory window.

Using a Memory Window

The Memory window displays data in several columns. The column on the left side of the window shows the beginning address of each line. The remaining columns display the requested information, from left to right. If you select **Bytes** in the **Display format** menu, the ASCII characters that correspond to these bytes are displayed in the right side of the window.

Note By default, the Memory window displays virtual memory. This type of memory is the only type of memory that is available in user mode. In kernel mode, you can use the **Memory Options** dialog box to display physical memory and other data spaces. The **Memory Options** dialog box is described later in this topic.

In the Memory window, you can do the following:

- To write to memory, click inside the Memory window and type new data. You can edit only hexadecimal data—you cannot directly edit ASCII and Unicode characters. Changes take effect as soon as you type new information.

- To see other sections of memory, use the **Previous** and **Next** buttons on the Memory window toolbar, or press the PAGE UP or PAGE DOWN keys. These buttons and keys display the immediately preceding or following sections of memory. If you request an invalid page, an error message appears.
- To navigate within the window, use the RIGHT ARROW, LEFT ARROW, UP ARROW, and DOWN ARROW keys. If you use these keys to move off of the page, a new page is displayed. Before you use these keys, you should resize the Memory window so that it does not have scroll bars. This sizing enables you to distinguish between the actual page edge and the window cutoff.
- To change the memory location that is being viewed, enter a new address into the address box at the top of the Memory window. Note that the Memory window refreshes its display while you enter an address, so you could get error messages before you have completed typing the address. **Note** The address that you enter into the box is interpreted in the current radix. If the current radix is not 16, you should prefix a hexadecimal address with **0x**. To change the default radix, use the **n (Set Number Base)** command in the Debugger Command window. The display within the Memory window itself is not affected by the current radix.
- To change the data type that the window uses to display memory, use the **Display format** menu in the Memory window toolbar. Supported data types include short words, double words, and quad-words; short, long, and quad integers and unsigned integers; 10-byte, 16-byte, 32-byte, and 64-byte real numbers; ASCII characters; Unicode characters; and hexadecimal bytes. The display of hexadecimal bytes includes ASCII characters as well.

The Memory window has a toolbar that contains two buttons, a menu, and a box and has a shortcut menu with additional commands. To access the menu, right-click the title bar or click the icon near the upper-right corner of the window (). The toolbar and shortcut menu contain the following choices:

- (Toolbar only) The address box enables you to specify a new address or offset. The exact meaning of this box depends on the memory type you are viewing. For example, if you are viewing virtual memory, the box enables you to specify a new virtual address or offset.
- (Toolbar only) **Display format** enables you to select a new display format.
- (Toolbar and menu) **Previous** (on the toolbar) and **Previous page** (on the shortcut menu) cause the previous section of memory to be displayed.
- (Toolbar and menu) **Next** (on the toolbar) and **Next page** (on the shortcut menu) cause the next section of memory to be displayed.
- (Menu only) **Toolbar** turns the toolbar on and off.
- (Menu only) **Auto-fit columns** ensures that the number of columns displayed in the Memory window fits the width of the Memory window.
- (Menu only) **Dock** or **Undock** causes the window to enter or leave the docked state.
- (Menu only) **Move to new dock** closes the Memory window and opens it in a new dock.
- (Menu only) **Set as tab-dock target for window type** sets the selected Memory window as the tab-dock target for other Memory windows. All Memory windows that are opened after one is chosen as the tab-dock target are automatically grouped with that window in a tabbed collection.
- (Menu only) **Always floating** causes the window to remain undocked even if it is dragged to a docking location.
- (Menu only) **Move with frame** causes the window to move when the WinDbg frame is moved, even if the window is undocked. For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#).

- (Menu only) **Properties** opens the **Memory Options** dialog box, which is described in the following section within this topic.
- (Menu only) **Help** opens this topic in the Debugging Tools for Windows documentation.
- (Menu only) **Close** closes this window.

Memory Options Dialog Box

When you click **Properties** on the shortcut menu, the **Memory Options** dialog box appears.

In kernel mode, there are six memory types available as tabs in this dialog box: **Virtual Memory**, **Physical Memory**, **Bus Data**, **Control Data**, **I/O** (I/O port information), and **MSR** (model-specific register information). Click the tab that corresponds to the information that you want to access.

In user mode, only the **Virtual Memory** tab is available.

Each tab enables you to specify the memory that you want to display:

- In the **Virtual Memory** tab, in the **Offset** box, specify the address or offset of the beginning of the memory range that you want to view.
- In the **Physical Memory** tab, in the **Offset** box, specify the physical address of the beginning of the memory range that you want to view. The Memory window can display only described, cacheable physical memory. If you want to display physical memory that has other attributes, use the **d* (Display Memory)** command or the **!d*** extension.
- In the **Bus Data** tab, in the **Bus Data Type** menu, specify the bus data type. Then, use the **Bus number**, **Slot number**, and **Offset** boxes to specify the bus data that you want to view.
- In the **Control Data** tab, use the **Processor** and **Offset** text boxes to specify the control data that you want to view.
- In the **I/O** tab, in the **Interface Type** menu, specify the I/O interface type. Use the **Bus number**, **Address space**, and **Offset** boxes to specify the data that you want to view.
- In the **MSR** tab, in the **MSR** box, specify the model-specific register that you want to view.

Each tab also includes a **Display format** menu. This menu has the same effect as the **Display format** menu in the Memory window.

Click **OK** in the **Memory Options** dialog box to cause your changes to take effect.

Additional Information

For more information about memory manipulation and a description of other memory-related commands, see [Reading and Writing Memory](#).

[Send comments about this topic to Microsoft](#)

Viewing and Editing Global Variables in WinDbg

5/26/2017 • 1 min to read • [Edit Online](#)

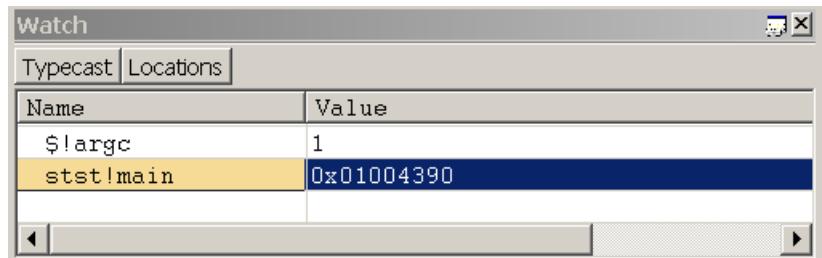

The debugger interprets the name of a global variable as a virtual address. Therefore, you can use all of the commands that are described in [Accessing Memory by Virtual Address](#) to read or write global variables.

In addition, you can use the **? (Evaluate Expression)** command to display the address that is associated with any symbol.

In WinDbg, you can also use the Watch window to display and change global and local variables. The Watch window can display any list of variables that you want. These variables can include global variables and local variables from any function. At any time, the Watch window displays the values of those variables that match the current function's scope. You can also change the values of these variables through the Watch window.

To open the Watch window, choose **Watch** from the **View** menu. You can also press ALT+2 or click the **Watch** button on the toolbar:  ALT+SHIFT+2 closes the Watch window.

The following screen shot shows an example of a Watch window.

The Watch window can contain four columns. The **Name** and **Value** columns are always displayed, and the **Type** and **Location** columns are optional. To display the **Type** and **Location** columns, click the **Typecast** and **Locations** buttons, respectively, on the toolbar.

[Send comments about this topic to Microsoft](#)

Viewing and Editing Local Variables in WinDbg

5/26/2017 • 7 min to read • [Edit Online](#)

In WinDbg, you can view local variables by entering commands, by using the Locals window, or by using the Watch window.

Debugger Command Window

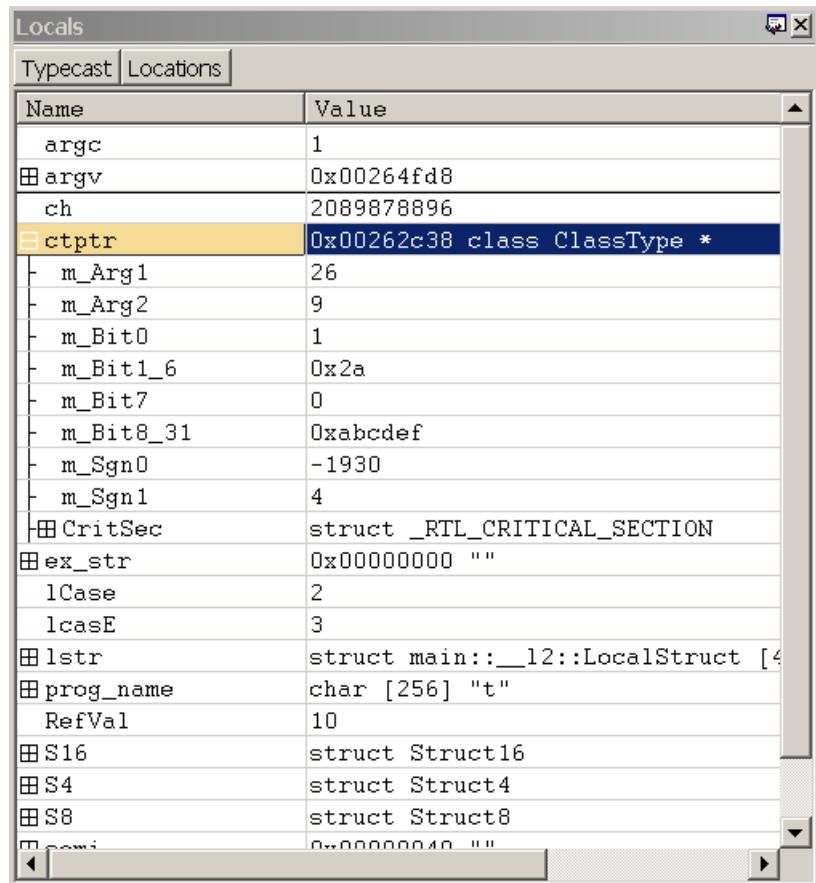

You can view local variables and parameters by entering the **dv** command or the **dt** command in the Debugger Command window.

Opening the Locals Window

The Locals window displays information about all of the local variables in the current scope.

To open or switch to the Locals window, in the WinDbg window, on the **View** menu, click **Locals**. (You can also press ALT+3 or click the **Locals** button (_locals) on the toolbar. ALT+SHIFT+3 closes the Locals window.)

The following screen shot shows an example of a Locals window.

The Locals window can contain four columns. The **Name** and **Value** columns are always displayed, and the **Type** and **Location** columns are optional. To display the **Type** and **Location** columns, click the **Typecast** and **Locations** buttons, respectively, on the toolbar.

Using the Locals Window

In the Locals window, you can do the following:

- The **Name** column displays the name of each local variable. If a variable is a data structure, a check box appears next to its name. To expand or collapse the display of structure members, select or clear the check box.
- The **Value** column displays the current value of each variable.
 - To enter a new value for the variable, double-click the current value and type the new value, or edit the old value. (The cut, copy, and paste commands are available to use for editing.) You can type any [C++ expression](#).
 - To save the new value, press ENTER.
 - To discard the new value, press ESC.
 - If you type an invalid value, the old value will reappear when you press ENTER.

Integers of type **int** are displayed as decimal values; integers of type **UINT** are displayed in the current radix. To change the current radix, use the [n \(Set Number Base\)](#) command in the Debugger Command window.

- The **Type** column (if it is displayed in the Locals window) shows the current data type of each variable. Each variable is displayed in the format that is proper for its own data type. Data structures have their type names in the **Type** column. Other variable types display "Enter new type" in this column.

If you double-click "Enter new type", you can cast the type by entering a new data type. This cast alters the current display of this variable only in the Locals window; it does not change anything in the debugger or on the target computer. Moreover, if you enter a new value in the **Value** column, the text you enter will be parsed based on the actual type of the symbol, rather than any new type you may have entered in the **Type** column. If you close and reopen the Locals window, you will lose the data type changes.

You can also enter an extension command in the **Type** column. The debugger will pass the address of the symbol to this extension, and will display the resulting output in a series of collapsible rows beneath the current row. For example, if the symbol in this row is a valid address for a thread environment block, you can enter **!teb** in the **Type** column to run the [!teb](#) extension on this symbol's address.

- The **Location** column (if it is displayed in the Locals window) shows the offset of each member of a data structure.
- If a local variable is an instance of a class that contains Vtables, the **Name** column displays the Vtables, and you can expand the Vtables to show the function pointers. If a Vtable is contained in a base class that points to a derived implementation, the notation **_vtcast_Class** is displayed to indicate the members that are being added because of the derived class. These members expand like the derived class type.
- The [local context](#) determines which set of local variables will be displayed in the Locals window. When the local context changes for any reason, the Locals window is automatically updated. By default, the local context matches the current position of the program counter. For more information about how to change the local context, see Local Context.

The Locals window has a toolbar that contains two buttons (**Typecast** and **Locations**) and a shortcut menu with additional commands. To access the menu, right-click the title bar of the window or click the icon near the upper-right corner of the window (☒). The toolbar and menu contain the following buttons and commands:

- (Toolbar and menu) **Typecast** turns the display of the **Type** column on and off.
- (Toolbar and menu) **Locations** turns the display of the **Location** column on and off.
- (Menu only) **Display 16-bit values as Unicode** displays Unicode strings in this window. This command turns on and off a global setting that affects the Locals window, the Watch window, and debugger command output. This command is equivalent to using the [.enable_unicode \(Enable Unicode Display\)](#) command.

- (Menu only) **Always display numbers in default radix** causes integers to be displayed in the default radix instead of displaying them in decimal format. This command turns on and off a global setting that affects the Locals window, the Watch window, and debugger command output. This command is equivalent to using the [.force radix output \(Use Radix for Integers\)](#) command.

Note The **Always display numbers in default radix** command does not affect long integers. Long integers are displayed in decimal format unless the [.enable_long_status \(Enable Long Integer Display\)](#) command is set. The **.enable_long_status** command affects the display in the Locals window, the Watch window, and in debugger command output; there is no equivalent for this command in the menu in the Locals window.

- (Menu only) **Open memory window for selected value** opens a new docked Memory window that displays memory starting at the address of the selected expression.
- (Menu only) **Invoke dt for selected memory value** runs the [dt \(Display Type\)](#) command with the selected symbol as its parameter. The result appears in the Debugger Command window. The **-n** option is automatically used to differentiate the symbol from a hexadecimal address. No other options are used. Note that the content that is produced by using this menu selection is identical to the content produced when running the **dt** command from the command line, but the format is slightly different.
- (Menu only) **Toolbar** turns the toolbar on and off.
- (Menu only) **Dock** or **Undock** causes the window to enter or leave the docked state.
- (Menu only) **Move to new dock** closes the Locals window and opens it in a new dock.
- (Menu only) **Set as tab-dock target for window type** is unavailable for the Locals window. This option is only available for Source or Memory windows.
- (Menu only) **Always floating** causes the window to remain undocked even if it is dragged to a docking location.
- (Menu only) **Move with frame** causes the window to move when the WinDbg frame is moved, even if the window is undocked. For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#).
- (Menu only) **Help** opens this topic in the Debugging Tools for Windows documentation.
- (Menu only) **Close** closes this window.

The Watch Window

In WinDbg, you can use the Watch window to display and change local variables. The Watch window can display any list of variables that you want. These variables can include global variables and local variables from any function. At any time, the Watch window displays the values of those variables that match the current function's scope. You can also change the values of these variables through the Watch window.

Unlike the Locals window, the Watch window is not affected by changes to the local context. Only those variables that are defined in the scope of the current program counter can have their values displayed or modified.

To open the Watch window, choose **Watch** from the **View** menu. You can also press ALT+2 or click the **Watch** button on the toolbar:  ALT+SHIFT+2 closes the Watch window.

The following screen shot shows an example of a Watch window.

Name	Type	Value	Location
\$!argc		1	
stst!main		0x01004390	

The Watch window can contain four columns. The **Name** and **Value** columns are always displayed, and the **Type** and **Location** columns are optional. To display the **Type** and **Location** columns, click the **Typecast** and **Locations** buttons, respectively, on the toolbar.

Additional Information

For more information about controlling local variables, an overview of using variables and changing the scope, and a description of other memory-related commands, see [Reading and Writing Memory](#).

[Send comments about this topic to Microsoft](#)

Viewing and Editing Registers in WinDbg

5/26/2017 • 4 min to read • [Edit Online](#)

Registers are small volatile memory units that are located on the CPU. Many registers are dedicated to specific uses, and other registers are available for user-mode applications to use. The x86-based and x64-based processors have different collections of registers available. For more information about the registers on each processor, see [Processor Architecture](#).

In WinDbg, you can view and edit registers by entering commands, by using the Registers window, or by using the Watch Window.

Commands

You can view and edit registers by entering the **r (Registers)** command in the Debugger Command window. You can customize the display by using several options or by using the **rm (Register Mask)** command.

Registers are also automatically displayed every time that the target stops. If you are stepping through your code with the **p (Step)** or **t (Trace)** commands, you see a register display at every step. To stop this display, use the **r** option when you use these commands.

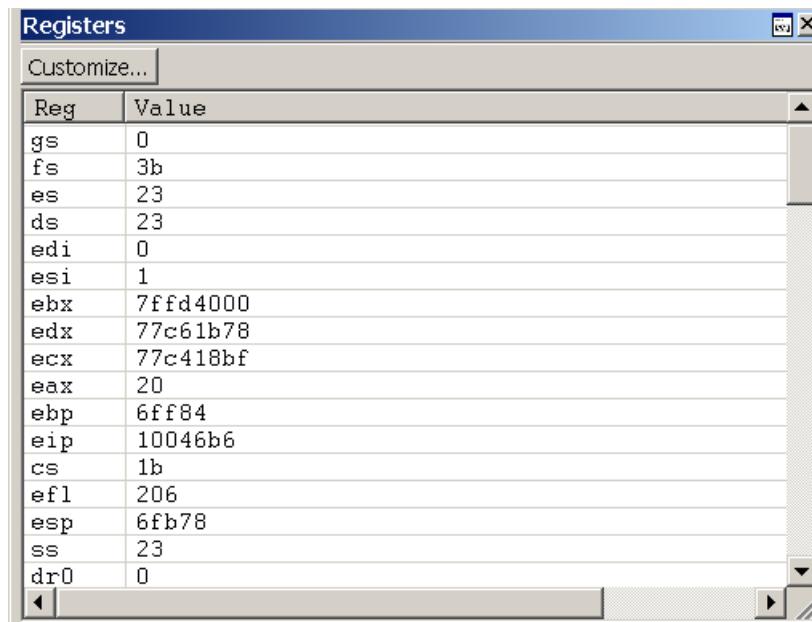

On an x86-based processor, the **r** option also controls several one-bit registers known as flags. To change these flags, you use a slightly different syntax than when changing regular registers. For more information about these flags and an explanation of this syntax, see [x86 Flags](#).

The Registers Window

Opening the Registers Window

To open or switch to the Registers window, choose **Registers** from the **View** menu. (You can also press ALT+4 or click the **Registers** button () on the toolbar. ALT+SHIFT+4 closes the Registers window.)

The following screen shot shows an example of a Registers window.

Reg	Value
gs	0
fs	3b
es	23
ds	23
edi	0
esi	1
ebx	7ffd4000
edx	77c61b78
ecx	77c418bf
eax	20
ebp	6ff84
eip	10046b6
cs	1b
efl	206
esp	6fb78
ss	23
dr0	0

The Registers window contains two columns. The **Reg** column lists all of the registers for the target processor. The **Value** column displays the current value of each register. This window also contains a **Customize** button on the

toolbar that opens the **Customize Register List** dialog box.

Using the Registers Window

In the Registers window, you can do the following:

- The **Value** column displays the current value of each register. The value of the most recently changed register is displayed in red text.
 - To enter a new value, double-click a **Value** cell, and then type a new value or edit the old value. (The cut, copy, and paste commands are available to use for editing.)
 - To save the new value, press ENTER.
 - To discard the new value, press ESC.
 - If you type an invalid value, the old value will reappear when you press ENTER.
- Register values are displayed in the current radix, and you must type new values in the same radix. To change the current radix, use the **n (Set Number Base)** command in the Debugger Command window.
- In user mode, the Registers window displays the registers that are associated with the current thread. For more information about the current thread, see [Controlling Processes and Threads](#).
- In kernel mode, the Registers window displays the registers that are associated with the current [register context](#). You can set the register context to match a specific thread, context record, or trap frame. Only the most important registers for the specified register context are actually displayed; you cannot change their values.

The Registers window has a toolbar that contains a **Customize** button and has a shortcut menu with additional commands. To access the menu, right-click the title bar or click the icon near the upper-right corner of the window (☞). The toolbar and menu contain the following button and commands:

- (Toolbar and menu) **Customize** opens the **Customize Register List** dialog box, which is described in the following section within this topic.
- (Menu only) **Toolbar** turns the toolbar on and off.
- (Menu only) **Dock** or **Undock** causes the window to enter or leave the docked state.
- (Menu only) **Move to new dock** closes the Registers window and opens it in a new dock.
- (Menu only) **Set as tab-dock target for window type** is unavailable for the Registers window. This option is only available for Source or Memory windows.
- (Menu only) **Always floating** causes the window to remain undocked even if it is dragged to a docking location.
- (Menu only) **Move with frame** causes the window to move when the WinDbg frame is moved, even if the window is undocked. For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#).
- (Menu only) **Help** opens this topic in the Debugging Tools for Windows documentation.
- (Menu only) **Close** closes this window.

Customize Register List Dialog Box

To change the list of registers that are displayed, click the **Customize** button. The **Customize Register List** dialog box will appear.

In this dialog box, you can edit the list of registers to change the order in which registers are displayed. (You cannot actually delete a register from the list; if you do, it will reappear at the end.) There must be a space between register names.

If you select the **Display modified register values first** check box, the register whose values have been changed most recently appears at the top.

If you select the **Do not display subregisters** check box, subregisters are not displayed. For example, **eax** will be displayed, but not **ax**, **ah**, or **al**.

Click **OK** to save your changes or **Cancel** to discard your changes.

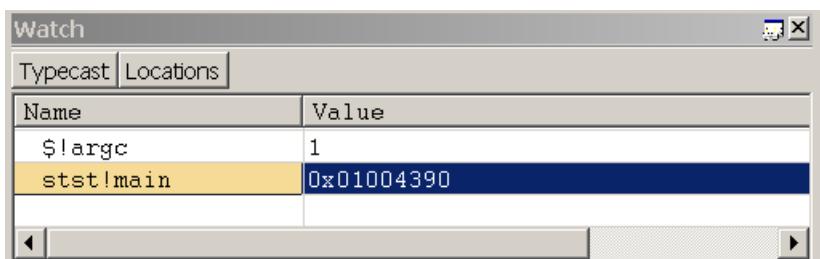

If you are debugging a multi-processor computer with more than one kind of processor, WinDbg stores the customization settings for each processor type separately. This separation enables you to customize the display of each processor's registers simultaneously.

The Watch Window

In WinDbg, you can use the Watch window to display registers. You cannot use the Watch window to alter the values of registers.

To open the Watch window, choose **Watch** from the **View** menu. You can also press ALT+2 or click the **Watch** button on the toolbar:  ALT+SHIFT+2 closes the Watch window.

The following screen shot shows an example of a Watch window.

Additional Information

For more information about the register context and other context settings, see [Changing Contexts](#).

[Send comments about this topic to Microsoft](#)

Controlling Processes and Threads in WinDbg

5/26/2017 • 1 min to read • [Edit Online](#)

In WinDbg, the Processes and Threads window displays information about the systems, processes, and threads that are being debugged. This window also enables you to select a new system, process, and thread to be active.

Opening the Processes and Threads Window

To open the Processes and Threads window, choose **Processes and Threads** from the **View** menu. (You can also press ALT+9 or click the **Processes and Threads** button () on the toolbar. ALT+SHIFT+9 closes the Processes and Threads window.)

The following screen shot shows an example of a Processes and Threads window.

The Processes and Threads window displays a list of all processes that are currently being debugged. The threads in the process appear under each process. If the debugger is attached to multiple systems, the systems are shown at the top level of the tree, with the processes subordinate to them, and the threads subordinate to the processes.

Each system listing includes the server name and the protocol details. The system that the debugger is running on is identified as **<Local>**.

Each process listing includes the internal decimal process index that the debugger uses, the hexadecimal process ID, and the name of the application that is associated with the process.

Each thread listing includes the internal decimal thread index that the debugger uses and the hexadecimal thread ID.

Using the Processes and Threads Window

In the Processes and Threads window, the current or active system, process, and thread appear in bold type. To make a new system, process, or thread active, click its line in the window.

The Processes and Threads window has a shortcut menu with additional commands. To access the menu, right-click the title bar or click the icon near the upper-right corner of the window (). The following list describes some of the menu commands:

- **Move to new dock** closes the Processes and Threads window and opens it in a new dock.
- **Always floating** causes the window to remain undocked even if it is dragged to a docking location.
- **Move with frame** causes the window to move when the WinDbg frame is moved, even if the window is undocked.

Additional Information

For other methods of displaying or controlling systems, see [Debugging Multiple Targets](#). For other methods of displaying or controlling processes and threads, see [Controlling Processes and Threads](#).

Configuring Exceptions and Events in WinDbg

5/26/2017 • 1 min to read • [Edit Online](#)

You can configure WinDbg to react to specified exceptions and events in a specific way. For each exception, you can set the break status and the handling status. For each event, you can set the break status.

You can configure the break status by doing one of the following:

- Choose **Event Filters** from the **Debug** menu, click the event that you want from the list in the **Event Filters** dialog box, and then select **Enabled**, **Disabled**, **Output**, or **Ignore**.
- Use the **SXE**, **SXD**, **SXN**, or **SXI** command.

You can configure the handling status by doing one of the following:

- Choose **Event Filters** from the **Debug** menu, click the event that you want from the list in the **Event Filters** dialog box, and then select **Handled** or **Not Handled**.
- Use the **SXE**, **SXD**, **SXN**, or **SXI** command.

For a detailed discussion of exceptions and events, see [Controlling Exceptions and Events](#).

[Send comments about this topic to Microsoft](#)

Keeping a Log File in WinDbg

5/26/2017 • 1 min to read • [Edit Online](#)

WinDbg can write a log file that records the debugging session. This log file contains all of the contents of the [Debugger Command window](#), including the commands that you type and the responses from the debugger.

Opening a New Log File

To open a new log file, or to overwrite a previous log file, do one of the following:

- Choose **Open/Close Log file** from the **Edit** menu.
- When you start WinDbg in a Command Prompt window, use the **-log0** command-line option.
- Enter the **.logopen (Open Log File)** command. If you use the **/t** option, the date and time are appended to your specified file name. If you use the **/u** option, the log file is written in Unicode instead of in ASCII.

Appending to an Existing Log File

To append command window text to a log file, do one of the following:

- Choose **Open/Close Log file** from the **Edit** menu.
- When you start WinDbg in a Command Prompt window, use the **-loga** command-line option.
- Enter the **.logappend (Append Log File)** command. If you are appending to a Unicode log file, you must use the **/u** option.

Closing a Log File

To close an open log file, do one of the following:

- Choose **Open/Close Log file** from the **Edit** menu.
- Enter the **.logclose (Close Log File)** command.

Checking Log File Status

To determine the log file status, do one of the following:

- Choose **Open/Close Log file** from the **Edit** menu, and see whether a log file is listed.
- Enter the **.logfile (Display Log File Status)** command.

[Send comments about this topic to Microsoft](#)

Using the Watch Window

5/26/2017 • 7 min to read • [Edit Online](#)

The Watch window displays information about global variables, local variables, and registers. You can customize this window to show the items that you are tracking.

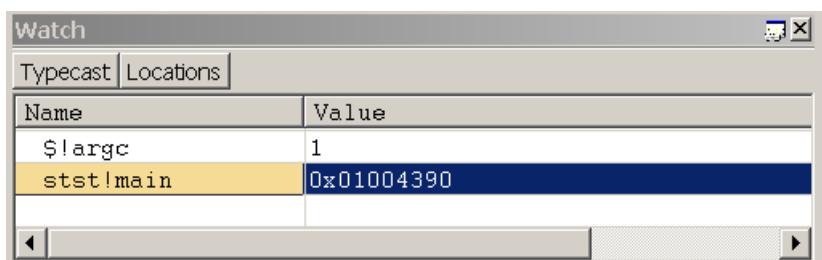

Opening the Watch Window

To open or switch to the Watch window, in the WinDbg window, on the **View** menu, click **Watch**.

You can also press ALT+2 or click the **Watch (ALT+2)** button on the toolbar: 

ALT+SHIFT+2 will close the Watch window.

The following screen shot shows an example of a Watch window.

The Watch window can contain four columns. The **Name** and **Value** columns are always displayed, and the **Type** and **Location** columns are optional. To display the **Type** and **Location** columns, click the **Typecast** and **Locations** buttons, respectively, on the toolbar.

Using the Watch Window

In the Watch window, you can do the following:

- To add a variable to the Watch window, select the first empty cell in the **Name** column, type the variable name, and then press ENTER. Separate the module name from the variable with an exclamation point (!). If you do not specify a module, the current module is used. To enter an address in the **Name** field, the address must begin with a decimal digit (if necessary, use the prefix **0x**).

If the variable name that you have entered is defined in the current function's scope, its value appears in the **Value** column. If it is not defined, the **Value** column displays "Error: Cannot get value".

Even if a variable is not defined, it can be useful to add it to the Watch window. If the program counter enters a function in which a variable of this name is defined, its value appears in the window at that time.

- To remove a variable from the Watch window, double-click its name, press DELETE, and then press ENTER. You can also replace an old name with a new name by double-clicking the old name, typing the new name, and then pressing ENTER.
- If a variable is a data structure, a check box appears next to its name. To expand and collapse the display of structure members, select or clear the check box.
- Integers of type **int** are displayed as decimal values; integers of type **UINT** are displayed in the current radix. To change the current radix, use the **n (Set Number Base)** command in the Debugger Command window.
- To change the value of a local variable, double-click its **Value** cell. Enter the new value, or edit the old value. (The cut, copy, and paste commands are available to use for editing.) The value that you enter can include any **C++ expression**. After you enter a new value or edit the old value, you can press ENTER to store the new

value or press ESC to discard it. If you submit an invalid value, the old value will reappear after you press ENTER.

Integers of type **int** are displayed as decimal values; integers of type **UINT** are displayed in the current radix. To change the current radix, use the [n \(Set Number Base\)](#) command in the Debugger Command window.

- The **Type** column (if it is displayed in the Watch window) shows the current data type of each variable. Each variable is displayed in the format that is proper for its own data type. Data structures have their type names in the **Type** column. Other variable types display "Enter new type" in this column.

If you double-click "Enter new type", you can cast the type by entering a new data type. This cast alters the current display of this variable only in the Watch window; it does not change anything in the debugger or on the target computer. Moreover, if you enter a new value in the **Value** column, the text you enter will be parsed based on the actual type of the symbol, rather than any new type you may have entered in the **Type** column. If you close and reopen the Watch window, you will lose the data type changes.

You can also enter an extension command in the **Type** column. The debugger will pass the address of the symbol to this extension, and will display the resulting output in a series of collapsible rows beneath the current row. For example, if the symbol in this row is a valid address for a thread environment block, you can enter **!teb** in the **Type** column to run the **!teb** extension on this symbol's address.

- The **Location** column (if it is displayed in the Watch window) shows the offset of each member of a data structure.
- In addition to variables, you can also monitor the following items in the Watch window:
 - Registers. When you add a register to the Watch window, prefix its name with an at sign (@). Unlike variables, you cannot change register values through the Watch window.
 - Vtables that contain function pointers. When a Vtable appears in the Watch window, you can browse the function entries in the table. If a Vtable is contained in a base class that points to a derived implementation, the notation **_vtcast_Class** is displayed to indicate the members that are being added because of the derived class. These members expand like the derived class type.
 - The return values of extension functions, such as **_EFN_GetPoolData**.

Unlike the [Locals window](#), the Watch window is not affected by changes to the [register context](#). In the Watch window, you can see and modify only those variables that are defined in the scope of the current program counter.

If you open a new workspace, the Watch window contents are discarded and replaced with those in the new workspace.

Toolbar and Shortcut Menu

The Watch window has a toolbar that contains two buttons (**Typecast** and **Locations**) and a shortcut menu with additional commands. To access the menu, right-click the title bar of the window or click the icon near the upper-right corner of the window: 

The toolbar and menu contain the following buttons and commands:

- (Toolbar and menu) **Typecast** turns the display of the **Type** column on and off.
- (Toolbar and menu) **Locations** turns the display of the **Location** column on and off.
- (Menu only) **Display 16-bit values as Unicode** displays Unicode strings in this window. This command turns on and off a global setting that affects the [Locals window](#), the Watch window, and debugger command output. This command is equivalent to using the [.enable_unicode \(Enable Unicode Display\)](#) command.
- (Menu only) **Always display numbers in default radix** causes integers to be displayed in the default radix instead of always displaying them in decimal format. This command turns on and off a global setting that affects the Locals window, the Watch window, and debugger command output. This command is equivalent

to using the [.force_radix_output \(Use Radix for Integers\)](#) command. **Note** The **Always display numbers in default radix** command does not affect long integers. Long integers are displayed in decimal format unless the [.enable_long_status \(Enable Long Integer Display\)](#) command is used. The [.enable_long_status](#) command affects the display in the Locals window, the Watch window, and debugger command output. There is no equivalent for this command in the menu in the Watch window.

- (Menu only) **Open memory window for selected value** opens a new docked Memory window that displays memory starting at the address of the selected expression.
- (Menu only) **Invoke dt for selected memory value** runs the [dt \(Display Type\)](#) command with the selected symbol as its parameter. The result appears in the [Debugger Command window](#). The **-n** option is automatically used to differentiate the symbol from a hexadecimal address. No other options are used. Note that the content produced using this menu selection is identical to the content produced when running the **dt** command from the command line, but the format is slightly different.
- (Menu only) **Toolbar** turns the toolbar on and off.
- (Menu only) **Dock** or **Undock** causes the window to enter or leave the docked state.
- (Menu only) **Move to new dock** closes the Watch window and opens it in a new dock.
- (Menu only) **Set as tab-dock target for window type** is unavailable for the Watch window. This option is only available for [Source](#) or [Memory](#) windows.
- (Menu only) **Always floating** causes the window to remain undocked even if it is dragged to a docking location.
- (Menu only) **Move with frame** causes the window to move when the WinDbg frame is moved, even if the window is undocked. For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#).
- (Menu only) **Help** opens this topic in the Debugging Tools for Windows documentation.
- (Menu only) **Close** closes this window.

Additional Information

For more information about controlling variables and a description of other memory-related commands, see [Reading and Writing Memory](#). For more information about registers and their manipulation, see [Viewing and Editing Registers in WinDbg](#). For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#). For more information about all techniques that you can use to control debugging information windows, see [Using Debugging Information Windows](#).

[Send comments about this topic to Microsoft](#)

Using the Scratch Pad

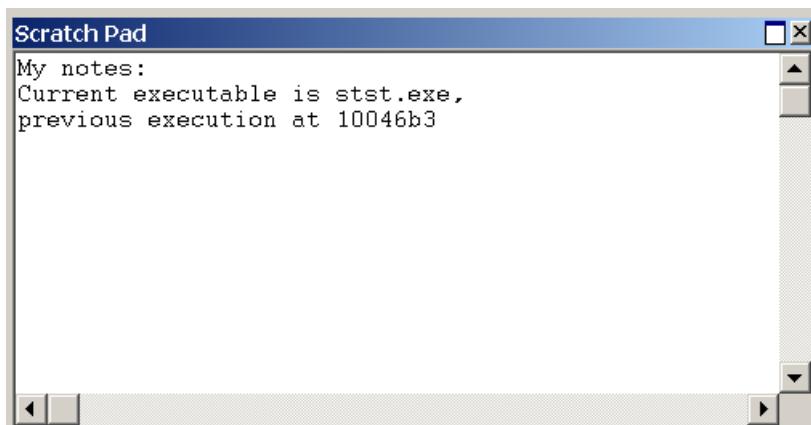

5/26/2017 • 2 min to read • [Edit Online](#)

The Scratch Pad window is a clipboard on which you can type and save text.

Opening the Scratch Pad Window

To open or switch to the Scratch Pad window, in the WinDbg window, on the **View** menu, click **Scratch Pad**. (You can also press ALT+8 or click the **Scratch Pad (Alt+8)** button () on the toolbar.)

The following screen shot shows an example of a Scratch Pad window.

Using the Scratch Pad Window

In the Scratch Pad window, you can do the following:

- To type in the Scratch Pad window, click in the window where you want to add text and begin typing. You can also use standard copy-and-paste features. The contents of the Scratch Pad window do not affect the operation of the debugger. This window exists solely to help with text editing.
- If you close the Scratch Pad window, your text is preserved and is available when you reopen the window. You can also save text from the Scratch Pad window by associating it with a file.

The Scratch Pad window has a shortcut menu with additional commands. To access the menu, right-click the title bar or click the icon near the upper-right corner of the window (). This menu contains the following commands:

- (Menu only) **Associate with file** opens a dialog box through which you can select a text file. After the file is selected, the current text in the Scratch Pad is cleared and replaced with the text in the selected file. While Scratch Pad is associated with this file, all new text typed into Scratch Pad is saved to the file. Association with the file can be ended either by selecting the **End file association** short-cut menu option or by closing and reopening Scratch Pad.
- (Menu only) **End file association** ends Scratch Pad's association with a specified text file. All text in Scratch Pad prior to selecting this option is saved in the file. All text typed in Scratch Pad after the association is ended is no longer saved in the text file.
- **Dock** or **Undock** causes the window to enter or leave the docked state.
- (Menu only) **Move to new dock** closes Scratch Pad and opens it in a new dock.
- (Menu only) **Set as tab-dock target for window type** is unavailable for Scratch Pad. This option is only available for **Source** or **Memory** windows.
- **Always floating** causes the window to remain undocked even if it is dragged to a docking location.

- **Move with frame** causes the window to move when the WinDbg frame is moved, even if the window is undocked. For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#).
- **Help** opens this topic in the Debugging Tools for Windows documentation.
- **Close** closes this window.

Additional Information

For more information about docked, tabbed, and floating windows, see [Positioning the Windows](#). For more information about all techniques that you can use to control debugging information windows, see [Using Debugging Information Windows](#).

Debugging Using KD and NTKD

5/26/2017 • 1 min to read • [Edit Online](#)

This section describes how to perform basic debugging tasks using the KD and NTKD debuggers.

KD and NTKD are identical in every way, except that NTKD spawns a new text window when it is started, whereas KD inherits the Command Prompt window from which it was invoked. The instructions in this section are given for KD, but they work equally well for NTKD. For a discussion of when to use KD or NTKD, see [Debugging Environments](#).

Details are given in the following topics:

- [Opening a Dump File Using KD](#)
- [Live Kernel-Mode Debugging Using KD](#)
- [Ending a Debugging Session in KD](#)
- [Setting Symbol and Executable Image Paths in KD](#)
- [Setting Breakpoints in KD](#)
- [Viewing the Call Stack in KD](#)
- [Viewing and Editing Memory in KD](#)
- [Viewing and Editing Registers in KD](#)
- [Remote Debugging Using KD](#)
- [Configuring Exceptions and Events in KD](#)
- [Keeping a Log File in KD](#)

[Send comments about this topic to Microsoft](#)

Opening a Dump File Using KD

5/26/2017 • 1 min to read • [Edit Online](#)

Command Prompt

In a Command Prompt window, you can open a dump file when you launch KD. Use the following command.

kd -y SymbolPath -i ImagePath -z DumpFileName

The **-v** option (verbose mode) is also useful. For more information about the command-line syntax, see **KD Command-Line Options**.

KD Command Line

You can also open a dump file after the debugger is running by entering the **.opendump (Open Dump File)** command, followed by **g (Go)**.

[Send comments about this topic to Microsoft](#)

Live Kernel-Mode Debugging Using KD

5/31/2017 • 3 min to read • [Edit Online](#)

In a Command Prompt window, you can initiate a live kernel-mode debugging session when you launch KD. Enter one of the following commands.

```
kd [-y SymbolPath] -k net:port=PortNumber,Key kd [-y SymbolPath] -k  
1394:channel=1394Channel[,symlink=1394Protocol] kd [-y SymbolPath] -k usb:targetname=USBString kd [-y  
SymbolPath] -k com:port=ComPort,baud=BaudRate kd [-y SymbolPath] -k  
com:pipe,port=\\VMHost\\pipe\PipeName[,resets=0][,reconnect] kd [-y SymbolPath] -k com:modem kd [-y  
SymbolPath] -kl kd [-y SymbolPath] -k
```

For more information, see [KD Command-Line Options](#).

Environment Variables

For debugging over a serial (COM port) or 1394 connection, you can use environment variables to specify the connection settings.

Use the following variables to specify a serial connection.

set _NT_DEBUG_PORT = *ComPort* **set _NT_DEBUG_BAUD_RATE** = *BaudRate* Use the following variables to specify a 1394 connection.

set _NT_DEBUG_BUS = 1394 **set _NT_DEBUG_1394_CHANNEL** = 1394Channel **** **set _NT_DEBUG_1394_SYMLINK** = 1394Protocol **** For more information, see [Kernel-Mode Environment Variables](#).

Parameters

SymbolPath

A list of directories where symbol files are located. Directories in the list are separated by semicolons. For more information, see [Symbol Path](#).

PortNumber

A port number to use for network debugging. You can choose any number from 49152 through 65535. For more information, see [Setting Up a Network Connection Manually](#).

Key

The encryption key to use for network debugging. We recommend that you use an automatically generated key, which is provided by bcdedit when you configure the target computer. For more information, see [Setting Up a Network Connection Manually](#).

1394Channel

The 1394 channel number. Valid channel numbers are any integer between 0 and 62, inclusive. *1394Channel* must match the number used by the target computer, but does not depend on the physical 1394 port chosen on the adapter. For more information, see [Setting Up a 1394 Connection Manually](#).

1394Protocol

The connection protocol to be used for the 1394 kernel connection. This can almost always be omitted, because the debugger will automatically choose the correct protocol. If you wish to set this manually, and the target computer is running Windows XP, *1394Protocol* should be set equal to "channel". If the target computer is running Windows Server 2003 or later, *1394Protocol* should be set equal to "instance". If it is omitted, the debugger will default to the protocol appropriate for the current target computer. This can only be specified through the command line or the environment variables, not through the WinDbg graphical interface.

USBString

A USB connection string. This must match the string specified with the /targetname boot option. For more information, see [Setting Up a USB 3.0 Connection Manually](#) and [Setting Up a USB 2.0 Connection Manually](#).

ComPort

The name of the COM port. This can be in the format "com2" or in the format "\\.\com2", but should not simply be a number. For more information, see [Setting Up a Serial Connection Manually](#).

BaudRate

The baud rate. This can be 9600, 19200, 38400, 57600, or 115200.

VMHost

When debugging a virtual machine, *VMHost* specifies the name of the physical computer on which the virtual machine is running. If the virtual machine is running on the same computer as the kernel debugger itself, use a single period (.) for *VMHost*. For more information, see [Setting Up a Connection to a Virtual Machine](#).

PipeName

The name of the pipe created by the virtual machine for the debugging connection.

resets=0

Specifies that an unlimited number of reset packets can be sent to the target when the host and target are synchronizing. This parameter is only needed when debugging certain kinds of virtual machines.

reconnect

Causes the debugger to automatically disconnect and reconnect the pipe if a read/write failure occurs. Additionally, if the named pipe is not found when the debugger is started, the reconnect parameter will cause it to wait for a pipe of this name to appear. This parameter is only needed when debugging certain kinds of virtual machines.

-kl

Causes the debugger to perform local kernel-mode debugging. For more information, see [Local Kernel-Mode Debugging](#).

Examples

The following batch file could be used to set up and start a debugging session over a COM port connection.

```
set _NT_SYMBOL_PATH=d:\mysymbols
set _NT_DEBUG_PORT=com1
set _NT_DEBUG_BAUD_RATE=115200
set _NT_DEBUG_LOG_FILE_OPEN=d:\debuggers\logfile1.log
kd
```

The following batch file could be used to set up and start a debugging session over a 1394 connection.

```
set _NT_SYMBOL_PATH=d:\mysymbols
set _NT_DEBUG_BUS=1394
set _NT_DEBUG_1394_CHANNEL=44
set _NT_DEBUG_LOG_FILE_OPEN=d:\debuggers\logfile1.log
kd
```

The following command lines could be used to start WinDbg without any environment variables.

```
kd -y d:\mysymbols -k com:port=com2,baud=57600 kd -y d:\mysymbols -k
com:port=\\.\com2,baud=115200 kd -y d:\mysymbols -k 1394:channel=20,symlink=instance kd -y
d:\mysymbols -k net:port=50000,key=AutoGeneratedKey
```

[Send comments about this topic to Microsoft](#)

Ending a Debugging Session in KD

5/31/2017 • 1 min to read • [Edit Online](#)

There are two different ways to exit KD.

- Issue a **q (Quit)** command in KD to save the log file, end the debugging session, and exit the debugger. The target computer remains locked.
- Press **CTRL+B** and then press ENTER to end the debugger abruptly. If you want the target computer to continue to run after the debugger is ended, you must use this method. Because CTRL+B does not remove breakpoints, you should use the following commands first.

```
kd> bc *
kd> g
```

Exiting the debugger by using CTRL+B does not clear kernel-mode breakpoints, but attaching a new kernel debugger does clear these breakpoints.

When you are performing remote debugging, **q** ends the debugging session. CTRL+B exits the debugger but leaves the session active. This situation enables another debugger to connect to the session.

If the **q (Quit)** command does not work, press **CTRL+R** and then press ENTER on the host computer's keyboard, and then retry the **q** command. If this procedure does not work, you must use CTRL+B to exit the debugger.

[Send comments about this topic to Microsoft](#)

Setting Symbol and Executable Image Paths in KD

5/26/2017 • 3 min to read • [Edit Online](#)

Symbol Path

The symbol path specifies the directories where the symbol files are located. For more information about symbols and symbol files, see [Symbols](#).

Note If you are connected to the Internet or a corporate network, the most efficient way to access symbols is to use a symbol server. You can use a symbol server by using the `srv*` or `symsrv*` string within your symbol path. For more information about symbol servers, see [Symbol Stores and Symbol Servers](#).

To control the symbol path in KD, do one of the following:

- Enter the [.sympath \(Set Symbol Path\)](#) command. If you are using a symbol server, the [.symfix \(Set Symbol Store Path\)](#) command is similar to `.sympath` but saves you typing.
- When you start the debugger, use the `-y` command-line option. See [KD Command-Line Options](#).
- Before you start the debugger, use the `_NT_SYMBOL_PATH` and `_NT_ALT_SYMBOL_PATH` [environment variables](#) to set the path. The symbol path is created by appending `_NT_SYMBOL_PATH` after `_NT_ALT_SYMBOL_PATH`. (Typically, the path is set through the `_NT_SYMBOL_PATH`. However, you might want to use `_NT_ALT_SYMBOL_PATH` to override these settings in special cases, such as when you have private versions of shared symbol files.)

Note If you use the `-sins` command-line option, the debugger ignores the symbol path environment variable.

Executable Image Path

An executable file is a binary file that the processor can run. These files typically have the `.exe`, `.dll`, or `.sys` file name extension. Executable files are also known as modules, especially when executable files are described as units of a larger application. Before the Windows operating system runs an executable file, it loads it into memory. The copy of the executable file in memory is called the executable image or the image.

Note These terms are sometimes used imprecisely. For example, some documents might use "image" for the actual file on the disk. Also, Windows-based applications refer to the executable name, which typically includes the file name extension. But these applications refer to the module name, which does not include the file name extension. Also, the Windows kernel and HAL have special module names. For example, the `nt` module corresponds to the `Ntoskrnl.exe` file.

The executable image path specifies the directories that the binary executable files are located in.

In most situations, the debugger knows the location of the executable files, so you do not have to set the path for this file.

However, there are situations when this path is required. For example, kernel-mode [small memory dump](#) files do not contain all of the executable files that exist in memory at the time of a stop error (that is, a crash). Similarly, user-mode minidump files do not contain the application binaries. If you set the path of the executable files, the debugger can find these binary files.

The debugger's executable image path is a string that consists of multiple directory paths, separated by semicolons. Relative paths are supported. However, unless you always start the debugger from the same directory,

you should add a drive letter or a network share before each path. Network shares are also supported. The debugger searches the executable image path recursively. That is, the debugger searches the subdirectories of each directory that is listed in this path.

To control the executable image path in KD, do one of the following:

- Enter the [.exepath \(Set Executable Path\)](#) command.
- When you start the debugger, use the `-i` command-line option. See [KD Command-Line Options](#).
- Before you start the debugger, use the `_NT_EXECUTABLE_IMAGE_PATH` [environment variable](#) to set the path.

Note If you use the `-sins` command-line option, the debugger ignores the executable image path environment variable.

[Send comments about this topic to Microsoft](#)

Setting Breakpoints in KD

5/26/2017 • 1 min to read • [Edit Online](#)

You can set, view, and manipulate breakpoints in KD by entering commands. For a list of commands, see [Methods of Controlling Breakpoints](#).

[Send comments about this topic to Microsoft](#)

Viewing the Call Stack in KD

5/26/2017 • 1 min to read • [Edit Online](#)

The call stack is the chain of function calls that have led to the current location of the program counter. The top function on the call stack is the current function, the next function is the function that called the current function, and so on. The call stack that is displayed is based on the current program counter, unless you change the register context. For more information about how to change the register context, see [Changing Contexts](#).

In KD, you can view the call stack by entering one of the **k (Display Stack Backtrace)** commands.

[Send comments about this topic to Microsoft](#)

Viewing and Editing Memory in KD

5/26/2017 • 1 min to read • [Edit Online](#)

Viewing and Editing Memory

In KD, you can view and edit memory by entering one of the **Display Memory** commands, and you can edit memory by entering one of the **Enter Values** commands. For a detailed discussion of these commands, see [Accessing Memory by Virtual Address](#) and [Accessing Memory by Physical Address](#).

Viewing and Editing Variables

In KD, you can view and edit global variables by entering commands. The debugger interprets the name of a global variable as a virtual address. Therefore, all of the commands that are described in [Accessing Memory by Virtual Address](#) can be used to read or write global variables. For additional information about viewing and editing global variables, see [Accessing Global Variables](#).

In KD you can view and edit local variables by entering commands. The debugger interprets the name of a local variable as an address. Therefore, all of the commands that are described in [Accessing Memory by Virtual Address](#) can be used to read or write local variables. However, if it is necessary to indicate to a command that a symbol is local, precede the symbol with a dollar sign (\$) and an exclamation point (!), as in `$!var`. For additional information about viewing and editing local variables, see [Accessing Local Variables](#).

[Send comments about this topic to Microsoft](#)

Viewing and Editing Registers in KD

5/26/2017 • 1 min to read • [Edit Online](#)

Registers are small volatile memory units that are located on the CPU. Many registers are dedicated to specific uses, and other registers are available for user-mode applications to use. The x86-based and x64-based processors have different collections of registers available. For more information about the registers on each processor, see [Processor Architecture](#).

In KD, you can view and edit registers by entering the **r (Registers)** command. You can customize the display by using several options or by using the **rm (Register Mask)** command.

Registers are also automatically displayed every time that the target stops. If you are stepping through your code with the **p (Step)** or **t (Trace)** commands, you see a register display at every step. To stop this display, use the **r** option when you use these commands.

On an x86-based processor, the **r** option also controls several one-bit registers known as flags. To change these flags, you use a slightly different syntax than when changing regular registers. For more information about these flags and an explanation of this syntax, see [x86 Flags](#).

Remote Debugging Using KD

5/31/2017 • 1 min to read • [Edit Online](#)

Remote debugging involves two debuggers running at two different locations. The debugger that performs the debugging is called the *debugging server*. The second debugger, called the *debugging client*, controls the debugging session from a remote location. To establish a remote session, you must set up the debugging server first and then activate the debugging client.

The code that is being debugged could be running on the same computer that is running the debugging server, or it could be running on a separate computer. If the debugging server is performing user-mode debugging, then the process that is being debugged can run on the same computer as the debugging server. If the debugging server is performing kernel-mode debugging, then the code being debugged would typically run on a separate target computer.

The following diagram illustrates a remote session where the debugging server, running on a host computer, is performing kernel-mode debugging of code that is running on a separate target computer.

There are several transport protocols you can use for a remote debugging connection: TCP, NPIPE, SPIPE, SSL, and COM Port. Suppose you have chosen to use TCP as the protocol and you have chosen to use KD as both the debugging client and the debugging server. You can use the following procedure to establish a remote kernel-mode debugging session:

1. On the host computer, open KD and establish a kernel-mode debugging session with a target computer. (See [Performing Kernel-Mode Debugging Using KD.](#))
2. Break in by pressing CRTL-Break.
3. Enter the following command.

.server tcp:port=5005

Note The port number 5005 is arbitrary. The port number is your choice.

4. KD will respond with output similar to the following.

```
Server started. Client can connect with any of these command lines
0: <debugger> -remote tcp:Port=5005,Server=YourHostComputer
```

5. On the remote computer, open a Command Prompt window, and enter the following command.

kd -remote tcp:Port=5005,Server=YourHostComputer

where *YourHostComputer* is the name of your host computer, which is running the debugging server.

Additional Information

For complete information about launching KD (and establishing remote debugging) at the command line, see [KD Command-Line Options](#).

Configuring Exceptions and Events in KD

5/26/2017 • 1 min to read • [Edit Online](#)

You can configure KD to react to specified exceptions and events in a specific way. For each exception, you can set the break status and the handling status. For each event, you can set the break status.

You can configure the break status or the handling status by using the **SXE**, **SXD**, **SXN**, or **SXI** command.

For a detailed discussion of exceptions and events, see [Controlling Exceptions and Events](#).

[Send comments about this topic to Microsoft](#)

Keeping a Log File in KD

5/26/2017 • 1 min to read • [Edit Online](#)

KD can write a log file that records the debugging session. This log file contains all of the commands that you type and the responses from the debugger.

Opening a New Log File

To open a new log file, or to overwrite a previous log file, do one of the following:

- Before you start the debugger, set the `_NT_DEBUG_LOG_FILE_OPEN` [environment variable](#).
- When you start the debugger, use the `-log0` command-line option.
- Enter the [.logopen \(Open Log File\)](#) command. If you use the `/t` option, the date and time are appended to your specified file name. If you use the `/u` option, the log file is written in Unicode instead of in ASCII.

Appending to an Existing Log File

To append text to an existing log file, do one of the following:

- Before you start the debugger, set the `_NT_DEBUG_LOG_FILE_APPEND` [environment variable](#).
- When you start the debugger, use the `-loga` command-line option.
- Enter the [.logappend \(Append Log File\)](#) command. If you are appending to a Unicode log file, you must use the `/u` option.

Closing a Log File

To close an open log file, do the following:

- Enter the [.logclose \(Close Log File\)](#) command.

Checking Log File Status

To determine the log file status, do the following:

- Enter the [.logfile \(Display Log File Status\)](#) command.

Debugging Using CDB and NTSD

5/26/2017 • 1 min to read • [Edit Online](#)

This section describes how to perform basic debugging tasks using the Microsoft Console Debugger (CDB) and Microsoft NT Symbolic Debugger (NTSD).

CDB and NTSD are identical in every way, except that NTSD spawns a new text window when it is started, whereas CDB inherits the Command Prompt window from which it was invoked. The instructions in this section are given for CDB, but they work equally well for NTSD. For a discussion of when to use CDB or NTSD, see [Debugging Environments](#).

Details are given in the following topics:

- [Debugging a User-Mode Process Using CDB](#)
- [Opening a Dump File Using CDB](#)
- [Ending a Debugging Session in CDB](#)
- [Setting Symbol and Executable Image Paths in CDB](#)
- [Setting Breakpoints in CDB](#)
- [Viewing the Call Stack in CDB](#)
- [Viewing and Editing Memory in CDB](#)
- [Viewing and Editing Registers in CDB](#)
- [Configuring Exceptions and Events in CDB](#)
- [Keeping a Log File in CDB](#)

[Send comments about this topic to Microsoft](#)

Debugging a User-Mode Process Using CDB

5/26/2017 • 3 min to read • [Edit Online](#)

You can use CDB to attach to a running process or to spawn and attach to new process.

Attaching to a Running Process

Command Prompt

In a Command Prompt window, you can attach to a running process when you launch CDB. Use one of the following commands:

- **cdb -p** *ProcessID*
- **cdb -pn** *ProcessName*

where *ProcessID* is the Process ID of a running process or *ProcessName* is the name of a running process.

For more information about the command-line syntax, see [CDB Command-Line Options](#).

CDB Command Window

If the debugger is already debugging one or more processes, you can attach to a running process by using the [.attach \(Attach to Process\)](#) command.

The debugger always starts multiple target processes simultaneously, unless some of their threads are frozen or suspended.

If the [.attach](#) command is successful, the debugger attaches to the specified process the next time that the debugger issues an execution command. If you use this command several times in a row, execution has to be requested by the debugger as many times as you use this command.

Attaching to a Running Process Noninvasively

If you want to debug a running process and interfere only minimally in its execution, you should debug the process [noninvasively](#).

Command Prompt

To noninvasively debug a running process from the CDB command line, specify the **-pv** option, the **-p** option, and the process ID, in the following syntax.

cdb -pv -p *ProcessID*

Or, to noninvasively debug a running process by specifying the process name, use the following syntax instead.

cdb -pv -pn *ProcessName*

There are several other useful command-line options. For more information about the command-line syntax, see [CDB Command-Line Options](#).

CDB Command Window

If the debugger is already active, you can noninvasively debug a running process by entering the [.attach -v \(Attach to Process\)](#) command.

You can use the [.attach](#) command if the debugger is already debugging one or more processes invasively.

If the [.attach -v](#) command is successful, the debugger debugs the specified process the next time that the

debugger issues an execution command. Because execution is not permitted during noninvasive debugging, the debugger cannot noninvasively debug more than one process at a time. This restriction also means that using the **.attach -v** command might make an existing invasive debugging session less useful.

Spawning a New Process

CDB can start a user-mode application and then debug the application. The application is specified by name. The debugger can also automatically attach to child processes (additional processes that the original target process started).

Processes that the debugger creates (also known as spawned processes) behave slightly differently than processes that the debugger does not create.

Instead of using the standard heap API, processes that the debugger creates use a special debug heap. You can force a spawned process to use the standard heap instead of the debug heap by using the **_NO_DEBUG_HEAP environment variable** or the **-hd** command-line option.

Also, because the target application is a child process of the debugger, it inherits the debugger's permissions. This permission might enable the target application to perform certain actions that it could not perform otherwise. For example, the target application might be able to affect protected processes.

In a Command Prompt window, you can spawn a new process when you launch CDB. Enter the following command.

cdb [-o] ProgramName [Arguments]

The **-o** option causes the debugger to attach to child processes. There are several other useful command-line options. For more information about the command-line syntax, see [CDB Command-Line Options](#).

If the debugger is already debugging one or more processes, you can create a new process by entering the [.create \(Create Process\)](#) command.

The debugger will always start multiple target processes simultaneously, unless some of their threads are frozen or suspended.

If the [.create](#) command is successful, the debugger creates the specified process the next time that the debugger issues an execution command. If you use this command several times in a row, execution has to be requested by the debugger as many times as you use this command.

You can control the application's starting directory by using the [.createdir \(Set Created Process Directory\)](#) command before [.create](#). You can use the [.createdir -I](#) command or the **-noinh** command-line option to control whether the target application inherits the debugger's handles.

You can activate or deactivate the debugging of child processes by using the [.childdbg \(Debug Child Processes\)](#) command.

Reattaching to a Process

If the debugger stops responding or freezes, you can attach a new debugger to the target process. For more information about how to attach a debugger in this situation, see [Reattaching to the Target Application](#).

[Send comments about this topic to Microsoft](#)

Opening a Dump File Using CDB

5/26/2017 • 1 min to read • [Edit Online](#)

Command Prompt

In a Command Prompt window, you can open a user-mode dump file when you launch CDB. Enter the following command.

cdb -y SymbolPath -i ImagePath -z DumpFileName

The **-v** option (verbose mode) is also useful. For more information about the command-line syntax, see [CDB Command-Line Options](#)

CDB Command Line

You can also open a dump file after the debugger is running by entering the [.opendump \(Open Dump File\)](#) command, followed by **g (Go)**. This allows you to debug multiple dump files at the same time.

[Send comments about this topic to Microsoft](#)

Ending a Debugging Session in CDB

5/26/2017 • 1 min to read • [Edit Online](#)

You can exit CDB by entering the **q (Quit)** command. This command also closes the application that you are debugging.

The **qd (Quit and Detach)** command detaches CDB from the target application, exits the debugger, and leaves the target application running. If you used the **-pd** command-line option when you started the debugger, detaching occurs if the session is ended for any reason. (This technique makes **-pd** especially useful when you are debugging a sensitive process, such as the Client Server Run-Time Subsystem (CSRSS), that you do not want to end.)

If the debugger is not responding, you can exit by pressing **CTRL+B** and then ENTER. This method is a secondary exit mechanism. It abruptly ends the debugger and is similar to ending a process through Task Manager or by closing the window.

To end a user-mode debugging session, return the debugger to dormant mode, and close the target application, you can use the following method:

- Enter the **.kill (Kill Process)** command.

To end a user-mode debugging session, return the debugger to dormant mode, and set the target application running again, you can use the following methods:

- Enter the **.detach (Detach from Process)** command. If you are debugging multiple targets, this command detaches from the current target and continues the debugging session with the remaining targets.
- Enter the **qd (Quit and Detach)** command.
- Enter the **q (Quit)** command, if you started the debugger with the **-pd** option.

To end a user-mode debugging session, return the debugger to dormant mode, but leave the target application in the debugging state, you can use the following method:

- Enter the **.abandon (Abandon Process)** command.

For more information about reattaching to the target, see [Reattaching to the Target Application](#).

[Send comments about this topic to Microsoft](#)

Setting Symbol and Executable Image Paths in CDB

5/26/2017 • 2 min to read • [Edit Online](#)

Symbol Path

The symbol path specifies the directories where the symbol files are located. For more information about symbols and symbol files, see [Symbols](#).

Note If you are connected to the Internet or a corporate network, the most efficient way to access symbols is to use a symbol server. You can use a symbol server by using the `srv*` or `symsrv*` string within your symbol path. For more information about symbol servers, see [Symbol Stores and Symbol Servers](#).

To control the symbol path in CDB, do one of the following:

- Enter the [.sympath \(Set Symbol Path\)](#) command. If you are using a symbol server, the [.symfix \(Set Symbol Store Path\)](#) command is similar to `.sympath` but saves you typing.
- When you start the debugger, use the `-y` command-line option. See [CDB Command-Line Options](#).
- Before you start the debugger, use the `_NT_SYMBOL_PATH` and `_NT_ALT_SYMBOL_PATH` [environment variables](#) to set the path. The symbol path is created by appending `_NT_SYMBOL_PATH` after `_NT_ALT_SYMBOL_PATH`. (Typically, the path is set through the `_NT_SYMBOL_PATH`. However, you might want to use `_NT_ALT_SYMBOL_PATH` to override these settings in special cases, such as when you have private versions of shared symbol files.)

Note If you use the `-sins` command-line option, the debugger ignores the symbol path environment variable.

Executable Image Path

An executable file is a binary file that the processor can run. These files typically have the `.exe`, `.dll`, or `.sys` file name extension. Executable files are also known as modules, especially when executable files are described as units of a larger application. Before the Windows operating system runs an executable file, it loads it into memory. The copy of the executable file in memory is called the executable image or the image.

Note These terms are sometimes used imprecisely. For example, some documents might use "image" for the actual file on the disk. Also, the Windows kernel and HAL have special module names. For example, the `nt` module corresponds to the `Ntoskrnl.exe` file.

The executable image path specifies the directories that the binary executable files are located in.

In most situations, the debugger knows the location of the executable files, so you do not have to set the path for this file.

However, there are situations when this path is required. For example, kernel-mode [small memory dump](#) files do not contain all of the executable files that exist in memory at the time of a stop error (that is, a crash). Similarly, user-mode minidump files do not contain the application binaries. If you set the path of the executable files, the debugger can find these binary files.

The debugger's executable image path is a string that consists of multiple directory paths, separated by semicolons. Relative paths are supported. However, unless you always start the debugger from the same directory, you should add a drive letter or a network share before each path. Network shares are also supported. The debugger searches the executable image path recursively. That is, the debugger searches the subdirectories of each

directory that is listed in this path.

To control the executable image path in CDB, do one of the following:

- Enter the [.exepath \(Set Executable Path\)](#) command.
- When you start the debugger, use the `-i` command-line option. See [CDB Command-Line Options](#).
- Before you start the debugger, use the `_NT_EXECUTABLE_IMAGE_PATH` [environment variable](#) to set the path.

Note If you use the `-sins` command-line option, the debugger ignores the executable image path environment variable.

Setting Breakpoints in CDB

5/26/2017 • 1 min to read • [Edit Online](#)

You can set, view, and manipulate breakpoints in CDB by entering commands. For a list of commands, see [Methods of Controlling Breakpoints](#).

[Send comments about this topic to Microsoft](#)

Viewing the Call Stack in CDB

5/26/2017 • 1 min to read • [Edit Online](#)

The call stack is the chain of function calls that have led to the current location of the program counter. The top function on the call stack is the current function, the next function is the function that called the current function, and so on. The call stack that is displayed is based on the current program counter, unless you change the register context. For more information about how to change the register context, see [Changing Contexts](#).

In CDB, you can view the call stack by entering one of the **k (Display Stack Backtrace)** commands.

[Send comments about this topic to Microsoft](#)

Viewing and Editing Memory in CDB

5/26/2017 • 1 min to read • [Edit Online](#)

Viewing and Editing Memory

In CDB, you can view and edit memory by entering one of the **Display Memory** commands, and you can edit memory by entering one of the **Enter Values** commands. For a detailed discussion of these commands, see [Accessing Memory by Virtual Address](#) and [Accessing Memory by Physical Address](#).

Viewing and Editing Variables

In CDB, you can view and edit global variables by entering commands. The debugger interprets the name of a global variable as a virtual address. Therefore, all of the commands that are described in [Accessing Memory by Virtual Address](#) can be used to read or write global variables. For additional information about viewing and editing global variables, see [Accessing Global Variables](#).

In CDB you can view and edit local variables by entering commands. The debugger interprets the name of a local variable as an address. Therefore, all of the commands that are described in [Accessing Memory by Virtual Address](#) can be used to read or write local variables. However, if it is necessary to indicate to a command that a symbol is local, precede the symbol with a dollar sign (\$) and an exclamation point (!), as in `$!var`. For additional information about viewing and editing local variables, see [Accessing Local Variables](#).

[Send comments about this topic to Microsoft](#)

Viewing and Editing Registers in CDB

5/26/2017 • 1 min to read • [Edit Online](#)

Registers are small volatile memory units that are located on the CPU. Many registers are dedicated to specific uses, and other registers are available for user-mode applications to use. The x86-based and x64-based processors have different collections of registers available. For more information about the registers on each processor, see [Processor Architecture](#).

In CDB, you can view registers by entering the **r (Registers)** command in the Debugger Command window. You can customize the display by using several options or by using the **rm (Register Mask)** command.

Registers are also automatically displayed every time that the target stops. If you are stepping through your code with the **p (Step)** or **t (Trace)** commands, you see a register display at every step. To stop this display, use the **r** option when you use these commands.

On an x86-based processor, the **r** option also controls several one-bit registers known as flags. To change these flags, you use a slightly different syntax than when changing regular registers. For more information about these flags and an explanation of this syntax, see [x86 Flags](#).

[Send comments about this topic to Microsoft](#)

Configuring Exceptions and Events in CDB

5/26/2017 • 1 min to read • [Edit Online](#)

You can configure CDB to react to specified exceptions and events in a specific way. For each exception, you can set the break status and the handling status. For each event, you can set the break status.

You can configure the break status or handling status by doing one of the following:

- Use the **SXE**, **SXD**, **SXN**, or **SXI** command.
- Use the **-x**, **-xe**, **-xd**, **-xn**, or **-xi** option on the [CDB command line](#).
- Use the **sxe** or **sxd** keyword in the Tools.ini file.

For a detailed discussion of exceptions and events, see [Controlling Exceptions and Events](#).

[Send comments about this topic to Microsoft](#)

Keeping a Log File in CDB

5/26/2017 • 1 min to read • [Edit Online](#)

CDB can write a log file that records the debugging session. This log file contains all of the commands that you type and the responses from the debugger.

Opening a New Log File

To open a new log file, or to overwrite a previous log file, do one of the following:

- Before you start the debugger, set the `_NT_DEBUG_LOG_FILE_OPEN` [environment variable](#).
- When you start the debugger, use the `-log0` command-line option.
- Enter the [.logopen \(Open Log File\)](#) command. If you use the `/t` option, the date and time are appended to your specified file name. If you use the `/u` option, the log file is written in Unicode instead of in ASCII.

Appending to an Existing Log File

To append command window text to a log file, do one of the following:

- Before you start the debugger, set the `_NT_DEBUG_LOG_FILE_APPEND` [environment variable](#).
- When you start the debugger, use the `-loga` command-line option.
- Enter the [.logappend \(Append Log File\)](#) command. If you are appending to a Unicode log file, you must use the `/u` option.

Closing a Log File

To close an open log file, do the following:

- Enter the [.logclose \(Close Log File\)](#) command.

Checking Log File Status

To determine the log file status, do the following:

- Enter the [.logfile \(Display Log File Status\)](#) command.

[Send comments about this topic to Microsoft](#)

Local Kernel-Mode Debugging

5/26/2017 • 2 min to read • [Edit Online](#)

Debugging Tools for Windows supports *local kernel debugging*. This is kernel-mode debugging on a single computer. In other words, the debugger runs on the same computer that is being debugged.

Setting Up Local Kernel-Mode Debugging

For information on setting up local kernel-mode debugging, see [Setting Up Local Kernel-Mode Debugging of a Single Computer Manually](#).

Starting the Debugging Session

Using WinDbg

Open WinDbg as Administrator. On the **File** menu, choose **Kernel Debug**. In the Kernel Debugging dialog box, open the **Local** tab. Click **OK**.

You can also start a session with WinDbg by opening a Command Prompt window as Administrator and entering the following command:

```
windbg -kl
```

Using KD

Open a Command Prompt window as Administrator, and enter the following command:

```
kd -kl
```

Commands That Are Not Available

Not all commands are available in a local kernel debugging session. Typically, you cannot use any command that causes the target computer to stop, even momentarily, because you cannot resume operation.

In particular, you cannot use the following commands:

- Execution commands, such as **g (Go)**, **p (Step)**, **t (Trace)**, **wt (Trace and Watch Data)**, **tb (Trace to Next Branch)**, **gh (Go with Exception Handled)**, and **gn (Go with Exception Not Handled)**
- Shutdown and dump file commands, such as **.crash**, **.dump**, and **.reboot**
- Breakpoint commands, such as **bp**, **bu**, **ba**, **bc**, **bd**, **be**, and **bl**
- Register display commands, such as **r** and variations
- Stack trace commands, such as **k** and variations

If you are performing local kernel debugging with WinDbg, all of the equivalent menu commands and buttons are also unavailable.

Commands That Are Available

All memory input and output commands are available. You can freely read from user memory and kernel memory. You can also write to memory. Make sure that you do not write to the wrong part of kernel memory, because it can corrupt data structures and frequently causes the computer to stop responding (that is, *crash*).

Difficulties in Performing Local Kernel Debugging

Local kernel debugging is a very delicate operation. Be careful that you do not corrupt or crash the system.

One of the most difficult aspects of local kernel debugging is that the machine state is constantly changing. Memory is paged in and out, the active process constantly changes, and virtual address contexts do not remain constant. However, under these conditions, you can effectively analyze things that change slowly, such as certain device states.

Kernel-mode drivers and the Windows operating system frequently send messages to the kernel debugger by using **DbgPrint** and related functions. These messages are not automatically displayed during local kernel debugging. You can display them by using the **!dbgprint** extension.

LiveKD

The LiveKD tool simulates local kernel debugging. This tool creates a "snapshot" dump file of the kernel memory, without actually stopping the kernel while this snapshot is made. (Therefore, the snapshot might not actually show a single instant state of the computer.)

LiveKD is not part of the Debugging Tools for Windows package. You can download [LiveKd](#) from the Windows Sysinternals site.

[Send comments about this topic to Microsoft](#)

Controlling the Target

5/31/2017 • 6 min to read • [Edit Online](#)

While you are debugging a target application in user mode or a target computer in kernel mode, the target can be *running* or *stopped*.

When the debugger connects to a kernel-mode target, the debugger leaves the target running, unless you use the **-b** command-line option, the target system has stopped responding (that is, *crashed*), or the target system is still stopped because of an earlier kernel debugging action.

When the debugger starts or connects to a user-mode target, the debugger immediately stops the target, unless you use the **-g** command-line option. For more information, see [Initial Breakpoint](#).

When the Target is Running

When the target is running, most debugger actions are unavailable.

If you want to stop a running target, you can issue a **Break** command. This command causes the debugger to *break into the target*. That is, the debugger stops the target and all control is given to the debugger. The application might not break immediately. For example, if all threads are currently executing system code, or are in a wait operation, the application breaks only after control has returned to the application's code.

If a running target encounters an exception, if certain [events](#) occur, if a [breakpoint](#) is hit, or if the application closes normally, the target *breaks into the debugger*. This action stops the target and gives all control to the debugger. A message appears in the [Debugger Command window](#) and describes the error, event, or breakpoint.

When the Target is Stopped

To start or control the target's execution, you can do the following:

- To cause the application to begin running, issue the **Go** command.
- To step through the application one instruction at a time, use the **Step Into** or **Step Over** commands. If a function call occurs, **Step Into** enters the function and continues stepping through each instruction. **Step Over** treats the function call as a single step. When the debugger is in [Assembly Mode](#), stepping occurs one machine instruction at a time. When the debugger is in [Source Mode](#), stepping occurs one source line at a time.
- To finish the current function and stop when the return occurs, use the **Step Out** or **Trace and Watch** commands. The **Step Out** command continues until the current function ends. **Trace and Watch** continues until the current function ends and also displays a summary of the function's calls. However, you must issue the **Trace and Watch** command on the first instruction of the function in question.
- If an exception occurs, you can use the **Go with Exception Handled** and **Go with Exception Not Handled** commands to resume execution and control the status of the exception. (For more information about exceptions, see [Controlling Exceptions and Events](#).)
- (WinDbg only) If you select a line in the [Disassembly window](#) or a [Source window](#) and then use the **Run to Cursor** command, the program runs until it encounters the selected line.
- (User Mode only) To close the target application and restart it from the beginning, use the **Restart** command. You can use this command only with a process that the debugger created. After the process is restarted, it immediately breaks into the debugger.
- (WinDbg only) To close the target application and clear the debugger, use the **Stop Debugging**

command. This command enables you to start debugging a different target.

Command Forms

Most commands for starting or controlling the target's execution exist as text commands, menu commands, toolbar buttons, and shortcut keys. As basic text commands, you can use these commands in CDB, KD, or WinDbg. (The text form of the commands frequently supports additional options, such as changing the location of the program counter or executing a fixed number of instructions.) You can use the menu commands, toolbar buttons, and shortcut keys in WinDbg.

You can use the commands in the following forms.

COMMAND	WINDBG BUTTON	WINDBG COMMAND	WINDBG SHORTCUT KEYS	EFFECT
		Debug Run to Cursor	F7 CTRL + F10	(WinDbg only) Executes until it reaches the line that the cursor marks.
		Debug Stop Debugging	SHIFT + F5	Stops all debugging and closes the target.
(CDB/KD only) CTRL+C		Debug Break	CTRL + BREAK	Execution stops, and the debugger breaks into the target.
.restart (Restart Target Application)		Debug Restart	CTRL + SHIFT + F5	(User mode only) Restarts the target application.
g (Go)		Debug Go	F5	Target executes freely.
gc (Go from Conditional Breakpoint)				Resumes execution after a conditional breakpoint .
gh (Go with Exception Handled)		Debug Go Handled Exception		Same as g (Go) , except that the current exception is treated as handled.

COMMAND	WINDBG BUTTON	WINDBG COMMAND	WINDBG SHORTCUT KEYS	EFFECT
gn (Go with Exception Not Handled)		Debug Go Unhandled Exception		Same as g (Go) , except that the current exception is treated as unhandled.
gu (Go Up)		Debug Step Out	SHIFT + F11	Target executes until the current function is complete.
p (Step)		Debug Step Over	F10	Target executes one instruction. If this instruction is a function call, that function is executed as a single step.
pa (Step to Address)				Target executes until it reaches the specified address. All steps in this function are displayed (but steps in called functions are not).
pc (Step to Next Call)				Target executes until the next call instruction. If the current instruction is a call instruction, this call is executed completely and execution continues until the next call .
pct (Step to Next Call or Return)				Target executes until it reaches a call instruction or a return instruction.

COMMAND	WINDBG BUTTON	WINDBG COMMAND	WINDBG SHORTCUT KEYS	EFFECT
ph (Step to Next Branching Instruction)				Target executes until it reaches any kind of branching instruction, including conditional or unconditional branches, calls, returns, and system calls.
pt (Step to Next Return)				Target executes until it reaches a return instruction.
t (Trace)		Debug Step Into	F11 F8	Target executes one instruction. If this instruction is a function call, debugger traces into that call.
ta (Trace to Address)				Target executes until it reaches the specified address. All steps in this function and called functions are displayed.
tb (Trace to Next Branch)				(All modes, except kernel mode, only on x86-based systems) Target executes until it reaches the next branch instruction.
tc (Trace to Next Call)				Target executes until the next call instruction. If the current instruction is a call instruction, the instruction is traced into until a new call is reached.

COMMAND	WINDBG BUTTON	WINDBG COMMAND	WINDBG SHORTCUT KEYS	EFFECT
tct (Trace to Next Call or Return)				Target executes until it reaches a call instruction or return instruction. If the current instruction is a call instruction or return instruction, the instruction is traced into until a new call or return is reached.
th (Trace to Next Branching Instruction)				Target executes until it reaches any kind of branching instruction, including conditional or unconditional branches, calls, returns, and system calls. If the current instruction is a branching instruction, the instruction is traced into until a new branching instruction is reached.
tt (Trace to Next Return)				Target executes until it reaches a return instruction. If the current instruction is a return instruction, the instruction is traced into until a new return is reached.

COMMAND	WINDBG BUTTON	WINDBG COMMAND	WINDBG SHORTCUT KEYS	EFFECT
wt (Trace and Watch Data)				Target executes until the completion of the whole specified function. Statistics are then displayed.

For more information about how to restart the target computer, see [Crashing and Rebooting the Target Computer](#).

Command-Line Options

If you do not want the application to stop immediately when it starts or loads, use CDB or WinDbg together with the **-g** command-line option. For more information about this situation, see [Initial Breakpoint](#).

CDB and WinDbg also support the **-G** [command-line option](#). This option causes the debugging session to end if the application completes properly.

The following command tries to run the application from start to finish, and the debugger prompt appears only if an error occurs.

```
cdb -g -G ApplicationName
```

You can use the **-pt** [command-line option](#) to set the break time-out. There are certain problems that can make the target unable to communicate with the debugger. If a break command is issued and the debugger cannot break into the target after this time, the debugger displays a "Break-in timed out" message.

At this point, the debugger stops trying to break into the target. Instead, the debugger pauses the target and enables you to examine (but not control) the target application.

The default time-out is 30 seconds.

Enabling Postmortem Debugging

5/31/2017 • 12 min to read • [Edit Online](#)

User Mode Exception Handling

Exceptions and Breakpoints

The most common application errors are called exceptions. These include access violations, division-by-zero errors, numerical overflows, CLR exceptions, and many other kinds of errors. Applications can also cause breakpoint interrupts. These occur when Windows is unable to run the application (for example, when a necessary module cannot be loaded) or when a breakpoint is encountered. Breakpoints can be inserted into the code by a debugger, or invoked through a function such as **DebugBreak**.

Exception Handlers Precedence

Based on configuration values and which debuggers are active, Windows handles user-mode errors in a variety of ways. The following sequence shows the precedence used for user mode error handling:

1. If a user-mode debugger is currently attached to the faulting process, all errors will cause the target to break into this debugger.

As long as the user-mode debugger is attached, no other error-handling methods will be used -- even if the **gn (Go With Exception Not Handled)** command is used.
2. If no user-mode debugger is attached and the executing code has its own exception handling routines (for example, **try - except**), this exception handling routine will attempt to deal with the error.
3. If no user-mode debugger is attached, and Windows has an open kernel-debugging connection, and the error is a breakpoint interrupt, Windows will attempt to contact the kernel debugger.

Kernel debugging connections must be opened during Windows' boot process. If you wish to prevent a user-mode interrupt from breaking into the kernel debugger, you can use the KDbgCtrl utility with the **-du** parameter. For details on how to configure kernel-debugging connections and how to use KDbgCtrl, see [Getting Set Up for Debugging](#).

- In the kernel debugger, you can use **gh (Go With Exception Handled)** to disregard the error and continue running the target. You can use **gn (Go With Exception Not Handled)** to bypass the kernel debugger and go on to step 4.
4. If the conditions in steps 1, 2, and 3 do not apply, Windows will activate a debugging tool configured in the AeDebug registry values. Any program can be selected in advance as the tool to use in this situation. The chosen program is referred to as the *postmortem debugger*.
 5. If the conditions in steps 1, 2, and 3 do not apply, and there is no postmortem debugger registered, Windows Error Reporting (WER) displays a message and provides solutions if any are available. WER also writes a memory dump file if the appropriate values are set in the Registry. For more information, see [Using WER](#) and [Collecting User-Mode Dumps](#).

DebugBreak Function

If a postmortem debugger has been installed, you can deliberately break into the debugger from a user-mode application by calling the **DebugBreak** function.

Specifying a Postmortem Debugger

This section describes how to configure tools such as WinDbg as the postmortem debugger. Once configured, the postmortem debugger will be automatically started whenever an application crashes.

Post Mortem Debugger Registry Keys

Windows Error Reporting (WER) creates the postmortem debugger process using the values set in the AeDebug registry key.

HKLM\Software\Microsoft\Windows NT\CurrentVersion\AeDebug

There are two primary registry values of interest, *Debugger* and *Auto*. The *Debugger* registry value specifies the command line for the postmortem debugger. The *Auto* registry value specifies if the postmortem debugger is automatically started, or if a confirmation message box is presented first.

Debugger (REG_SZ)

This REG_SZ value specifies the debugger that will handle postmortem debugging.

The full path to the debugger must be listed unless the debugger is located in a directory that is in the default path.

The command line is generated from the Debugger string via a printf style call that includes 3 parameters. Although the order is fixed, there is no requirement to use any or all of the available parameters.

DWORD (%Id) - Process ID of the target process.

DWORD (%Id) - Event Handle duplicated into the postmortem debugger process. If the postmortem debugger signals the event, WER will continue the target process without waiting for the postmortem debugger to terminate. The event should only be signaled if the issue has been resolved. If the postmortem debugger terminates without signaling the event, WER continues the collection of information about the target processes.

void* (%p) - Address of a JIT_DEBUG_INFO structure allocated in the target process's address space. The structure contains additional exception information and context.

Auto (REG_SZ) This REG_SZ value is always either **0** or **1**.

If **Auto** is set to **0**, a confirmation message box is displayed prior to postmortem debugging process being started.

If **Auto** is set to **1**, the postmortem debugger is immediately created.

When you manually edit the registry, do so very carefully, because improper changes to the registry may not allow Windows to boot.

Example Command Line Usage

Many postmortem debuggers use a command line that includes -p and -e switches to indicate the parameters are a PID and Event (respectively). For example, installing WinDbg via windbg.exe -I creates the following values:

```
Debugger = "<Path>\WinDbg -p %ld -e %ld -g"
Auto = 1
```

There is flexibility in how the WER %Id %Id %p parameters can be used. For example, there is no requirement to specify any switches around or between the WER parameters. For example, installing [Windows Sysinternals ProcDump](#) using procdump.exe -i creates the following values with no switches between the WER %Id %Id %p parameters:

```
Debugger = "<Path>\procdump.exe" -accepteula -j "c:\Dumps" %ld %ld %p
Auto = 1
```

32 and 64 bit Debuggers

On a 64-bit platform, the Debugger (REG_SZ) and Auto (REG_SZ) registry values are defined individually for 64-bit and 32-bit applications. An additional Windows on Windows (WOW) key is used to store the 32 bit application post mortem debugging values.

HKLM\Software\Wow6432Node\Microsoft\Windows NT\CurrentVersion\AeDebug

On a 64-bit platform, use a 32-bit post-mortem debugger for 32-bit processes and a 64-bit debugger for 64-bit processes. This avoids a 64-bit debugger focusing on the WOW64 threads, instead of the 32-bit threads, in a 32-bit process.

For many postmortem debuggers, including the Debugging Tools for Windows postmortem debuggers, this involves running the installation command twice; once with the x86 version and once with the x64 version. For example, to use WinDbg as the interactive postmortem debugger, the `windbg.exe -I` command would be run twice, once for each version.

64-bit Installation:

```
C:\Program Files (x86)\Windows Kits\10\Debuggers\x64\windbg.exe -I
```

This updates the registry key with these values.

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\AeDebug
Debugger = "C:\Program Files (x86)\Windows Kits\10\Debuggers\x64\windbg.exe" -p %ld -e %ld -g
```

32-bit Installation:

```
C:\Program Files (x86)\Windows Kits\10\Debuggers\x86\windbg.exe -I
```

This updates the registry key with these values.

```
HKEY_LOCAL_MACHINE\SOFTWARE\Wow6432Node\Microsoft\Windows NT\CurrentVersion\AeDebug
Debugger = "C:\Program Files (x86)\Windows Kits\10\Debuggers\x86\windbg.exe" -p %ld -e %ld -g
```

Configuring Post Mortem Debuggers

Debugging Tools for Windows

The Debugging Tools for Windows debuggers all support being set as the postmortem debugger. The `install` command intends for the process to be debugged interactively.

WinDbg

To set the postmortem debugger to WinDbg, run **windbg -I**. (The **I** must be capitalized.) This command will display a success or failure message after it is used. To work with both 32 and 64 bit applications, run the command for the both the 64 and 32 debuggers.

```
C:\Program Files (x86)\Windows Kits\10\Debuggers\x64\windbg.exe -I
C:\Program Files (x86)\Windows Kits\10\Debuggers\x86\windbg.exe -I
```

This how the AeDebug registry entry will be configured when **windbg -I** is run.

```
Debugger = "<Path>\WinDbg -p %ld -e %ld -g"
Auto = 1
```

In the examples, **<Path>** is the directory where the debugger is located.

The **-p** and **-e** parameters pass the Process ID and Event, as discussed previously.

The **-g** passes the g (Go) command to WinDbg and continues execution from the current instruction.

Note

There is a significant issue passing the g (Go) command. The issue with this approach, is that exceptions do not always repeat, typically, because of a transient condition that no longer exists when the code is restarted. For more information about this issue, see [.jdinfo \(Use JIT_DEBUG_INFO\)](#).

To avoid this issue, use `jdinfo` or `.dump /j`. This approach allows the debugger to be in the context of the code failure of interest. For more information, see [Just In Time \(JIT\) Debugging](#) later in this topic.

CDB

To set the postmortem debugger to CDB, run **cdb -iae** (Install AeDebug) or **cdb -iaec KeyString** (Install AeDebug with Command).

```
C:\Program Files (x86)\Windows Kits\10\Debuggers\x64\cdb.exe -iae
C:\Program Files (x86)\Windows Kits\10\Debuggers\x86\cdb.exe -iae
```

When the **-iaec** parameter is used, *KeyString* specifies a string to be appended to the end of command line used to launch the postmortem debugger. If *KeyString* contains spaces, it must be enclosed in quotation marks.

```
C:\Program Files (x86)\Windows Kits\10\Debuggers\x64\cdb.exe -iaec [KeyString]
C:\Program Files (x86)\Windows Kits\10\Debuggers\x86\cdb.exe -iaec [KeyString]
```

This command display nothing if it succeeds, and an error message if it fails.

NTSD

To set the postmortem debugger to NTSD, run **ntsd -iae** (Install AeDebug) or **ntsd -iaec KeyString** (Install AeDebug with Command).

```
C:\Program Files (x86)\Windows Kits\10\Debuggers\x64\ntsd.exe -iae
C:\Program Files (x86)\Windows Kits\10\Debuggers\x86\ntsd.exe -iae
```

When the **-iaec** parameter is used, *KeyString* specifies a string to be appended to the end of command line used to launch the postmortem debugger. If *KeyString* contains spaces, it must be enclosed in quotation marks.

```
C:\Program Files (x86)\Windows Kits\10\Debuggers\x64\ntsd.exe -iaec [KeyString]
C:\Program Files (x86)\Windows Kits\10\Debuggers\x86\ntsd.exe -iaec [KeyString]
```

This command display nothing if it succeeds, and an error to a new console window on failure.

Note Because the **-p %ld -e %ld -g** parameters always appear first on the command line of the postmortem debugger, you should not use the **-iaec** switch to specify the **-server** parameter because **-server** will not work unless it appears first on the command line. To install a postmortem debugger that includes this parameter, you must edit the registry manually.

Visual Studio JIT Debugger

If Visual Studio has been installed, `vsjitdebugger.exe` will be registered as the post mortem debugger. The Visual Studio JIT Debugger intends for the process to be debugged interactively.

```
Debugger = "C:\WINDOWS\system32\vsjitdebugger.exe" -p %ld -e %ld
```

If Visual Studio is updated or re-installed, this entry will be re-written, overwriting any alternate values set.

Window Sysinternals ProcDump

The Windows Sysinternals ProcDump utility can also be used for postmortem dump capture. For more information about using and downloading ProcDump, see [ProcDump](#) on TechNet.

Like the [.dump](#) WinDbg command, ProcDump is able to be capture a dump of the crash non-interactively. The capture may occur in any Windows system session.

ProcDump exits when the dump file capture completes, WER then reports the failure and the faulting process is terminated.

Use procdump -i to install procdump and -u to uninstall ProcDump for both the 32 and 64 bit post mortem debugging.

```
<Path>\procdump.exe -i
```

The install and uninstall commands output the registry values modified on success, and the errors on failure.

The ProcDump command line options in the registry are set to:

```
Debugger = <Path>\ProcDump.exe -accepteula -j "<DumpFolder>" %ld %ld %p
```

ProcDump uses all 3 parameters - PID, Event and JIT_DEBUG_INFO. For more information on the JIT_DEBUG_INFO parameter, see [Just In Time \(JIT\) Debugging](#) below.

The size of dump captured defaults to Mini (process/threads/handles/modules/address space) without a size option set, MiniPlus (Mini plus MEM_PRIVATE pages) with -mp set, or Full (all memory - equivalent to ".dump /mA") with -ma set.

For systems with sufficient drive space, a Full (-ma) capture is recommended.

Use -ma with the -i option to specify an all memory capture. Optionally, provide a path for the dump files.

```
<Path>\procdump.exe -ma -i c:\Dumps
```

For systems with limited drive space, a MiniPlus (-mp) capture is recommended.

```
<Path>\procdump.exe -mp -i c:\Dumps
```

The folder to save the dump file to is optional. The default is the current folder. The folder should be secured with an ACL that is equal or better than what is used for C:\Windows\Temp. For more information on managing security related to folders, see [Security During Postmortem Debugging](#).

To uninstall ProcDump as the postmortem debugger, and restore the previous settings, use the -u (Uninstall) option.

```
<Path>\procdump.exe -u
```

The install and uninstall commands set both the 64-bit and 32-bit values on 64-bit platforms.

ProcDump is a "packed" executable containing both the 32-bit and 64-bit version of application - as such, the same executable is used for both 32-bit and 64-bit. When ProcDump runs, it automatically switches the version, if the version running doesn't match the target process.

Just In Time (JIT) Debugging

Setting Context to the Faulting Application

As discussed previously, it is very desirable to set the context to the exception that caused the crash using the `JIT_DEBUG_INFO` parameter. For more information about this, see [.jdinfo \(Use JIT_DEBUG_INFO\)](#).

Debugging Tools for Windows

This example shows how to edit the registry to run an initial command (-c) that uses the `jdinfo <address>` command to display the additional exception information, and change the context to the location of the exception (similar to how `.ecxr` is used set the context to the exception record).

```
Debugger = "<Path>\windbg.exe -p %ld -e %ld -c ".jdinfo 0x%p"
Auto = 1
```

The `%p` parameter is the address of a `JIT_DEBUG_INFO` structure in the target process's address space. The `%p` parameter is pre-appended with `0x` so that it is interpreted as a hex value. For more information, see [.jdinfo \(Use JIT_DEBUG_INFO\)](#).

To debug a mix of 32 and 64 bit apps, configure both the 32 and 64 bit registry keys (described above), setting the proper path to the location of the 64-bit and 32-bit `WinDbg.exe`.

Creating a dump file using `.dump`

To capture a dump file whenever a failure occurs that includes the `JIT_DEBUG_INFO` data, use `.dump /j <address>`.

```
<Path>\windbg.exe -p %ld -e %ld -c ".dump /j %p /u <DumpPath>\AeDebug.dmp; qd"
```

Use the `/u` option to generate a unique filename to allow multiple dump files to be automatically created. For more information about the options see, [.dump \(Create Dump File\)](#).

The created dump will have the `JITDEBUG_INFO` data stored as the default exception context. Instead of using `jdinfo` to view the exception information and set the context, use `.exr -1` to display the exception record and `.ecxr` to set the context. For more information see [.exr \(Display Exception Record\)](#) and [.ecxr \(Display Exception Context Record\)](#).

Windows Error Reporting - `q` / `qd`

The way the debug session ends determines if Windows Error Reporting reports the failure.

If the debug session is detached using `qd` prior to the closing of the debugger, WER will report the failure.

If the debug session is quit using `q` (or if the debugger is closed without detaching), WER will not report the failure.

Append `;q` or `;qd` to the end of the command string to invoke the desired behavior.

For example, to allow WER to report the failure after CDB captures a dump, configure this command string.

```
<Path>\cdb.exe -p %ld -e %ld -c ".dump /j 0x%p /u c:\Dumps\AeDebug.dmp; qd"
```

This example would allow WER to report the failure after WinDbg captures a dump.

```
<Path>\windbg.exe -p %ld -e %ld -c ".dump /j %p /u <DumpPath>\AeDebug.dmp; qd""
```

Security Vulnerabilities

If you are considering enabling postmortem debugging on a computer that you share with other people, see [Security During Postmortem Debugging](#).

Using Debugger Commands

5/31/2017 • 7 min to read • [Edit Online](#)

For KD or CDB, "Debugger Command window" refers to the whole window. You enter commands at the prompt at the bottom of the window. If the commands have any output, the window displays the output and then displays the prompt again.

For Visual Studio, "Debugger Command window" refers to a window that is labeled "Debugger Immediate Window" in the title bar. This window has two panes:

- In the small, bottom pane, you enter commands.
- In the large, upper pane, you view command output.

For WinDbg, "Debugger Command window" refers to the window that is labeled "Command" in the title bar. This window contains two panes:

- In the small, bottom pane, you enter commands.
- In the large, upper pane, you view command output.

This window is always open at the beginning of a debugging session. You can reopen or switch to this window by clicking **Command** on the **View** menu, pressing ALT+1, or clicking the **Command (Alt+1)** button (��) on the toolbar.

You can use the UP ARROW and DOWN ARROW keys to scroll through the command history. When a previous command appears, you can edit it and then press ENTER to execute the previous command (or the edited version of the previous command). The cursor does not have to be at the end of the line for this procedure to work correctly.

Debugger Command Window Prompt

When you are performing user-mode debugging, the prompt in the Debugger Command window looks like the following example.

```
2:005>
```

In the preceding example, 2 is the current process number, and 005 is the current thread number.

If you attach the debugger to more than one computer, the system number is included before the process and thread number, as in the following example.

```
3:2:005>
```

In this example, 3 is the current system number, 2 is the current process number, and 005 is the current thread number.

When you are performing kernel-mode debugging on a target computer that has only one processor, the prompt looks like the following example.

```
kd>
```

However, if the target computer has multiple processors, the number of the current processor appears before the

prompt, as in the following example.

```
0: kd>
```

If the debugger is busy processing a previously issued command, new commands will temporarily not be processed, although they can be added to the command buffer. In addition, you can still use [control keys](#) in KD and CDB, and you can still use menu commands and [shortcut keys](#) in WinDbg. When KD or CDB is in this busy state, no prompt is displayed. When WinDbg is in this busy state, the following indicator will appear in place of the prompt:

```
*BUSY*
```

You can use the [.pcmd \(Set Prompt Command\)](#) command to add text to this prompt.

Kinds of Commands

WinDbg, KD, and CDB support a variety of commands. Some commands are shared between the debuggers, and some are available only on one or two of the debuggers.

Some commands are available only in live debugging, and other commands are available only when you debug a dump file.

Some commands are available only during user-mode debugging, and other commands are available only during kernel-mode debugging.

Some commands are available only when the target is running on certain processors. For more information about all of the commands and their restrictions, see [Debugger Commands](#).

Editing, Repeating, and Canceling Commands

You can use standard editing keys when you enter a command:

- Use the UP ARROW and DOWN ARROW keys to find previous commands.
- Edit the current command with the BACKSPACE, DELETE, INSERT, and LEFT ARROW and RIGHT ARROW keys.
- Press the ESC key to clear the current line.

You can press the TAB key to automatically complete your text entry. In any of the debuggers, press the TAB key after you enter at least one character to automatically complete a command. Press the TAB key repeatedly to cycle through text completion options, and hold down the SHIFT key and press TAB to cycle backward. You can also use wildcard characters in the text and press TAB to expand to the full set of text completion options. For example, if you type **fo*!ba** and then press TAB, the debugger expands to the set of all symbols that start with "ba", in all modules with module names that start with "fo". As another example, you can complete all extension commands that have "prcb" in them by typing **!*prcb** and then pressing TAB.

When you use the TAB key to perform text completion, if your text fragment begins with a period (.), the text is matched to a dot command. If your text fragment begins with an exclamation point (!), the text is matched to an extension command. Otherwise, the text is matched with a symbol. When you use the TAB key to enter symbols, pressing the TAB key completes code and type symbols and module names. If no module name is apparent, local symbols and module names are completed. If a module or module pattern is given, symbol completion completes code and type symbols from all matches.

You can right-click in the Debugger Command window to automatically paste the contents of the clipboard into the command that you are typing.

The maximum command length is 4096 characters. However, if you are [controlling the user-mode debugger from](#)

the kernel debugger, the maximum line length is 512 characters.

In CDB and KD, press the ENTER key by itself to repeat the previous command. In WinDbg, you can enable or disable this behavior. For more information about this behavior, see [ENTER \(Repeat Last Command\)](#).

If the last command that you issued presents a long display and you want to cut it off, use the **CTRL+C** key in CDB or KD. In WinDbg, use [Debug | Break](#) or press CTRL+BREAK.

In kernel-mode debugging, you can cancel commands from the keyboard of the target computer by pressing **CTRL+C**.

You can use the **.cls (Clear Screen)** command to clear all of the text from the [Debugger Command window](#). This command clears the whole command history. In WinDbg, you can clear the command history by using the [Edit | Clear Command Output](#) command or by clicking **Clear command output** on the shortcut menu of the Debugger Command window.

Expression Syntax

Many commands and extension commands accept *expressions* as their arguments. The debugger evaluates these expressions before executing the command. For more information about expressions, see [Evaluating Expressions](#).

Aliases

Aliases are text macros that you can use to avoid having to retype complex phrases. There are two kinds of aliases. For more information about aliases, see [Using Aliases](#).

Self-Repeating Commands

You can use the following commands to repeat an action or conditionally execute other commands:

- The **j (Execute If-Else)** conditional command
- The **z (Execute While)** conditional command
- The **~e (Thread-Specific Command)** command qualifier
- (Windows XP and later versions of Windows) The **!list** extension command

For more information about each command, see the individual command topics.

Controlling Scrolling

You can use the scrollbar to view your previous commands and their output.

When you are using CDB or KD, any keyboard entry automatically scrolls down the Debugger Command window back to the bottom.

In WinDbg, the display automatically scrolls down to the bottom whenever a command produces output or you press the ENTER key. If you want to disable this automatic scrolling, click the [Options](#) on the [View](#) menu and then clear the **Automatically scroll** check box.

WinDbg Text Features

In WinDbg, you can use several additional features to change how text is displayed in the [Debugger Command window](#). You can access some of these features in the WinDbg window, some in the shortcut menu in the Debugger Command window, and some by clicking on the appropriate menu icon.

- The **Word wrap** command on the shortcut menu turns on and off the word wrap status. This command affects the whole window, not only commands that you use after this state is changed. Because many commands and extensions produce formatted displays, we typically do not recommend word wrap.
- The [Edit | Add to Command Output](#) menu command adds a comment in the Debugger Command window. The **Add to command output** command on the shortcut menu has the same effect.

- You can customize the colors that are used for the text and the background of the Debugger Command window. You can specify different colors for different kinds of text. For example, you can display the automatic register output in one color, error messages in another color, and **DbgPrint** messages in a third color. For more information about this customization, see [View | Options](#).
- You can use all of the features common to WinDbg's debugging information windows, such as customizing the fonts and using special editing commands. For more information about these features, see [Using Debugging Information Windows](#).

Remote Debugging

When you are performing remote debugging through the debugger, the debugging client can access a limited number of commands. To change the number of commands that the client can access, use the **-clines command-line option** or the **_NT_DEBUG_HISTORY_SIZE environment variable**.

[Send comments about this topic to Microsoft](#)

Evaluating Expressions

5/26/2017 • 4 min to read • [Edit Online](#)

The debugger understands two different forms of expressions: *MASM expressions* and *C++ expressions*.

Microsoft Macro Assembler (MASM) expressions are used in the examples in this Help documentation, except when otherwise noted. In MASM expressions, all symbols are treated as addresses.

C++ expressions are the same as those used in actual C++ code. In these expressions, symbols are understood as the appropriate data types.

When Each Syntax is Used

You can select the default expression evaluator in one of the following ways:

- Use the `_NT_EXPR_EVAL` environment variable before the debugger is started.
- Use the `-ee {masm|c++}` command-line option when the debugger is started.
- Use the [.expr \(Choose Expression Evaluator\)](#) command to display or change the expression evaluator after the debugger is running.

If you do not use one of the preceding methods, the debugger uses the MASM expression evaluator.

If you want to evaluate an expression without changing the debugger state, you can use the [? \(Evaluate Expression\)](#) command.

All commands and debugging information windows interpret their arguments through the default expression evaluator, with the following exceptions:

- The [?? \(Evaluate C++ Expression\)](#) command always uses the C++ expression evaluator.
- The Watch window always uses the C++ expression evaluator.
- The [Locals window](#) always uses the C++ expression evaluator.
- Some extension commands always use the MASM expression evaluator (and other extension commands accept only numeric arguments instead of full expressions).
- If any part of an expression is enclosed in parentheses and you insert two at signs (@@) before the expression, the expression is evaluated by the expression evaluator that would not typically be used in this case.

The two at signs (@@) enable you to use two different evaluators for different parameters of a single command. It also enables you to evaluate different pieces of a long expression by different methods. You can nest the two at signs. Each appearance of the two at signs switches to the other expression evaluator.

Warning C++ expression syntax is useful for manipulating structures and variables, but it is not well-suited as a parser for the parameters of debugger commands. When you are using debugger commands for general purposes or you are using debugger extensions, you should set MASM expression syntax as the default expression evaluator. If you must have a specific parameter use C++ expression syntax, use the two at sign (@@) syntax.

For more information about the two different expression types, see [Numerical Expression Syntax](#).

Numbers in Expressions

Numbers in MASM expressions are interpreted according to the current radix. The [n \(Set Number Base\)](#)

command can be used to set the default radix to 16, 10, or 8. All un-prefixed numbers will be interpreted in this base. The default radix can be overridden by specifying the **0x** prefix (hexadecimal), the **0n** prefix (decimal), the **0t** prefix (octal), or the **0y** prefix (binary).

Numbers in C++ expressions are interpreted as decimal numbers unless you specify differently. To specify a hexadecimal integer, add **0x** before the number. To specify an octal integer, add **0** (zero) before the number. (However, in the debugger's *output*, the **0n** decimal prefix is sometimes used.)

If you want to display a number in several bases at the same time, use the [.formats \(Show Number Formats\)](#) command.

Symbols in Expressions

The two types of expressions interpret symbols differently:

- In MASM expressions, each symbol is interpreted as an address. Depending on what the symbol refers to, this address is the address of a global variable, local variable, function, segment, module, or any other recognized label.
- In C++ expressions, each symbol is interpreted according to its type. Depending on what the symbol refers to, it might be interpreted as an integer, a data structure, a function pointer, or any other data type. A symbol that does not correspond to a C++ data type (such as an unmodified module name) creates a syntax error.

If a symbol might be ambiguous, precede it with the module name and an exclamation point (!). If the symbol name could be interpreted as a hexadecimal number, precede it with the module name and an exclamation point (!) or only an exclamation point. In order to specify that a symbol is meant to be local, omit the module name, and include a dollar sign and an exclamation point (\$!) before the symbol name. For more information about interpreting symbols, see [Symbol Syntax and Symbol Matching](#).

Operators in Expressions

Each expression type uses a different collection of operators.

For more information about the operators that you can use in MASM expressions and their precedence rules, see [MASM Numbers and Operators](#).

For more information about the operators that you can use in C++ expressions and their precedence rules, see [C++ Numbers and Operators](#).

Remember that MASM operations are always byte-based, and C++ operations follow C++ type rules (including the scaling of pointer arithmetic).

For some examples of the different syntaxes, see [Expression Examples](#).

Using Shell Commands

5/26/2017 • 1 min to read • [Edit Online](#)

The debugger can transmit certain commands to the Microsoft Windows environment in which the debugger is running.

You can use the **.shell (Command Shell)** command in any Windows debugger. With this command, you can execute an application or a Microsoft MS-DOS command directly from the debugger. If you are performing [remote debugging](#), these shell commands are executed on the server.

The **.noshell (Prohibit Shell Commands)** command or the **-noshell** command-line option disables all shell commands. The commands are disabled while the debugger is running, even if you begin a new debugging session. The commands remain disabled even if you issue a **.restart (Restart Kernel Connection)** command in KD.

If you are running a debugging server, you might want to disable shell commands. If the shell is available, a remote connection can use the **.shell** command to change your computer.

Network Drive Control

In WinDbg, you can use the **File | Map Network Drive** and **File | Disconnect Network Drive** commands to control the network drive mappings. These changes always occur on the computer that WinDbg is running on, never on any computer that is remotely connected to WinDbg.

[Send comments about this topic to Microsoft](#)

Using Aliases

5/31/2017 • 9 min to read • [Edit Online](#)

Aliases are character strings that are automatically replaced with other character strings. You can use them in debugger commands and to avoid retyping certain common phrases.

An alias consists of an *alias name* and an *alias equivalent*. When you use an alias name as part of a debugger command, the name is automatically replaced by the alias equivalent. This replacement occurs immediately, before the command is parsed or executed.

The debugger supports three kinds of aliases:

- You can set and name *user-named aliases*.
- You can set *fixed-name aliases*, but they are named **\$u0, \$u1, ..., \$u9**.
- The debugger sets and names *automatic aliases*.

Defining a User-Named Alias

When you define a user-named alias, you can choose the alias name and the alias equivalent:

- The alias name can be any string that does not contain white space.
- The alias equivalent can be any string. If you enter it at the keyboard, the alias equivalent cannot contain leading spaces or carriage returns. Alternatively, you can set it equal to a string in memory, the value of a numeric expression, the contents of a file, the value of an environment variable, or the output of one or more debugger commands.

Both the alias name and the alias equivalent are case sensitive.

To define or redefine a user-named alias, use the **as (Set Alias)** or **aS (Set Alias)** command.

To remove an alias, use the **ad (Delete Alias)** command.

To list all current user-named aliases, use the **al (List Aliases)** command.

Defining a Fixed-Name Alias

There are 10 fixed-name aliases. Their alias names are **\$u0, \$u1, ..., \$u9**. Their alias equivalents can be any string that does not contain the ENTER keystroke.

Use the **r (Registers)** command to define the alias equivalents for fixed-name aliases. When you define a fixed-name alias, you must insert a period (.) before the letter "u". The text after the equal sign (=) is the alias equivalent. The alias equivalent can include spaces or semicolons, but leading and trailing spaces are ignored. You should not enclose the alias equivalent in quotation marks (unless you want quotation marks in the results).

Note Do not be confused by using the **r (Registers)** command for fixed-name aliases. These aliases are not registers or pseudo-registers, even though you use the **r** command to set their alias equivalents. You do not have to add an at (@) sign before these aliases, and you cannot use the **r** command to *display* the value of one of these aliases.

By default, if you do not define a fixed-name alias, it is an empty string.

Automatic Aliases

The debugger sets the following automatic aliases.

ALIAS NAME	ALIAS EQUIVALENT
\$ntnsym	The most appropriate module for NT symbols on the computer's native architecture. This alias can equal either ntdll or nt .
\$ntwsym	The most appropriate module for NT symbols during 32-bit debugging that uses WOW64. This alias could be ntdll32 or some other 32-bit version of Ntdll.dll.
\$ntsym	The most appropriate module for NT symbols that match the current machine mode. When you are debugging in native mode, this alias is the same as \$ntnsym . When you are debugging in a non-native mode, the debugger tries to find a module that matches this mode. (For example, during 32-bit debugging that uses WOW64, this alias is the same as \$ntwsym .)
\$CurrentDumpFile	The name of the last dump file that the debugger loaded.
\$CurrentDumpPath	The directory path of the last dump file that the debugger loaded.
\$CurrentDumpArchiveFile	The name of the last dump archive file (CAB file) that the debugger loaded.
\$CurrentDumpArchivePath	The directory path of the last dump archive file (CAB file) that the debugger loaded.

Automatic aliases are similar to [automatic pseudo-registers](#), except that you can use automatic aliases with alias-related tokens (such as `$()`), while you cannot use pseudo-registers with these tokens.

Using an Alias in the Debugger Command Window

After you define an alias, you can use it in any command entry. The alias name is automatically replaced with the alias equivalent. Therefore, you can use the alias as an expression or as a macro.

An alias name expands correctly even if it is enclosed in quotation marks. Because the alias equivalent can include any number of quotation marks or semicolons, the alias equivalent can represent multiple commands.

A user-named alias is recognized only if its name is separated from other characters by white space. The first character of its alias name must begin the line or follow a space, a semicolon, or a quotation mark. The last character of its alias name must end the line or be followed by a space, a semicolon, or a quotation mark.

Note Any text that you enter into the [Debugger Command window](#) that begins with "as", "aS", "ad", or "al" does not receive alias replacement. This restriction prevents the alias commands from being rendered inoperable. However, this restriction also means that commands that follow **ad** or **al** on a line do not have their aliases replaced. If you want aliases to be replaced in a line that begins with one of these strings, add a semicolon before the alias.

However, you can use the `$()` token to expand a user-named alias even when it is next to other text. You can also use this token together with certain switches to prevent an alias from being expanded or to display certain alias-

related values. For more information about these situations, see [\\$\{ } \(Alias Interpreter\)](#).

A fixed-name alias expands correctly from any point within a line, regardless of how it is embedded within the text of the line.

You cannot use commands that are available only in WinDbg ([.open](#), [.write_cmd_hist \(Write Command History\)](#), [.lsrcpath](#), and [.lsrcfix](#)) and a few additional commands ([.hh](#), [.cls](#), [.wtitle](#), [.remote](#), kernel-mode [.restart](#), and user-mode [.restart](#)) with aliases.

Using an Alias in a Script File

When you use an alias in a script file, you must take special care to make sure that the alias is expanded at the correct time. Consider the following script:

```
.foreach (value {dd 610000 L4})  
{  
    as /x ${/v:myAlias} value + 1  
    .echo value myAlias  
}  
  
ad myAlias
```

The first time through the loop, the [as, aS \(Set Alias\)](#) command assigns a value to the myAlias. The value assigned to myAlias is 1 plus 610000 (the first output of the dd command). However, when the [.echo \(Echo Comment\)](#) command is executed, myAlias has not yet been expanded, so instead of seeing 610001, we see the text "myAlias".

```
0:001> $$< c:\Script02.txt  
00610000 myAlias  
00905a4d 0x610001  
00000003 0x905a4e  
00000004 0x4  
0000ffff 0x5
```

The problem is that myAlias is not expanded until a new block of code is entered. The next entry to the loop is a new block, so myAlias gets expanded to 610001. But it is too late: we should have seen 610001 the first time through the loop, not the second time. We can fix this problem by enclosing the [.echo \(Echo Comment\)](#) command in a new block as shown in the following script.

```
.foreach (value {dd 610000 L4})  
{  
    as /x ${/v:myAlias} value + 1  
    .block{.echo value myAlias}  
}  
  
ad myAlias
```

With the altered script, we get the following correct output.

```
0:001> $$< c:\Script01.txt  
00610000 0x610001  
00905a4d 0x905a4e  
00000003 0x4  
00000004 0x5  
0000ffff 0x10000
```

For more information, see [.block](#) and [\\$\{ } \(Alias Interpreter\)](#).

Using a `.foreach` Token in an Alias

When you use a `.foreach` token in the definition of an alias, you must take special care to ensure that the token is expanded. Consider the following sequence of commands.

```
r $t0 = 5
ad myAlias
.foreach /ps 2 /ps 2 (Token {@$t0}) {as myAlias Token}
al
```

The first command sets the value of the `$t0` pseudo register to 5. The second command deletes any value that might have been previously assigned to `myAlias`. The third command takes the third token of the `?@$t0` command and attempts to assign the value of that token to `myAlias`. The fourth command lists all aliases and their values. We would expect the value of `myAlias` to be 5, but instead the value is the word "Token".

Alias	Value
-----	-----
myAlias	Token

The problem is that the `as` command is at the beginning of the line in the body of the `.foreach` loop. When a line begins with an `as` command, aliases and tokens in that line are not expanded. If we put a semicolon or blank space before the `as` command, then any alias or token that already has a value is expanded. In this example, `myAlias` is not expanded because it does not already have a value. `Token` is expanded because it has a value of 5. Here is the same sequence of commands with the addition of a semicolon before the `as` command.

```
r $t0 = 5
ad myAlias
.foreach /ps 2 /ps 2 (Token {@$t0}) ;as myAlias Token
al
```

Now we get the expected output.

Alias	Value
-----	-----
myAlias	5

Recursive Aliases

You can use a fixed-name alias in the definition of any alias. You can also use a user-named alias in the definition of a fixed-name alias. However, to use a user-named alias in the definition of another user-named alias, you have to add a semicolon before the `as` or `aS` command, or else the alias replacement does not occur on that line.

When you are using recursive definitions of this type, each alias is translated as soon as it is used. For example, the following example displays **3**, not **7**.

```
0:000> r $.u2=2
0:000> r $.u1=1+$u2
0:000> r $.u2=6
0:000> ? $u1
Evaluate expression: 3 = 00000003
```

Similarly, the following example displays **3**, not **7**.

```
0:000> as fred 2
0:000> r $.u1= 1 + fred
0:000> as fred 6
0:000> ? $u1
Evaluate expression: 3 = 00000003
```

The following example is also permitted and displays **9**.

```
0:000> r $.u0=2
0:000> r $.u0=7+$u0
0:000> ? $u0
Evaluate expression: 9 = 00000009
```

Examples

You can use aliases so that you do not have to type long or complex symbol names, as in the following example.

```
0:000> as Short usersrv!NameTooLongToWantToType
0:000> dw Short +8
```

The following example is similar to the preceding example but it uses a fixed-name alias.

```
0:000> r $.u0=usersrv!NameTooLongToWantToType
0:000> dw $u0+8
```

You can use aliases as macros for commands that you use frequently. The following example increments the **eax** and **ebx** registers two times.

```
0:000> as GoUp r eax=eax+1; r ebx=ebx+1
0:000> GoUp
0:000> GoUp
```

The following example uses an alias to simplify typing of commands.

```
0:000> as Cmd "dd esp 14; g"
0:000> bp MyApi Cmd
```

The following example is similar to the preceding example but it uses a fixed-name alias.

```
0:000> r $.u5="dd esp 14; g"
0:000> bp MyApi $u5
```

Both of the preceding examples are equivalent to the following command.

```
0:000> bp MyApi "dd esp 14; g"
```

Tools.ini File

In CDB (and NTSD), you can predefine fixed-name aliases in the [tools.ini](#) file. To predefine a fixed-name alias, add the **\$u** fields that you want to your [NTSD] entry, as in the following example.

```
[NTSD]
$u1:_ntdll!_RtlRaiseException
$u2:"dd esp 14;g"
$u9:$u1 + 42
```

You cannot set user-named aliases in the Tools.ini file.

Fixed-Name Aliases vs. User-Named Aliases

User-name aliases are easier to use than fixed-named aliases. Their definition syntax is simpler, and you can list them by using the [al \(List Aliases\)](#) command.

Fixed-named aliases are replaced if they are used next to other text. To make a user-named alias be replaced when it is next to other text, enclose it in the [\\${ } \(Alias Interpreter\)](#) token.

Fixed-name alias replacement occurs before user-named alias replacement.

[Send comments about this topic to Microsoft](#)

Using Script Files

5/26/2017 • 2 min to read • [Edit Online](#)

A *script file* is a text file that contains a sequence of debugger commands. There are a variety of ways for the debugger to load a script file and execute it. A script file can contain commands to be executed sequentially or can use a more complex flow of execution.

To execute a script file, you can do one of the following:

- (KD and CDB only; only when the debugger starts) Create a script file that is named Ntsd.ini and put it in the directory where you are starting the debugger from. The debugger automatically executes this file when the debugger starts. To use a different file for the startup script file, specify the path and file name by using the [-cf command-line option](#) or by using the [IniFile](#) entry in the [Tools.ini](#) file.
- (KD and CDB only; when each session starts) Create a script file and specify its path and file name by using the [-cfr command-line option](#). The debugger automatically executes this script file when the debugger starts and every time that the target is restarted.
- Use the `$<, $><, $$<, and $$><` commands to execute a script file after the debugger is running. For more information about the syntax, see [\\$<, \\$><, \\$\\$<, and \\$\\$>< \(Run Script File\)](#).

The `$><` and `$$><` commands differ from the other methods of running scripts in one important way. When you use these commands, the debugger opens the specified script file, replaces all carriage returns with semicolons, and executes the resulting text as a single command block. These commands are useful for running scripts that contain debugger command programs. For more information about these programs, see [Using Debugger Command Programs](#).

You cannot use commands that are available only in WinDbg (such as [.lsrcfix \(Use Local Source Server\)](#), [.lsrcpath \(Set Local Source Path\)](#), [.open \(Open Source File\)](#), and [.write_cmd_hist \(Write Command History\)](#)) in script files, even if the script file is executed in WinDbg. In addition, you cannot use the [.beep \(Speaker Beep\)](#), [.cls \(Clear Screen\)](#), [.hh \(Open HTML Help File\)](#), [.idle_cmd \(Set Idle Command\)](#), [.remote \(Create Remote.exe Server\)](#), kernel-mode [.restart \(Restart Kernel Connection\)](#), user-mode [.restart \(Restart Target Application\)](#), or [.wtitle \(Set Window Title\)](#) commands in a script file.

WinDbg supports the same scripts as KD and CDB, with one minor exception. You can use the [.remote_exit \(Exit Debugging Client\)](#) command only in a script file that KD or CDB uses. You cannot exit from a debugging client though a script that is executed in WinDbg.

Using Debugger Command Programs

5/26/2017 • 1 min to read • [Edit Online](#)

This section includes the following topics:

[Elements of a Debugger Command Program](#)

[Control Flow Tokens](#)

[Debugger Command Program Execution](#)

[Debugger Command Program Examples](#)

[Send comments about this topic to Microsoft](#)

Elements of a Debugger Command Program

5/26/2017 • 1 min to read • [Edit Online](#)

A *debugger command program* is a small application that consists of debugger commands and control flow tokens, such as **.if**, **.for**, and **.while**. (For a full list of control flow tokens and their syntax, see [Control Flow Tokens](#).)

You can use braces ({ }) to enclose a block of statements within a larger command block. When you enter each block, all aliases within the block are evaluated. If you later alter the value of an alias within a command block, commands after that point do not use the new alias value unless they are within a subordinate block.

You cannot create a block by using a pair of braces. You must add a control flow token before the opening brace. If you want to create a block only to evaluate aliases, you should use the **.block** token before the opening brace.

A debugger command program can use [user-named aliases](#) or [fixed-name aliases](#) as its local variables. If you want to use numeric or typed variables, you can use the [\\$tn](#)[pseudo-registers](#).

User-named aliases are evaluated only if they are not next to other text. If you want to evaluate an alias that is next to other text, use the **\$() (Alias Interpreter)** token. This token has optional switches that enable you to evaluate the alias in a variety of ways.

You can add comments to a debugger command program by using two dollar signs (**\$\$ (Comment Specifier)**). You should not insert a comment between a token and its elements (such as braces or conditions).

Note You should not use an asterisk (*** (Comment Line Specifier)**). Because comments that are specified with an asterisk do not end with a semicolon, the rest of the program is disregarded.

Typically, you should use MASM syntax within a debugger command program. When you have to use C++ elements (such as specifying a member of a structure or class), you can use the **@@c++()** token to switch to C++ syntax for that clause.

The **\$scmp**, **\$sicmp**, and **\$spat** string operators in MASM syntax are particularly useful. For more information about these operators, see [MASM Numbers and Operators](#).

[Send comments about this topic to Microsoft](#)

Control Flow Tokens

5/26/2017 • 2 min to read • [Edit Online](#)

You can use *control flow tokens* to create conditional execution and execution loops within debugger command programs.

Control flow tokens behave like their counterparts in C and C++, with the following general exceptions:

- You must enclose each block of commands that is executed conditionally or repeatedly in braces, even if there is only one such command. For example, you cannot omit the braces in the following command.

```
0:000> .if (ebx>0) { r ebx }
```

- Each condition must be a expression. Commands are not permitted. For example, the following example produces a syntax error.

```
0:000> .while (r ebx) { .... }
```

- The final command before a closing brace does not have to be followed by a semicolon.

The following control flow tokens are supported within a debugger command program. For more information about the syntax of each token, see the individual reference topics.

- The **.if** token behaves like the **if** keyword in C.
- The **.else** token behaves like the **else** keyword in C.
- The **.elseif** token behaves like the **else if** keyword combination in C.
- The **.foreach** token parses the output of debugger commands, a string, or a text file. This token then takes each item that it finds and uses them as the input to a specified list of debugger commands.
- The **.for** token behaves like the **for** keyword in C, except that you must separate multiple increment commands by semicolons, not by commas.
- The **.while** token behaves like the **while** keyword in C.
- The **.do** token behaves like the **do** keyword in C, except that you cannot use the word "while" before the condition.
- The **.break** token behaves like the **break** keyword in C. You can use this token within any **.for**, **.while**, or **.do** loop.
- The **.continue** token behaves like the **continue** keyword in C. You can use this token within any **.for**, **.while**, or **.do** loop.
- The **.catch** token prevents a program from ending if an error occurs. The **.catch** token is followed by braces that enclose one or more commands. If one of these commands generates an error, the error message is displayed, all remaining commands within the braces are ignored, and execution resumes with the first command after the closing brace.
- The **.leave** token is used to exit from a **.catch** block.
- The **.printf** token behaves like the **printf** statement in C.

- The **.block** token performs no action. You should use this token only to introduce a block, because you cannot create a block by only using a pair of braces. You must add a control flow token before the opening brace.

The **!for_each_module**, **!for_each_frame**, and **!for_each_local** extensions are also useful with a debugger command program.

[Send comments about this topic to Microsoft](#)

Executing a Debugger Command Program

5/26/2017 • 1 min to read • [Edit Online](#)

You can execute a debugger command program in one of the following ways:

- Enter all of the statements in the [Debugger Command window](#) as a single string, with individual statements and commands separated by semicolons.
- Add all of the statements in a script file on a single line, with individual statements and commands separated by semicolons. Then, run this script file by using one of the methods described in [Using Script Files](#).
- Add all of the statements in a script file, with each statement on a separate line. (Alternatively, separate statements by any combination of carriage returns and semicolons.) Then, run this script file by using the **\$> < (Run Script File)** or **\$\$>< (Run Script File)** command. These commands open the specified script file, replace all carriage returns with semicolons, and execute the resulting text as a single command block.

[Send comments about this topic to Microsoft](#)

Debugger Command Program Examples

5/31/2017 • 4 min to read • [Edit Online](#)

The following sections describe debugger command programs.

Using the **.foreach** Token

The following example uses the **.foreach** token to search for WORD values of 5a4d. For each 5a4d value that is found, the debugger displays 8 DWORD values, starting at the address of where the 5a4d DWORD was found.

```
0:000> .foreach (place { s-[1]w 77000000 L?4000000 5a4d }) { dc place L8 }
```

The following example uses the **.foreach** token to search for WORD values of 5a4d. For each 5a4d value that is found, the debugger displays 8 DWORD values, starting 4 bytes prior to the address where the 5a4d DWORD was found.

```
0:000> .foreach (place { s-[1]w 77000000 L?4000000 5a4d }) { dc place -0x4 L8 }
```

The following example displays the same values.

```
0:000> .foreach (place { s-[1]w 77000000 L?4000000 5a4d }) { dc ( place -0x4 ) L8 }
```

Note If you want to operate on the variable name in the *OutCommands* portion of the command, you must add a space after the variable name. For example, in the preceding example, there is a space between the variable *place* and the subtraction operator.

The **-[1]** option together with the **s (Search Memory)** command causes its output to include only the addresses it finds, not the values that are found at those addresses.

The following command displays verbose module information for all modules that are located in the memory range from 0x77000000 through 0x7F000000.

```
0:000> .foreach (place { 1m1m }) { .if ((${place} >= 0x77000000) & (${place} <= 0x7f000000)) { 1mva place } }
```

The **1m** option together with the **1m (List Loaded Modules)** command causes its output to include only the addresses of the modules, not the full description of the modules.

The preceding example uses the **\${ } (Alias Interpreter)** token to make sure aliases are replaced even if they are next to other text. If the command did not include this token, the opening parenthesis that is next to **place** prevents alias replacement. Note that the **\${ }** token works on the variables that are used in **.foreach** and on true aliases.

Walking the Process List

The following example walks through the kernel-mode process list and displays the executable name for each entry in the list.

This example should be stored as a text file and executed with the **\$\$>< (Run Script File)** command. This command loads the whole file, replaces all carriage returns with semicolons, and executes the resulting block. This command enables you to write readable programs by using multiple lines and indentation, instead of having to squeeze the whole program onto a single line.

This example illustrates the following features:

- The **\$t0**, **\$t1**, and **\$t2** pseudo-registers are used as variables in this program. The program also uses aliases named **Procc** and **\$ImageName**.
- This program uses the MASM expression evaluator. However, the **@@c++()** token appears one time. This token causes the program to use the C++ expression evaluator to parse the expression within the parentheses. This usage enables the program to use the C++ structure tokens directly.
- The **?** flag is used with the **r (Registers)** command. This flag assigns typed values to the pseudo-register **\$t2**.

```
## Get process list LIST_ENTRY in $t0.
r $t0 = nt!PsActiveProcessHead

## Iterate over all processes in list.
.for (r $t1 = poi(@$t0);
      (@$t1 != 0) & (@$t1 != @$t0);
      r $t1 = poi(@$t1))
{
    r? $t2 = #CONTAINING_RECORD(@$t1, nt!_EPROCESS, ActiveProcessLinks);
    as /x Procc @$t2

## Get image name into $ImageName.
as /ma $ImageName @@c++(&@$t2->ImageFileName[0])

.block
{
    .echo ${$ImageName} at ${Procc}
}

.ad $ImageName
.ad Procc
}
```

Walking the LDR_DATA_TABLE_ENTRY List

The following example walks through the user-mode LDR_DATA_TABLE_ENTRY list and displays the base address and full path of each list entry.

Like the preceding example, this program should be saved in a file and executed with the **\$\$>< (Run Script File)** command.

This example illustrates the following features:

- This program uses the MASM expression evaluator. However, in two places, the **@@c++()** token appears. This token causes the program to use the C++ expression evaluator to parse the expression within the parentheses. This usage enables the program to use C++ structure tokens directly.
- The **?** flag is used with the **r (Registers)** command. This flag assigns typed values to the pseudo-registers **\$t0** and **\$t1**. In the body of the loop, **\$t1** has the type **ntdll!_LDR_DATA_TABLE_ENTRY***, so the program can make direct member references.
- The user-named aliases **\$Base** and **\$Mod** are used in this program. The dollar signs reduce the possibility that these aliases have been used previously in the current debugger session. The dollar signs are not necessary. The **\$(/v:)** token interprets the alias literally, preventing it from being replaced if it was defined before the script is run. You can also use this token together with any block to prevent alias definitions before the block from being used.
- The **.block** token is used to add an extra alias replacement step. Alias replacement occurs one time for the whole script when it is loaded and one time when each block is entered. Without the **.block** token and its braces, the **.echo** command does not receive the values of the **\$Mod** and **\$Base** aliases that are assigned in

the previous lines.

```
## Get module list LIST_ENTRY in $t0.

Using the WinDbg Graphical Interface

5/31/2017 • 1 min to read • [Edit Online](#)

This section includes the following topics:

[Using Debugging Information Windows](#)

[Using Workspaces](#)

[Using the Toolbar and Status Bar](#)

[Using the Help Documentation](#)

[Send comments about this topic to Microsoft](#)

Using Debugging Information Windows

5/26/2017 • 1 min to read • [Edit Online](#)

WinDbg has ten kinds of debugging information windows. You can have only one instance of the following windows open at the same time: the [Debugger Command window](#), the Watch window, the [Locals window](#), the [Registers window](#), the [Calls window](#), the [Disassembly window](#), the [Processes and Threads window](#), and the Scratch Pad. In addition to these eight individual windows, WinDbg can display multiple [Source windows](#) and [Memory windows](#) at the same time.

This section describes the features that are common to all of these windows:

[Opening a Window](#)

[Closing a Window](#)

[Configuring a Window](#)

[Moving Through a Window](#)

[Cutting and Pasting Text](#)

[Changing Text Properties](#)

[Positioning the Windows](#)

[Send comments about this topic to Microsoft](#)

Opening a Window

5/26/2017 • 1 min to read • [Edit Online](#)

When WinDbg begins a debugging session, the [Debugger Command window](#) automatically opens. The [Disassembly window](#) also automatically opens, unless you deselect [Automatically Open Disassembly](#) on the **Window** menu.

Whenever WinDbg discovers a source file that corresponds to the current program counter, WinDbg opens a [Source window](#) for that file. For other ways to open Source windows, see [Source Path](#).

You can use the following menu commands, toolbar buttons, and shortcut keys to switch to these windows. That is, if a window is not open, it opens. If a window is open but inactive, it becomes active. If a window is docked and there is a floating window in front of it, the docked window becomes active but the floating window stays in front of the docked window.

WINDOW	MENU COMMAND	BUTTON	SHORTCUT KEYS
Debugger Command window	View Command		ALT+1
Watch window	View Watch		ALT+2
Locals window	View Locals		ALT+3
Registers window	View Registers		ALT+4
Memory window	View Memory		ALT+5
Calls window	View Call Stack		ALT+6
Disassembly window	View Disassembly		ALT+7
Scratch Pad window	View Scratch Pad		ALT+8
Processes and Threads window	View Processes and Threads		ALT+9
Source window	Click File Open Source File and then select a source file.		CTRL+O

You can also activate a window by selecting it from the [list of open windows](#) at the bottom of the **Window** menu.

[Send comments about this topic to Microsoft](#)

Closing a Window

5/26/2017 • 1 min to read • [Edit Online](#)

To close a debugging information window, click the **Close** button in the upper-right corner of the window.

If you want to close the active window, you can also click **Close Current Window** on the **File** menu or press **CTRL+F4**.

You can close one of the debugging information windows by pressing **ALT+SHIFT+number**, where **ALT+number** are the shortcut keys that open this window. (For a list of the possible shortcut keys, see [Opening a Window](#).)

To close all [Source windows](#) at the same time, click [Close All Source Windows](#) on the **Window** menu. This command will not close a Source window that has been designated as a tab-dock target. For more information on this setting, see the [Source Window](#) topic.

[Send comments about this topic to Microsoft](#)

Configuring a Window

5/26/2017 • 1 min to read • [Edit Online](#)

Each debugging information window has a shortcut menu that you can access by right-clicking the title bar of the window or by clicking the icon near the upper-right corner of the title bar. You can use the commands on this shortcut menu to configure the window.

Many debugging information windows also have toolbars that contain buttons. Most of these buttons have features that are the same as commands on the shortcut menu.

[Send comments about this topic to Microsoft](#)

Moving Through a Window

5/26/2017 • 2 min to read • [Edit Online](#)

There are several ways of moving through a debugging information window.

If a scrollbar appears in the window, you can use it to display more of the window.

In addition, some windows support the **Find**, **Go to Address**, or **Go to Line** commands. These commands only change the WinDbg display. They do not affect the execution of the target or any other debugger operations.

Find Command

You can use the **Find** command in the [Debugger Command window](#) or in a [Source window](#).

When one of these windows is active, click **Find** on the **Edit** menu or press CTRL+F. The **Find** dialog box opens.

Enter the text that you want to find in the dialog box, and select **Up** or **Down** to determine the direction of your search. The search begins wherever the cursor is in the window. You can put the cursor at any point by using the mouse.

Select the **Match whole word only** check box if you want to search for a single whole word. (If you select this check box and you enter multiple words, this check box is ignored.) Select the **Match case** check box to perform a case-sensitive search.

If you close the **Find** dialog box, you can repeat the previous search in a forward direction by clicking **Find Next** on the **Edit** menu or pressing F3. You can repeat the search in a backward direction by pressing SHIFT+F3.

Go to Address Command

The **Go to Address** command searches for an address in the application that you are debugging. To use this option, click **Go to Address** on the **Edit** menu or press CTRL+G.

When the **View Code Offset** dialog box appears, enter the address that you want to search for. You can enter this address as an expression, such as a function, symbol, or integer memory address. If the address is ambiguous, a list appears with all of the ambiguous items.

After you click **OK**, the debugger moves the cursor to the beginning of the function or address in the [Disassembly window](#) or a [Source window](#).

You can use the **Go to Address** command regardless of which debugging information window is open. If the debugger is in disassembly mode, the debugger finds the address that you are searching for in the Disassembly window. If the debugger is in source mode, the debugger tries to find the address in a Source window. If the debugger cannot find the address in a Source window, the debugger finds the address in the Disassembly window. If the needed window is not open, the debugger opens it.

Moving to a Specific Line

The **Go to Line** command searches for a line number in the active Source window. If the active window is not a Source window, you cannot use the **Go to Line** command.

To activate this option, click **Go to Line** on the **Edit** menu or press CTRL+L.

When the **Go to Line** dialog box appears, enter the line number that you want to find and then click **OK**. The debugger moves the cursor to that line. If the line number is larger than the last line in the file, the cursor moves to the end of the file.

[Send comments about this topic to Microsoft](#)

Cutting and Pasting Text

5/26/2017 • 3 min to read • [Edit Online](#)

WinDbg uses many common methods of manipulating text and several methods that are less familiar.

Selecting Text

To select text in a [Source window](#), in the [Disassembly window](#), in either pane of the [Debugger Command window](#), or in a dialog box, point to one end of the text, press and hold the left mouse button, and drag the pointer to the other end of the text.

To select all of the text in a window, you can also click **Select All** on the **Edit** menu or press CTRL+A.

In the [Calls window](#), [Watch window](#), [Locals window](#), [Registers window](#), and [Memory window](#), you cannot select an arbitrary span of text, but you can select a whole line or cell. Click in the desired line or cell to select its text.

While you are entering text, press the DELETE and BACKSPACE keys to delete the text to the right or left of the cursor, respectively. If you select text, you can press these keys to delete the selection. If you select text and then type any characters, the new characters replace what you selected.

Copying Text

To copy text, select that text and then do one of the following:

- Press the right mouse button. (This method works only in some locations. For more information about how to use the right mouse button, see [The Right Mouse Button](#).)
- Press CTRL+C.
- Press CTRL+INSERT.
- (Docked and tabbed windows only) Click **Copy** on the **Edit** menu.
- Click the **Copy (Ctrl+C)** button () on the toolbar.

Cutting Text

To cut text and move it to the clipboard, select the text and then do one of the following:

- Press CTRL+X.
- Press SHIFT+DELETE.
- (Docked and tabbed windows only) Click **Cut** on the **Edit** menu.
- Click the **Cut (Ctrl+X)** button () on the toolbar.

You can cut text from the bottom pane of the Debugger Command window, from the left column of the Watch window, and from any dialog box (that is, from any location that supports text entry).

Pasting Text

To paste text from the clipboard, put the cursor where you want to insert the text (or select the text that you want to replace) and then do one of the following:

- Press the right mouse button. (This method works only in some locations, and you cannot use this method to replace text. For more information about how to use this method, see [The Right Mouse Button](#).)
- Press CTRL+V.

- Press SHIFT+INSERT.
- (Docked and tabbed windows only) Click **Paste** on the **Edit** menu.
- Click the **Paste (Ctrl+V)** button (

You can paste text into the bottom pane of the Debugger Command window, into the left column of the Watch window, and into any dialog box (that is, into any location that supports text entry).

Right Mouse Button

The right mouse button has several effects that can make copying and pasting much quicker:

- If you select text in either pane of the Debugger Command window, in the Scratch Pad, in the Disassembly window, or in any Source window, and then you press the right mouse button, the text is copied to the clipboard. However, if **QuickEdit Mode** has been deselected in [View | Options](#), right-clicking in these locations will pop up the menu most relevant to the current location.
- If you put the cursor (without selecting any text) in either pane of the Debugger Command window, in the Scratch Pad, or in the text entry space of the Watch window, and then you press the right mouse button, the contents of the clipboard are pasted into the window. However, if **QuickEdit Mode** has been deselected in [View | Options](#), right-clicking in these locations will pop up the menu most relevant to the current location.
- If you put the cursor in any box and then press the right mouse button, a menu with **Undo**, **Cut**, **Copy**, **Paste**, and **Select All** options appears. You can choose any of these options.

[Send comments about this topic to Microsoft](#)

Changing Text Properties

5/26/2017 • 1 min to read • [Edit Online](#)

You can customize the font that is used in all of the debugging information windows. You can also change the tab width that is used in the [Source windows](#).

Setting the Font, Font Style, and Font Size

All debugging information windows share the same font. To change this font, click **Font** on the **View** menu, or click the **Font** button (A) on the toolbar.

In the **Font** dialog box, select the font, style, and size from the appropriate lists, and then click **OK**. All of the available fonts are fixed-pitch, because these kinds of fonts are the most useful for viewing code.

Setting the Tab Width

To change the tab width settings, click **Options** on the **View** menu or click the **Options** button (W) on the toolbar.

The **Options** dialog box then appears. In the **Tab width** box, enter the number of spaces that the tab width should be equivalent to, and then click **OK**.

The tab settings affect the display of the code in any Source window.

[Send comments about this topic to Microsoft](#)

Positioning the Windows

5/26/2017 • 1 min to read • [Edit Online](#)

Each debugging information window can be *floating* or *docked*.

You can position *floating windows* separately from other windows. *Docked windows* are connected to the WinDbg window or to an independent dock. Each docked window can occupy a unique position in its dock or can be combined with other docked windows in a *tabbed collection*.

This section includes the following topics:

[Debugging with Floating and Docked Windows](#)

[Docking a Window](#)

[Tabbing a Window](#)

[Undocking a Window](#)

[Creating a New Dock](#)

[Resizing and Moving Windows](#)

[Arranging Windows](#)

[Send comments about this topic to Microsoft](#)

Debugging with Floating and Docked Windows

5/26/2017 • 1 min to read • [Edit Online](#)

The features that are available in a debugging information window are not affected by whether the window is floating, docked, or docked in a tabbed collection.

Overview of the Window Configuration

A floating window is not connected to the WinDbg window or any other dock. Floating windows always appear directly in front of the WinDbg window.

A docked window occupies a fixed position within the WinDbg window or in a separate dock.

When two or more docked windows are tabbed together, they occupy the same position within the frame. You can see only one of these tabbed windows at one time. At the bottom of each tabbed window collection is a set of tabs. The selected tab indicates which window in the collection is visible.

Making a Window Active

You can make any window active, regardless of its position. When a floating window is active, it appears in the foreground. When a window that is inside an additional dock is active, that dock appears in the foreground. When a docked window within the WinDbg window is active, one or more floating windows might still obscure the docked window.

To make a floating window or a docked window active, click its title bar. To make a docked window in a tabbed collection active, click its tab.

You can also make a window active by using the WinDbg menu or toolbar. You can activate any window by clicking the window name at the bottom of the **Window** menu. You can also activate any window (other than a [Memory window](#) or a [Source window](#)) by clicking its name on the **View** menu or clicking its toolbar button.

Press CTRL+TAB to switch between debugging information windows. By pressing these keys repeatedly, you can scan through all of the windows, regardless of whether they are floating, docked by themselves, or part of a tabbed collection of docked windows. When you release the CTRL key, the window that you are currently viewing becomes active.

The ALT+TAB shortcut keys are the standard Microsoft Windows shortcut keys to switch between the windows on the desktop. You can use these shortcut keys to switch between the WinDbg window and any additional docks that you have created. You can also make a dock active by clicking its button in the Windows taskbar.

[Send comments about this topic to Microsoft](#)

Docking a Window

5/26/2017 • 3 min to read • [Edit Online](#)

To dock a floating window, do one of the following:

- Double-click the window's title bar.
- Open the shortcut menu by right-clicking the window's title bar or clicking the window's icon in the upper-right corner, and then click **Dock**.
- In the WinDbg window, on the **Window** menu, click **Dock All**. This command docks all of the windows except those that have the **Always floating** option selected on their individual shortcut menus.
- Drag the window to a docking location. This action causes the window to dock unless **Always floating** is selected on the shortcut menu for that window, or unless you press and hold the ALT key as you begin dragging the window.

When you dock a window by any method other than dragging it, WinDbg automatically positions the docked window. If the window has never been docked before, WinDbg moves the window to a new untabbed location within the WinDbg window. If the window has been docked before, WinDbg returns the window to its most recent docking location, which might be tabbed or untabbed.

When you dock a window by dragging it, you can control its destination position. As you drag the window, you will see a semi-transparent outline of the window appear. This outline shows where the window will be docked if you release the mouse button at that point. The following rules determine where a dragged window is docked:

- If you drag the mouse pointer over the WinDbg window when the window is empty or over an empty dock, and then you release the mouse button, the dragged window is docked in that location and completely fills the frame or dock.
- If you drag the mouse pointer over the left, right, top, or bottom portion of an already-docked window and then you release the mouse button, the dragged window is docked to the left, right, top, or bottom of the already-docked window, respectively.
- When you drag the mouse pointer over a floating window (including the original position of the window that you are dragging), no docking occurs. This exception means that you might have to drag other windows out of the way (or drag the current window two times) before you can move the window to where you want it.
- If you drag the mouse pointer to a position that is not inside the WinDbg frame or any other dock and then you release the mouse button, the dragged window remains floating.

All of the preceding rules apply to the mouse pointer location itself. They do not depend on where you originally clicked within the title bar of the window that you are dragging.

Re-docking

If you let WinDbg automatically dock a floating window that was previously docked, WinDbg tries to put the window in the same docking position that it previously occupied. Also, if you load a workspace, WinDbg tries to restore all of the debugging information windows to their previous positions, whether docked or floating.

However, multiple instances of **Memory windows** and **Source windows** are not distinguished when the docking position is saved. For example, if you combine the **Locals window** together with a Memory window in a tabbed collection, and this state is saved and later restored, the Locals window joins a Memory window in a tabbed collection, but it might not be the same Memory window as before.

If you load a workspace that includes one or more Source windows when the source files are inaccessible, those Source windows are not reopened. When this situation occurs, other windows that were tabbed together with those windows might return to the floating state. If you want to keep all of your Source windows tabbed together, you should include at least one source file that is always present, or include an additional window in the tabbed collection.

[Send comments about this topic to Microsoft](#)

Tabbing a Window

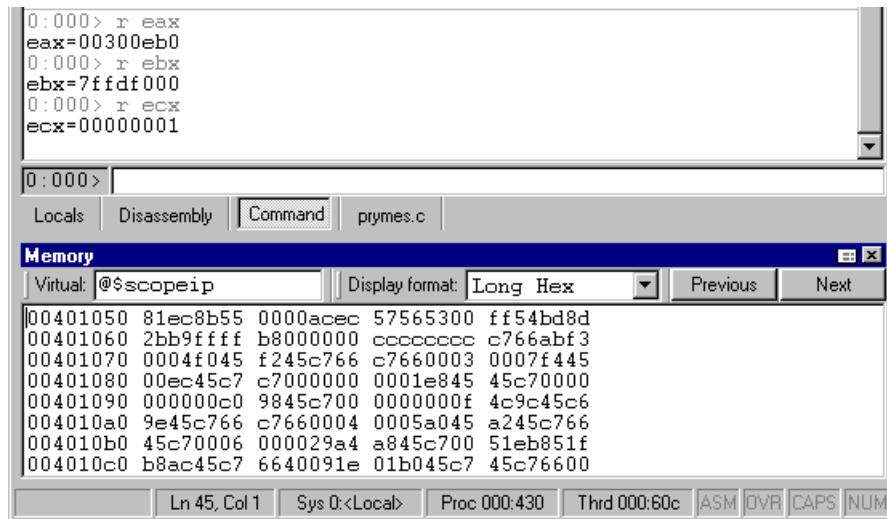

5/26/2017 • 1 min to read • [Edit Online](#)

To tab a floating or docked window, drag it on top of another docked window. Drag the window with the mouse pointer over the center of an already-docked window, and then release the mouse button. The dragged window joins the already-docked window as a tabbed window collection.

All Source windows can be grouped automatically into a tabbed collection by selecting one Source window and designating it as the tab-dock target for all Source windows by choosing the **Set as tab-dock target for window type** option in its short-cut menu. Once this is done, all future Source windows that are opened will automatically be included in a tabbed collection with this first Source window. The Source window marked as the tab-dock target will not be closed when the **Window | Close All Source Windows** menu command is selected. Thus you can set up a placeholder window for the Source windows without worrying that it will be closed when you don't want it to be. The same process also works for Memory windows.

Note If you want a window to join another window in a tabbed window collection, watch the outline of the window that moves as you drag the window. When this outline completely surrounds the window that you want to join, release the mouse button.

A set of tabs always controls the window immediately above the tabs. In the following illustration, the [Debugger Command window](#) is selected and is visible above the tabs.

[Send comments about this topic to Microsoft](#)

Undocking a Window

5/26/2017 • 1 min to read • [Edit Online](#)

To undock a window and make it a floating window, do one of the following:

- Double-click the window's title bar.
- Open the shortcut menu by right-clicking the window's title bar, right-clicking the window's tab if it is part of a tabbed collection, or clicking the window's icon in the upper-right corner, and then click **Undock**.
- In the WinDbg window, on the **Window** menu, click **Undock All**. This command changes all of the docked windows into floating windows.

When you undock a window by one of the preceding methods, the window returns to its previous undocked position.

You can also drag a docked window by clicking its title bar. This action enables you to move the window to a different docked position or undock it. (Dragging a docked window to a new position works exactly like dragging a floating window to a new position. For more information about dragging a floating window to a new position, see [Docking a Window](#).)

When you try to undock or drag a tabbed window by any of these methods, only the active window in the tabbed collection is moved.

[Send comments about this topic to Microsoft](#)

Creating a New Dock

5/26/2017 • 1 min to read • [Edit Online](#)

When WinDbg is started, the WinDbg window is the only possible docking location.

To create a new dock, on the **Window** menu, click **Open Dock**. This dock is an independent window that you can maximize, minimize, or drag like any other window on the desktop.

A new dock can also be created by using the **Move to new dock** option on the shortcut menu for any already open window. This selection will close the window and open it in a new dock.

You can create as many docks as you want.

To close a dock and any debugging information windows that are currently docked there, click the **Close** button in the upper-right corner of the dock.

[Send comments about this topic to Microsoft](#)

Resizing and Moving a Window

5/26/2017 • 1 min to read • [Edit Online](#)

Floating windows are always associated with the WinDbg window. If you minimize WinDbg, all floating windows are minimized. And if you restore WinDbg, all floating windows are restored. You can never put a floating window behind the WinDbg window.

Each floating window moves independently from each other and from the WinDbg window, unless you have selected **Move with frame** on the window's shortcut menu.

A docked window occupies a fixed position within the WinDbg frame. If you resize WinDbg, all of the docked windows are automatically scaled to the new size. The same situation applies to windows that have been docked in a separate dock.

If you move the mouse pointer to the border between two docked windows, the mouse pointer becomes an arrow. By dragging this arrow, you can resize the two adjacent windows and leave them in the docked state.

The WinDbg window is always filled with docked windows. There is never any empty area in the window unless there are no windows docked. The same situation applies to independent docks.

[Send comments about this topic to Microsoft](#)

Arranging Windows

5/26/2017 • 1 min to read • [Edit Online](#)

One useful window arrangement is to combine all of your [Source windows](#) into a single tabbed collection. The easiest way to do this is by marking your first source window as the tab-dock target for all Source windows by selecting the **Set as tab-dock target for window type** option in the Source window's short-cut menu. Once this is done, all future Source windows that are opened will automatically be included in a tabbed collection with this first Source window. The Source window marked as the tab-dock target will not be closed when the **Window | Close All Source Windows** menu command is selected. Thus you can set up a placeholder window for the Source windows that will only be closed when you want it to be.

This collection can occupy half of the WinDbg window or you can put it in a separate dock.

If you want each debugging information window to be completely separate, you can create one dock for each window. This arrangement enables you to minimize or maximize each window separately.

If you want all of your windows to be floating, you should select **Always floating** on each window's shortcut menu so that you can drag each window independently to any location.

Alternatively, you can use the [MDI Emulation](#) command on the **Window** menu. This command makes all of the windows floating windows and constrains them within the frame window. This behavior emulates the behavior of WinDbg before the introduction of docking mode.

If you are using dual monitors, you can put the WinDbg window in one monitor and an extra dock in the other.

Some standard window arrangements for various debugging scenarios are included in the Debugging Tools for Windows package. For details on these arrangements, see [Using and Customizing WinDbg Themes](#).

[Send comments about this topic to Microsoft](#)

Using Workspaces

5/26/2017 • 1 min to read • [Edit Online](#)

When you exit WinDbg, it saves your session configuration in a *workspace*. A workspace enables you to easily preserve your settings from one session to another. You can also save or clear the workspaces manually, or even use a workspace to save a debugging session that is still in progress.

This section includes the following topics:

[Creating and Opening a Workspace](#)

[Workspace Contents](#)

[Using and Customizing WinDbg Themes](#)

[Send comments about this topic to Microsoft](#)

Creating and Opening a Workspace

5/26/2017 • 3 min to read • [Edit Online](#)

WinDbg has two kinds of workspaces: *default workspaces* and *named workspaces*.

Default Workspaces

WinDbg has several different kinds of default workspaces:

- The *base workspace* is used when WinDbg is in a dormant state.
- The *default user-mode workspace* is used when you are attaching to a user-mode process (by using the **-p** [command-line option](#) or by using the [File | Attach to a Process](#) command).
- The *remote default workspace* is used when you are connecting to a debugging server.
- The *default kernel-mode workspace* is used when WinDbg begins a kernel-mode debugging session.
- The *processor-specific workspace* is used during kernel-mode debugging after WinDbg attaches to the target computer. There are separate processor-specific workspaces for x86-based and x64-based processors.

When WinDbg creates a user-mode process for debugging, a workspace is created for that executable file. Each created executable file has its own workspace.

When WinDbg analyzes a dump file, a workspace is created for that dump file analysis session. Each dump file has its own workspace.

When you begin a debugging session, the appropriate workspace is loaded. When you end a debugging session or exit WinDbg, a dialog box is displayed and asks you if you want to save the changes that you have made to the current workspace. If you start WinDbg with the **-Q** [command-line option](#), this dialog box does not appear, and workspaces are automatically saved. Also, if you start WinDbg by the **-Q** command-line option, this dialog box does not appear, and no changes are saved.

Workspaces load in a cumulative manner. The base workspace is always loaded first. When you begin a particular debugging action, the appropriate workspace is loaded. So most debugging is completed after two workspaces have been loaded. Kernel-mode debugging is completed after three workspaces have been loaded (the base workspace, the default kernel-mode workspace, and the processor-specific workspace).

For greatest efficiency, you should save settings in lower-level workspaces if you want them to apply to all of your WinDbg work.

Note The layout of the debugging information windows is one exception to the cumulative behavior of workspaces. The position, docking status, and size of each window are determined by only the most recent workspace that you opened. This behavior includes the contents of the Watch window and the locations that you viewed in each [Memory window](#). The command history in the [Debugger Command window](#) is not cleared when a new workspace is opened, but all other window states are reset.

To access the base workspace, start WinDbg with no target, or click [Stop Debugging](#) on the **Debug** menu after your session is complete. You can then make any edits that are allowed in the base workspace.

Named Workspaces

You can also give workspaces names and then save or load them individually. After you load a named workspace, all automatic loading and saving of default workspaces is disabled.

Named workspaces contain some additional information that default workspaces do not. For more information about this additional information, see [Workspace Contents](#).

Opening, Saving, and Clearing Workspaces

To control workspaces, you can do the following:

- Open and load a named workspace by using the **-W command-line option**.
- Open and load a workspace from a file by using the **-WF command-line option**.
- Disable all automatic workspace loading by using the **-WX command-line option**. Only explicit workspace commands cause workspaces to be saved or loaded.
- Open and load a named workspace by clicking [Open Workspace](#) on the **File** menu or pressing CTRL+W.
- Save the current default workspace or the current named workspace by clicking [Save Workspace](#) on the **File** menu.
- Assign a name to the current workspace and save it by clicking [Save Workspace As](#) on the **File** menu.
- Delete specific items and settings from the current workspace by clicking [Clear Workspace](#) on the **File** menu.
- Delete workspaces by clicking [Delete Workspaces](#) on the **File** menu.
- Open and load a workspace from a file by clicking [Open Workspace in File](#) on the **File** menu.
- Save a workspace to a file by clicking [Save Workspace to File](#) on the **File** menu.

[Send comments about this topic to Microsoft](#)

Workspace Contents

5/26/2017 • 3 min to read • [Edit Online](#)

Each workspace preserves the following information about the current debugging session. This information is applied cumulatively, starting with the base workspace and ending with the most recently-loaded workspace.

- All break and handling information for exceptions and events. For more information about the break and handling information, see [Breakpoints in Workspaces](#).
- All open source files. If a source file is not found, an error message appears. You can close these error messages individually or by using the [Window | Close All Error Windows](#) command.
- All user-defined aliases.

Each workspace preserves the following information about the debugger configuration settings. This information is applied cumulatively, starting with the base workspace and ending with the most recently-loaded workspace.

- The symbol path.
- The executable image path.
- The source path. (In remote debugging, the main source path and the local source path are saved.)
- The current source options that were set with [I+, I- \(Set Source Options\)](#).
- Log file settings.
- The COM or 1394 kernel connection settings, if the connection was started by using the graphical interface.
- The most recent paths in each [Open](#) dialog box (except for the workspace file and text file paths, which are not saved).
- The current [.enable_unicode](#), [.force_radix_output](#), and [.enable_long_status](#) settings.

All default workspaces and named workspaces preserve the following information about the WinDbg graphical interface. This information is loaded cumulatively, starting with the base workspace and ending with the most recently-loaded workspace.

- The title of the WinDbg window
- The [Automatically Open Disassembly](#) setting
- The default font

All default workspaces and named workspaces preserve the following information about the WinDbg graphical interface. This information is not applied cumulatively. It depends only on the most recently-loaded workspace.

- The size and position of the WinDbg window on the desktop.
- Which debugging information windows are open.
- The size and position of each open window, including the window's size, its floating or docked status, whether it is tabbed with other windows, and all of the related settings in its shortcut menu.
- The location of the pane boundary in the [Debugger Command window](#) and the word wrap setting in that window.
- Whether the toolbar and status bar, and the individual toolbars on each debugging information window, are

visible.

- The customization of the [Registers window](#).
- The flags in the [Calls window](#), Locals window, and Watch window.
- The items that were viewed in the Watch window.
- The cursor location in each [Source window](#).

Named Workspaces

Named workspaces contain additional information that is not stored in default workspaces.

This additional information includes information about the current session state. When a named workspace is saved, the current session is saved. If this workspace is later opened, this session is automatically restarted.

You can start only kernel debugging, dump file debugging, and debugging of spawned user-mode processes in this manner. Remote sessions and user-mode processes that the debugger attached to do not have this session information saved in their workspaces.

You cannot open this kind of named workspace if another session is already active.

Debugging Clients and Workspaces

When you use WinDbg as a debugging client, its workspace saves only values that you set through the graphical interface. Changes that you make through the Debugger Command window are not saved. (This restriction guarantees that only changes that the local client made are reflected, because the Debugger Command window accepts input from all clients and the debugging server.) For more information, see [Controlling a Remote Debugging Session](#).

Breakpoints in Workspaces

In addition, breakpoint information is saved in workspaces, including the break address and status. Breakpoints that are active when a session ends are active when the next session is started. However, some of these breakpoints might be unresolved if the proper modules have not yet been loaded.

Breakpoints that you specify by a symbol expression, by a line number, by a numeric address, or by using the mouse in a Source window are all saved in workspaces. Breakpoints that you specify by using the mouse in a Disassembly or Calls window are not saved in workspaces.

If you are debugging multiple user-mode processes, only breakpoints that are associated with process zero are saved.

Using and Customizing WinDbg Themes

5/26/2017 • 1 min to read • [Edit Online](#)

A theme is a preconfigured WinDbg workspace that contains a useful configuration of debugging information windows.

Any theme can be saved as your base workspace. Themes in the Debugging Tools for Windows package are provided as a set of registry files (with the .reg extension). As you accumulate more debugging sessions, various default workspaces are automatically set up. These default workspaces use the base workspace as a starting point. For more information on default workspaces, see [Creating and Opening a Workspace](#).

For the best user experience, we recommend that you follow the instructions in this topic before starting your debugging session.

This section includes the following topics:

[Loading a Theme](#)

[Customizing a Theme](#)

[Using Themes Provided in Debugging Tools for Windows](#)

[Send comments about this topic to Microsoft](#)

Loading a Theme

5/26/2017 • 1 min to read • [Edit Online](#)

Before loading a theme, we recommend that you clear all of your workspace data. This can be done in three ways:

By using the WinDbg user-interface. Under the **File** menu, select **Clear Workspace...** Select **Clear All** in the pop-up window and then click **OK**.

By deleting the registry key under **HKCU\Software\Microsoft\Windbg\Workspaces**.

By running the command **reg delete HKCU\Software\Microsoft\Windbg**.

After all of your workspace data has been cleared, run one of the themes. These are stored as .reg files in the Themes directory of your Debugging Tools for Windows installation. Running a theme imports its settings into the registry, redefining your base workspace.

After you have loaded a theme, you may alter it to more closely suit your preferences. For more details on some common options, see [Customizing a Theme](#).

[Send comments about this topic to Microsoft](#)

Customizing a Theme

5/26/2017 • 1 min to read • [Edit Online](#)

Before customizing a theme, it must first be loaded. See [Loading a Theme](#) for details.

After the theme is loaded, start WinDbg with no command-line parameters. This opens the base workspace. There are two common areas of focus for customizing a theme: setting paths and adjusting window position.

After you have completed any wanted adjustments, exit WinDbg and save your workspace by selecting **Save Workspace** from the **File** menu. If you want to save your new settings to a .reg file, open Regedit and export the registry key under **HKCU\Software\Microsoft\Windbg\Workspaces** to a .reg file.

Setting Paths

By setting the appropriate paths, you can ensure that WinDbg can locate all of the files that it needs to debug effectively. There are three main paths to set: the symbol path, the source path, and the executable image path.

Here are examples of how to set the symbol and source path. The executable image path is typically the same as your symbol path.

To set your symbol path:

```
SRV*c:\MySymCache*\CompanySymbolServer\Symbols;SRV*c:\WinSymCache*https://msdl.microsoft.com/download/symbols
```

To set your source path:

```
SRV*d:\MySourceRoot
```

Adjusting Window Position

Before using your theme, you should adjust the window positioning so that WinDbg handles your source files correctly. This ensures that Source windows knows where to dock.

Begin by opening a Source window in WinDbg. Tab-dock this window with the placeholder set aside for your Source windows. In order for the proper relationship to be made, the placeholder window must be the uppermost window in the dock before you perform this tab-docking operation. Now close the source window but not the placeholder window.

Because debugging information windows "remember" their last docking operation, each source window's last docking operation is associated with one of the placeholder windows after you have performed this procedure. Because of this memory attribute, you should not close any of your placeholder windows. Further, if you choose to change the theme's configuration, any window you reposition in a dock should always be tab-docked with a placeholder file.

The sample themes included with the Debugging Tools for Windows were created using the following actions:

Place and position the placeholder*.c files into the dock.

Tab-dock every window type above the wanted placeholder window.

For further information about adjusting window position in WinDbg, see [Positioning the Windows](#).

[Send comments about this topic to Microsoft](#)

Using Themes Provided in Debugging Tools for Windows

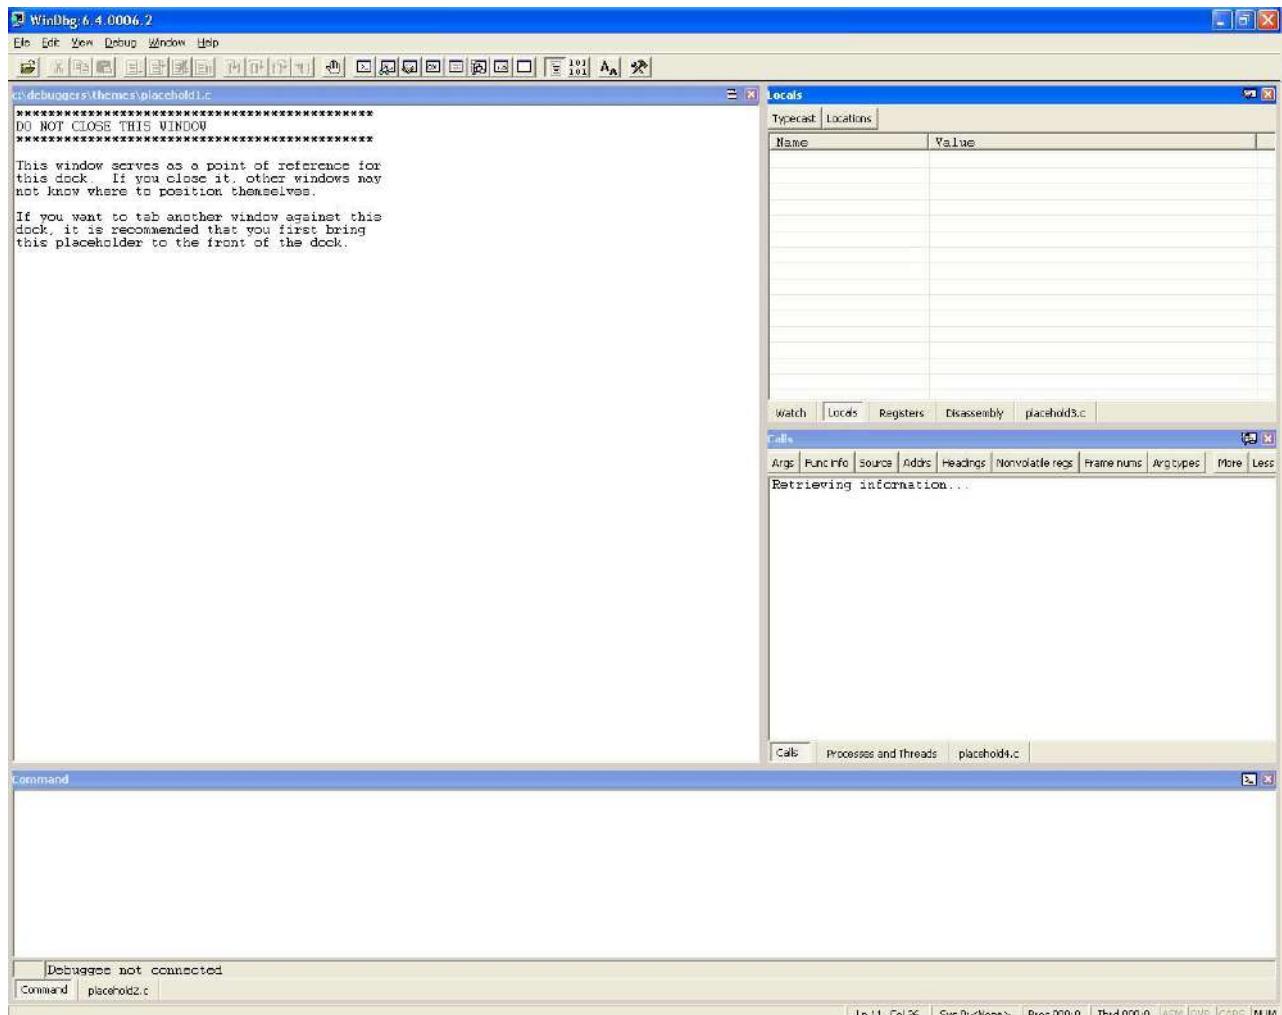

5/26/2017 • 3 min to read • [Edit Online](#)

This topic shows screen shots of the configurations from each of the four themes provided in Debugging Tools for Windows. Those themes are Standard.reg, Standardvs.reg, Srcdisassembly.reg, and Multimon.reg.

Standard.reg

The Standard.reg theme can be used for most debugging purposes. In this arrangement, the lower third of the WinDbg window is taken by the Debugger Command window. The upper two-thirds is divided roughly in half. The left half is taken up by a placeholder window that indicates where the Source windows open in a tabbed collection. The right half is further divided into halves vertically. The upper half contains a tabbed collection that includes the Watch, Locals, Registers, and Disassembly windows. The lower half contains a tabbed collection that includes the Calls and Processes and Threads windows.

In each docking location, a placeholder window is also included as a point of reference for the other windows. The placeholder windows should not be closed because closing them may change the configuration of the windows. All of the windows in this arrangement are docked. The following screen shot shows the Standard.reg theme.

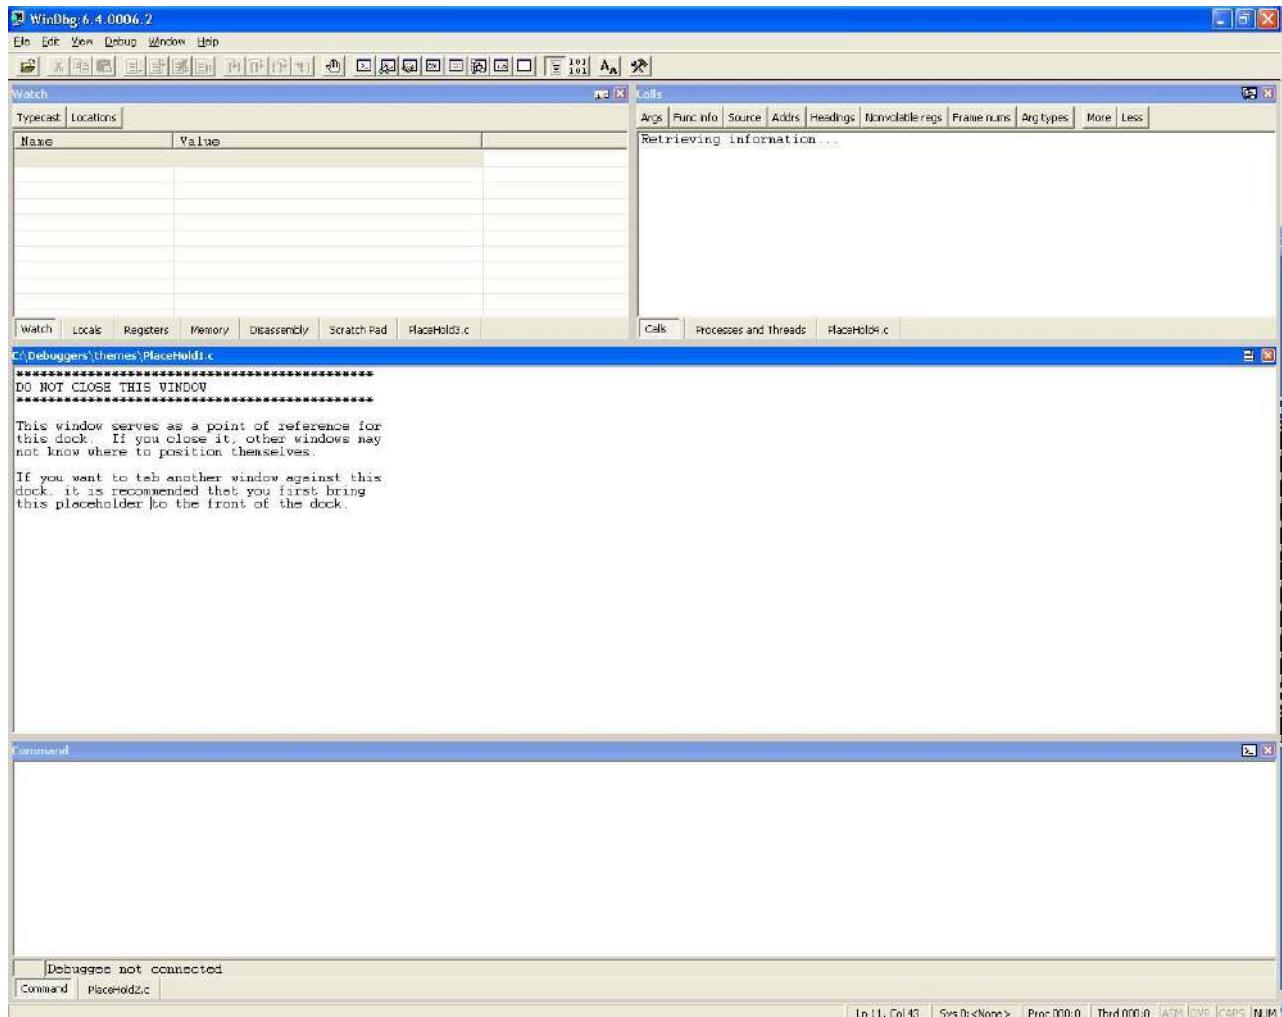

Standardvs.reg

The Standardvs.reg theme can be used for most debugging purposes, but is more similar in layout to Visual Studio. In this arrangement, the WinDbg window is divided horizontally into thirds. The upper third is further divided

vertically into halves. The left half of the upper third contains a tabbed collection that includes the Watch, Locals, Registers, Memory, Disassembly, and Scratchpad windows. The right half of the upper third contains a tabbed collection that includes the Calls and Processes and Threads windows. The lower third of the WinDbg window is taken by the Debugger Command window. The middle third is filled by a placeholder window that indicates where the Source windows are opened in a tabbed collection.

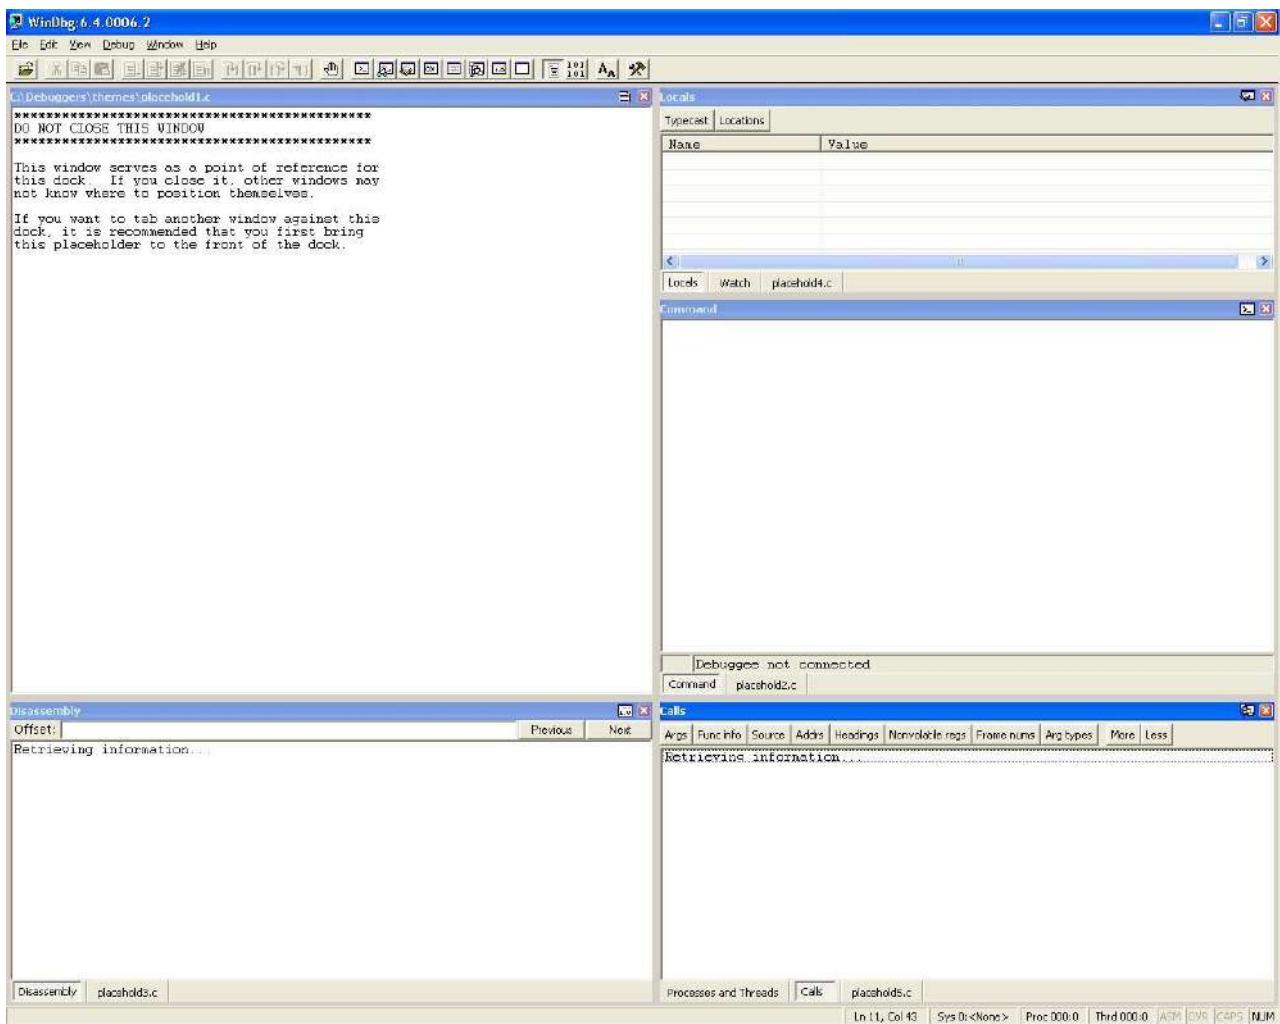

In each docking location, a placeholder window is also included as a point of reference for the other windows. The placeholder windows should not be closed because closing them may change the configuration of the windows. All of the windows in this arrangement are docked. The following screen shot shows the Standardvs.reg theme.

Srcdisassembly.reg

The Srcdisassembly.reg theme includes a Disassembly window, for debugging in assembly mode. In this arrangement, the WinDbg window is divided in half vertically, and each half formed is further divided into thirds horizontally. On the right half, the upper third is a tabbed collection of the Locals and Watch windows, the middle third is the Debugger Command window, and the lower third is a tabbed collection of the Processes and Threads and Calls windows. On the left half, the upper two-thirds are taken by a placeholder window that indicates where the Source windows opens in a tabbed collection; the lower third is taken up by the Disassembly window.

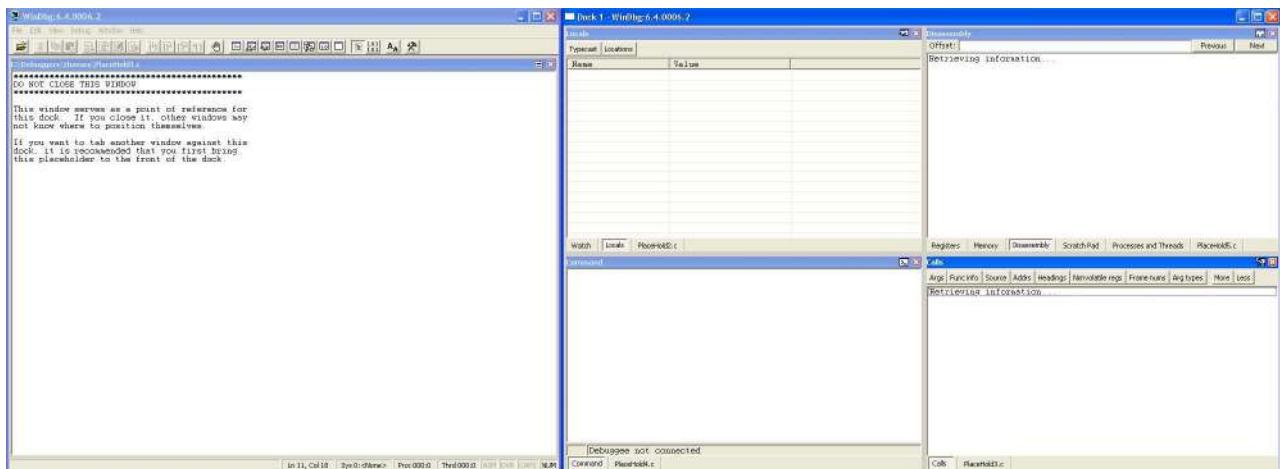

In each docking location, a placeholder window is also included as a point of reference for the other windows. The placeholder windows should not be closed because closing them may change the configuration of the windows. All of the windows in this arrangement are docked. The following screen shot shows the Srcdisassembly.reg theme.

Multimon.reg

The Multimon.reg theme is set up for debugging with multiple monitors. In this arrangement, a new dock is created so that the WinDbg window can be viewed on one monitor and the new dock can be viewed on the other monitor. The WinDbg window is filled by a placeholder window that indicates where the Source windows open in a tabbed collection. The new dock is divided into fourths. The upper left contains a tabbed collection that includes the Watch and Locals windows. The upper right contains a tabbed collection that includes the Registers, Memory, Disassembly, Scratchpad, and Processes and Threads windows. The lower left contains the Debugger Command window. The lower right contains the Calls window.

In each docking location, a placeholder window is also included as a point of reference for the other windows. The placeholder windows should not be closed because closing them may change the configuration of the windows. All of the windows in this arrangement are docked. The following screen shot shows the Multimon.reg theme.

Using the Toolbar and Status Bar

5/26/2017 • 1 min to read • [Edit Online](#)

The *toolbar* appears underneath the menu bar, near the top of the WinDbg window. The *status bar* appears at the bottom of the WinDbg window.

Using the Toolbar

The following screen shot shows the WinDbg toolbar.

The toolbar buttons have various effects. Most of them are equivalent to menu commands. To execute the command that is associated with a toolbar button, click the toolbar button. When you cannot use a button, it appears unavailable.

For more information about each button, see [Toolbar Buttons](#).

Using the Status Bar

The following screen shot shows the WinDbg status bar.

The following table describes the sections of the WinDbg status bar.

SECTION	DESCRIPTION
Message	Displays messages from the debugger.
Ln, Col	Displays the line number and column number at the cursor in the active Source window .
Sys	Shows the internal decimal number of the system that you are debugging, followed by its computer name (or <Local> if it is the same as the computer as the debugger is running on).
Proc	Shows the internal decimal number of the process that you are debugging, followed by its hexadecimal process ID.
Thrd	Shows the internal decimal number of the thread that you are debugging, followed by its hexadecimal thread ID.
ASM	Indicates that WinDbg is in assembly mode. If ASM is unavailable, WinDbg is in source mode.
OVR	Indicates that overtype mode is active. If OVR is unavailable, insert mode is active.

SECTION	DESCRIPTION
CAPS	Indicates that CAPS LOCK is on.
NUM	Indicates that NUM LOCK is on.

Hiding the Toolbar or Status Bar

To display or hide the toolbar, select or clear **Toolbar** on the **View** menu. To display or hide the status bar, select or clear **Status Bar** on the **View** menu.

If you hide the toolbar or the status bar, you have more space for debugging information windows in the WinDbg display area.

Setting the Window Title

You can change the title of the WinDbg window by using the **.wtitle (Set Window Title)** command.

[Send comments about this topic to Microsoft](#)

Using the Help Documentation

5/26/2017 • 3 min to read • [Edit Online](#)

The WinDbg Help documentation that you are reading is the documentation for the Debugging Tools for Windows package.

This documentation uses the viewer that is supplied with Microsoft HTML Help (hh.exe). This viewer provides a table of contents and index and enables you to search through the documentation, mark your favorite or frequently used topics, and print one or more topics.

The following sections in this topic describe the features of and how to use the Help documentation.

Contents Tab

The **Contents** tab provides an expandable view of the documentation's table of contents.

Click the plus sign (+) next to a node or double-click the node's title to expand or contract the table of contents under that node.

Index Tab

The **Index** tab displays the complete index of terms that are used in this documentation. You can enter the beginning of a term or use the scrollbar to look through this index.

Search Tab

In the **Search** tab, you can search for any word or phrase that is contained in the documentation. You can search all text or limit your search to topic titles.

To search for phrases that contain more than one word, enclose the phrase in quotation marks. You can connect multiple words and phrases with the AND, OR, and NOT operators. The default operator is AND.

Note that "AND NOT" is invalid. To search for topics that contain *x* and not *y*, use "*x* NOT *y*". You can also use NEAR in searches.

Wildcard characters are also permitted. Use a question mark (?) to represent any single character and an asterisk (*) to represent zero or more characters. However, you cannot use wildcard characters within quoted strings.

All letters and numbers are treated literally, but some symbols are not permitted in searches.

A search returns a list of all topics that match the specified criteria. If you select the **Search previous results** box, you can then search these results for more terms.

Favorites Tab

In the **Favorites** tab, you can save the titles of commonly-visited topics. While you are viewing a topic, click the **Favorites** tab and then click the **Add** button.

To rename a page on your favorites list, click its name two times slowly, and retype the name. To view a topic on the Favorites list, double-click its name or click it one time and then click **Display**. To remove a topic from the favorites list, click it one time and then click **Remove**.

Printing Topics

To print one or more topics, click a topic in the **Contents** tab, and then click the **Print** button on the toolbar. You will be asked whether you want to print only the selected topic or that topic and all of its subtopics.

You can also print the topic that you are viewing by right-clicking within the view window, and clicking **Print** on the shortcut menu. However, this method does not enable you to print subtopics.

Searching Within a Topic

To search for a text string within the topic that you are viewing, press CTRL+F, or click **Find in this Topic** on the **Edit** menu.

Accessing the Help Documentation

To open this Help documentation, do one of the following:

- Click **Start**, point to **All Programs**, point to **Debugging Tools for Windows**, and then click **Debugging Help**.
- Open Windows Explorer, locate the Debugger.chm file, and then double-click it.
- At a command prompt, browse to the folder that contains Debugger.chm and run **hh debugger.chm**.
- In any Windows debugger, use the **.hh (Open HTML Help File)** command.
- In WinDbg, click **Contents** on the **Help** menu. This command open the Help documentation and opens the **Contents** tab.
- In WinDbg, click **Index** on the **Help** menu. This command open the Help documentation and opens the **Index** tab.
- In WinDbg, click **Search** on the **Help** menu. This command opens the Help documentation and opens the **Search** tab.
- Many dialog boxes in WinDbg have **Help** buttons. Click **Help** to open this documentation and open the relevant page.

Using Debugger Extensions

5/31/2017 • 1 min to read • [Edit Online](#)

Visual Studio, WinDbg, KD, and CDB all allow the use of debugger extension commands. These extensions give these three Microsoft debuggers a great degree of power and flexibility.

Debugger extension commands are used much like the standard debugger commands. However, while the built-in debugger commands are part of the debugger binaries themselves, debugger extension commands are exposed by DLLs distinct from the debugger.

This allows you to write new debugger commands which are tailored to your specific need. In addition, a number of debugger extension DLLs are shipped with the debugging tools themselves.

This section includes:

[Loading Debugger Extension DLLs](#)

[Using Debugger Extension Commands](#)

[Writing New Debugger Extensions](#)

[Send comments about this topic to Microsoft](#)

Loading Debugger Extension DLLs

5/26/2017 • 1 min to read • [Edit Online](#)

There are several methods of loading debugger extension DLLs, as well as controlling the default debugger extension DLL and the default debugger extension path:

- (Before starting the debugger) Use the `_NT_DEBUGGER_EXTENSION_PATH` environment variable to set the default path for extension DLLs. This can be a number of directory paths, separated by semicolons.
- Use the [.load \(Load Extension DLL\)](#) command to load a new DLL.
- Use the [.unload \(Unload Extension DLL\)](#) command to unload a DLL.
- Use the [.unloadall \(Unload All Extension DLLs\)](#) command to unload all debugger extensions.
- (Before starting the debugger; CDB only) Use the `tools.ini` file to set the default extension DLL.
- (Before starting the debugger) Use the `-a` command-line option to set the default extension DLL.
- Use the [.expath \(Set Extension Path\)](#) command to set the extension DLL search path.
- Use the [.setdll \(Set Default Extension DLL\)](#) command to set the default extension DLL.
- Use the [.chain \(List Debugger Extensions\)](#) command to display all loaded debugger extension modules, in their default search order.

You can also load an extension DLL simply by using the full `!module.extension` syntax the first time you issue a command from that module. See [Using Debugger Extension Commands](#) for details.

The extension DLLs that you are using must match the operating system of the target computer. The extension DLLs that ship with the Debugging Tools for Windows package are each placed in a different subdirectory of the installation directory:

- The `winxp` directory contains extensions that can be used with Windows XP and later versions of Windows.
- The `winext` directory contains extensions that can be used with any version of Windows. The `dbghelp.dll` module, located in the base directory of Debugging Tools for Windows, also contains extensions of this type.

If you write your own debugger extensions, you can place them in any directory. However, it is advised that you place them in a new directory and add that directory to the debugger extension path.

There can be as many as 32 extension DLLs loaded.

[Send comments about this topic to Microsoft](#)

Using Debugger Extension Commands

5/26/2017 • 2 min to read • [Edit Online](#)

The use of debugger extension commands is very similar to the use of [debugger commands](#). The command is typed in the Debugger Command window, producing either output in this window or a change in the target application or target computer.

An actual debugger extension command is an entry point in a DLL called by the debugger.

Debugger extensions are invoked by the following syntax:

![module.]extension [arguments]

The module name should not be followed with the .dll file name extension. If *module* includes a full path, the default string size limit is 255 characters.

If the module has not already been loaded, it will be loaded into the debugger using a call to **LoadLibrary**(*module*). After the debugger has loaded the extension library, it calls the **GetProcAddress** function to locate the extension name in the extension module. The extension name is case-sensitive and must be entered exactly as it appears in the extension module's .def file. If the extension address is found, the extension is called.

Search Order

If the module name is not specified, the debugger will search the loaded extension modules for this export.

The default search order is as follows:

1. The extension modules that work with all operating systems and in both modes: Dbghelp.dll and winext\ext.dll.
2. The extension module that works in all modes but is operating-system-specific. For Windows XP and later versions of Windows, this is winxp\exts.dll. There is no corresponding module for Windows 2000.
3. The extension module that works with all operating systems but is mode-specific. For kernel mode, this is winext\kext.dll. For user mode, this is winext\uext.dll.
4. The extension module that is both operating-system-specific and mode-specific. The following table specifies this module.

WINDOWS BUILD	USER MODE	KERNEL MODE
Windows 2000 (free build)	w2kfre \ ntsdexts.dll	w2kfre \ kdextx86.dll
Windows 2000 (checked build)	w2kchk \ ntsdexts.dll	w2kchk \ kdextx86.dll
Windows XP and later	winxp \ ntsdexts.dll	winxp \ kdexts.dll

When an extension module is unloaded, it is removed from the search chain. When an extension module is loaded, it is added to the beginning of the search order. The [.setdll \(Set Default Extension DLL\)](#) command can be used to promote any module to the top of the search chain. By using this command repeatedly, you can completely control the search chain.

Use the [.chain \(List Debugger Extensions\)](#) command to display a list of all loaded extension modules in their

current search order.

If you attempt to execute an extension command that is not in any of the loaded extension modules, you will get an Export Not Found error message.

[Send comments about this topic to Microsoft](#)

Writing New Debugger Extensions

5/26/2017 • 1 min to read • [Edit Online](#)

You can create your own debugging commands by writing an extension DLL. For example, you might want to write a command to display a complex data structure, or a command that will stop and start the target depending on the value of certain variables or memory locations.

There are two different types of debugger extensions:

- *DbgEng extensions*. These are based on the prototypes in the dbgeng.h header file, and also those in the wdbgexts.h header file.
- *WdbgExts extensions*. These are based on the prototypes in the wdbgexts.h header file alone.

For information about how to write debugger extensions, see [Writing DbgEng Extensions](#) and [Writing WdbgExts Extensions](#).

[Send comments about this topic to Microsoft](#)

title: Remote Debugging description: This topic provides an overview of remote user-mode debugging. This involves two computers: the client and the server. ms.assetid: fa87b55c-c339-4b8c-8614-c7355d203a6e keywords: remote debugging ms.author: windowsdriverdev ms.date: 05/23/2017 ms.topic: article ms.prod: windows-hardware

ms.technology: windows-devices

Remote Debugging

Remote user-mode debugging involves two computers: the *client* and the *server*. The server is the computer that runs the application to be debugged. The server also runs the user-mode debugger or a process server. The client is the computer that remotely controls the debugging session.

Remote kernel-mode debugging involves three computers: the *client*, the *server*, and the *target computer*. The target computer is the computer to be debugged. The server is a computer that runs the kernel debugger or a KD connection server. The client is the computer that remotely controls the debugging session.

[Choosing the Best Remote Debugging Method](#)

[Send comments about this topic to Microsoft](#)

Choosing the Best Remote Debugging Method

5/26/2017 • 3 min to read • [Edit Online](#)

There are two primary methods of performing remote debugging, as well as several additional methods and a huge number of combination methods.

Here are some tips to help you choose the best technique.

- [Remote debugging through the debugger](#) is usually the best method. If you simply have one server and one client and they can freely connect to each other, the same debugger binaries are installed on both the client and the server, and the debugging technician who will be operating the client will be able to talk to someone in the room with the server, this is the recommended method.

The client and the server can be running any version of Windows. They do not have to be running the same version as each other.

If the client is unable to send a connection request to the server, but the server is able to send a request to the client, you can use remote debugging through the debugger with a *reverse connection* by using the **cicon** parameter.

- [Remote debugging through remote.exe](#) is used to remotely control a Command Prompt window. It can be used to remotely control KD, CDB, or NTSD. It cannot be used with WinDbg.

If your client does not have copies of the debugger binaries, you must use the remote.exe method.

- **A process server** or a **KD connection server** can be used if the debugging technician will not be able to talk to someone in the room with the server. All the actual debugging work is done by the client (called the *smart client*); this removes the need to have a second person present at the server itself.

Process servers are used for user-mode debugging; KD connection servers are used for kernel-mode debugging. Other than this distinction, they behave in similar ways.

This method is also useful if the computer where the server will be running cannot handle heavy process loads, or if the technician running the client has access to symbol files or source files that are confidential and cannot be accessed by the server. However, this method is not as fast or efficient as remote debugging through the debugger. This method cannot be used for dump-file debugging.

See [Process Servers \(User Mode\)](#) and [KD Connection Servers \(Kernel Mode\)](#) for details.

- **A repeater** is a lightweight proxy server that relays data between two computers. You can add a repeater between the client and the server if you are performing remote debugging through the debugger or if you are using a process server.

Using a repeater may be necessary if your client and your server are unable to talk directly to each other, but can each access an outside computer. You can use reverse-connections with repeaters as well. It is even possible to use two repeaters in a row, but this is rarely necessary.

See [Repeaters](#) for details.

- It is also possible to control CDB (or NTSD) from the kernel debugger. This is yet another form of remote debugging. See [Controlling the User-Mode Debugger from the Kernel Debugger](#) for details.

Variations on all of these methods are possible.

It is possible to chain several computers together to take advantage of more than one transport method. You can

create complicated transport sequences that take into account where the technician is, where the symbols are located, and whether there are firewalls preventing connections in certain directions. See [Advanced Remote Debugging Scenarios](#) for some examples.

You can even perform remote debugging on a single computer. For example, it might be useful to start a low-privilege process server and then connect to it with a high-privilege smart client. And on a Windows 2000 terminal server computer you can debug one session from another.

[Send comments about this topic to Microsoft](#)

Remote Debugging Through the Debugger

5/26/2017 • 1 min to read • [Edit Online](#)

Remote debugging directly through the debugger is usually the best and easiest method of performing remote debugging.

This technique involves running two debuggers at different locations. The debugger that is actually doing the debugging is called the *debugging server*. The debugger that is controlling the session from a distance is called the *debugging client*.

The two computers do not have to be running the same version of Windows; they can be running any version of Windows. The actual debuggers used need not be the same; a WinDbg debugging client can connect to a CDB debugging server, and so on.

However, it is best that the debugger binaries on the two computers both be from the same release of the Debugging Tools for Windows package, or at least both from recent releases.

To set up this remote session, the debugging server is set up first, and then the debugging client is activated. Any number of debugging clients can connect to a debugging server. A single debugger can turn itself into several debugging servers at the same time, to facilitate different kinds of connections.

However, no single debugger can be a debugging client and a debugging server simultaneously.

This section includes:

[Activating a Debugging Server](#)

[Searching for Debugging Servers](#)

[Activating a Debugging Client](#)

[Client and Server Examples](#)

[Controlling a Remote Debugging Session](#)

[Send comments about this topic to Microsoft](#)

Activating a Debugging Server

5/31/2017 • 6 min to read • [Edit Online](#)

There are two ways to activate the debugging server. It can be activated when the debugger is started by using the **-server** command-line option in a elevated Command Prompt window (Run as Administrator). It can also be activated after the debugger is running. Start the debugger with elevated privileges (Run as Administrator), and enter the **.server** command.

Note You can activate a debugging server without having elevated privileges, and debugging clients will be able to connect to the server. However, clients will not be able to discover a debugging server unless it was activated with elevated privileges. For information about how to discover debugging servers, see [Searching for Debugging Servers](#).

The debuggers support several transport protocols: named pipe (NPIPE), TCP, COM port, secure pipe (SPIPE), and secure sockets layer (SSL).

The general syntax for activating a debugging server depends on the protocol used.

```
Debugger -server npipe:pipe=PipeName[,hidden][,password=Password][,IcfEnable] [-noio] [Options]

Debugger -server tcp:port=Socket[,hidden][,password=Password][,ipversion=6][,IcfEnable] [-noio] [Options]

Debugger -server tcp:port=Socket,clicon=Client[,password=Password][,ipversion=6] [-noio] [Options]

Debugger -server com:port=COMPort,baud=BaudRate,channel=COMChannel[,hidden][,password=Password] [-noio] [Options]

Debugger -server spipe:proto=Protocol,{certuser=Cert|machuser=Cert},pipe=PipeName[,hidden]
[,password=Password] [-noio] [Options]

Debugger -server ssl:proto=Protocol,{certuser=Cert|machuser=Cert},port=Socket[,hidden][,password=Password] [-noio] [Options]

Debugger -server ssl:proto=Protocol,
{certuser=Cert|machuser=Cert},port=Socket,clicon=Client[,password=Password] [-noio] [Options]
```

Another method of activating a debugging server is to use the [.server \(Create Debugging Server\)](#) command after the debugger has already been started.

```
.server npipe:pipe=PipeName[,hidden][,password=Password][,IcfEnable]

.server tcp:port=Socket[,hidden][,password=Password][,ipversion=6][,IcfEnable]

.server tcp:port=Socket,clicon=Client[,password=Password][,ipversion=6]

.server com:port=COMPort,baud=BaudRate,channel=COMChannel[,hidden][,password=Password]

.server spipe:proto=Protocol,{certuser=Cert|machuser=Cert},pipe=PipeName[,hidden][,password=Password]

.server ssl:proto=Protocol,{certuser=Cert|machuser=Cert},port=Socket[,hidden][,password=Password]

.server ssl:proto=Protocol,{certuser=Cert|machuser=Cert},port=Socket,clicon=Client[,password=Password]
```

The parameters in the previous commands have the following possible values:

Debugger

Can be KD, CDB, NTSD, or WinDbg.

pipe= PipeName

When NPIPE or SPIPE protocol is used, *PipeName* is a string that will serve as the name of the pipe. Each pipe name should identify a unique debugging server. If you attempt to reuse a pipe name, you will receive an error message. *PipeName* must not contain spaces or quotation marks. *PipeName* can include a numerical **printf**-style format code, such as **%x** or **%d**. The debugger will replace this with the process ID of the debugger. A second such code will be replaced with the thread ID of the debugger.

Note You might need to enable file and printer sharing on the computer that is running the debugging server. In Control Panel, navigate to **Network and Internet > Network and Sharing Center > Advanced sharing settings**. Select **Turn on file and printer sharing**.

port= Socket

When TCP or SSL protocol is used, *Socket* is the socket port number.

It is also possible to specify a range of ports separated by a colon. The debugger will check each port in this range to see if it is free. If it finds a free port and no error occurs, the debugging server will be created. The debugging client will have to specify the actual port being used to connect to the server. To determine the actual port, use any of the methods described in [Searching for Debugging Servers](#); when this debugging server is displayed, the port will be followed by two numbers separated by a colon. The first number will be the actual port used; the second can be ignored. For example, if the port was specified as **port=51:60**, and port 53 was actually used, the search results will show "port=53:60". (If you are using the **clicon** parameter to establish a reverse connection, the debugging client can specify a range of ports in this manner, while the server must specify the actual port used.)

clicon= Client

When TCP or SSL protocol is used and the **clicon** parameter is specified, a *reverse connection* will be opened. This means that the debugging server will try to connect to the debugging client, instead of letting the client initiate the contact. This can be useful if you have a firewall that is preventing a connection in the usual direction. *Client* specifies the network name or IP address of the computer on which the debugging client exists or will be created. The two initial backslashes (\) are optional.

Since the server is looking for one specific client, you cannot connect multiple clients to the server if you use this method. If the connection is refused or is broken you will have to restart the server connection. A reverse-connection server will not appear when another debugger displays all active servers.

Note When **clicon** is used, it is best to start the debugging client before the debugging server is created, although the usual order (server before client) is also permitted.

port= COMPort

When COM protocol is used, *COMPort* specifies the COM port to be used. The prefix "COM" is optional -- for example, both "com2" and "2" are acceptable.

baud= BaudRate

When COM protocol is used, *BaudRate* specifies the baud rate at which the connection will run. Any baud rate that is supported by the hardware is permitted.

channel= COMChannel

If COM protocol is used, *COMChannel* specifies the COM channel to be used in communicating with the debugging client. This can be any value between 0 and 254, inclusive. You can use a single COM port for multiple connections using different channel numbers. (This is different from the use of a COM ports for a debug cable -- in that situation you cannot use channels within a COM port.)

proto= Protocol

If SSL or SPIPE protocol is used, *Protocol* specifies the Secure Channel (S-Channel) protocol. This can be any one of the strings **tls1**, **pct1**, **ssl2**, or **ssl3**.

Cert

If SSL or SPIPE protocol is used, *Cert* specifies the certificate. This can either be the certificate name or the certificate's thumbprint (the string of hexadecimal digits given by the certificate's snapin). If the syntax **certuser=Cert** is used, the debugger will look up the certificate in the system store (the default store). If the syntax **machuser=Cert** is used, the debugger will look up the certificate in the machine store. The specified certificate must support server authentication.

hidden

Prevents the server from appearing when another debugger displays all active servers.

password= *Password*

Requires a client to supply the specified password in order to connect to the debugging session. *Password* can be any alphanumeric string, up to twelve characters in length.

Warning Using a password with TCP, NPIPE, or COM protocol only offers a small amount of protection, because the password is not encrypted. When a password is used with SSL or SPIPE protocol, it is encrypted. If you want to establish a secure remote session, you must use SSL or SPIPE protocol.

ipversion=6

(Debugging Tools for Windows 6.6.07 and earlier only) Forces the debugger to use IP version 6 rather than version 4 when using TCP to connect to the Internet. In Windows Vista and later versions, the debugger attempts to auto-default to IP version 6, making this option unnecessary.

-noio

If the debugging server is created with the **-noio** option, no input or output can be done through the server itself. The debugger will only accept input from the debugging client (plus any initial command or command script specified by the **-c** command-line option). All output will be directed to the debugging client. The **-noio** option is only available with KD, CDB, and NTSD. If NTSD is used for the server, no console window will be created at all.

IcfEnable

(Windows XP and later versions only) Causes the debugger to enable the necessary port connections for TCP or named pipe communication when the Internet Connection Firewall is active. By default, the Internet Connection Firewall disables the ports used by these protocols. When **IcfEnable** is used with a TCP connection, the debugger causes Windows to open the port specified by the *Socket* parameter. When **IcfEnable** is used with a named pipe connection, the debugger causes Windows to open the ports used for named pipes (ports 139 and 445). The debugger does not close these ports after the connection terminates.

Options

Any additional command-line parameters can be placed here. See [Command-Line Options](#) for a full list.

You can use the **.server** command to start multiple servers using different protocol options. This allows different kinds of debugging clients to join the session.

[Send comments about this topic to Microsoft](#)

Searching for Debugging Servers

5/31/2017 • 1 min to read • [Edit Online](#)

You can use KD or CDB with the **-QR** command-line option to obtain a list of available debugging servers that are running on a network server.

This list may include servers that no longer exist but which were not shut down properly -- connecting to one of these generates an error message. The list will also include process servers and KD connection servers. The server type will be indicated in each case.

The syntax for this is as follows:

```
Debugger -QR \\Server
```

Debugger can be either KD or CDB -- the display will be the same in either case. The two backslashes (\\\) preceding *Server* are optional.

In WinDbg, you can use the **Connect to Remote Debugger Session** dialog box to browse a list of available servers. See [File | Connect to Remote Session](#) for details.

Note For a debugging server to be discoverable, it must be activated with elevated privileges. For more information, see [Activating a Debugging Server](#).

Note

If you are not logged on to the client computer with an account that has access to the server computer, you might need to provide a user name and password. On the client computer, in a Command Prompt window, enter the following command.

net use \\Server\ipc\$ /user:*UserName* where *Server* is the name of the server computer, and *UserName* is the name of an account that has access to the server computer.

When you are prompted, enter the password for *UserName*.

After this command succeeds, you can discover debugging servers (running on the server computer) by using **-QR** or **Connect to Remote Debugger Session**.

[Send comments about this topic to Microsoft](#)

Activating a Debugging Client

5/31/2017 • 3 min to read • [Edit Online](#)

Once the debugging server has been activated, you can start a debugging client on another computer and connect to the debugging session.

There are two ways to start a debugging client: by using the `-remote` [command-line option](#), or by using the WinDbg graphical interface.

The protocol of the client must match the protocol of the server. The general syntax for starting a debugging client depends on the protocol used. The following options exist:

```
Debugger -remote npipe:server=Server,pipe=PipeName[,password=Password]  
Debugger -remote tcp:server=Server,port=Socket[,password=Password][,ipversion=6]  
Debugger -remote tcp:clicon=Server,port=Socket[,password=Password][,ipversion=6]  
Debugger -remote com:port=COMPort,baud=BaudRate,channel=COMChannel[,password=Password]  
Debugger -remote spipe:proto=Protocol,  
{certuser=Cert|machuser=Cert},server=Server,pipe=PipeName[,password=Password]  
Debugger -remote ssl:proto=Protocol,  
{certuser=Cert|machuser=Cert},server=Server,port=Socket[,password=Password]  
Debugger -remote ssl:proto=Protocol,  
{certuser=Cert|machuser=Cert},clicon=Server,port=Socket[,password=Password]
```

To use the graphical interface to connect to a remote debugging session, WinDbg must be in dormant mode -- it must either have been started with no command-line parameters, or it must have ended the previous debugging session. Select the **File | Connect to Remote Session** menu command, or press the CTRL+R shortcut key. When the **Connect to Remote Debugger Session** dialog box appears, enter one of the following strings into the **Connection string** text box:

```
npipe:server=Server,pipe=PipeName[,password=Password]  
tcp:server=Server,port=Socket[,password=Password][,ipversion=6]  
tcp:clicon=Server,port=Socket[,password=Password][,ipversion=6]  
com:port=COMPort,baud=BaudRate,channel=COMChannel[,password=Password]  
spipe:proto=Protocol,{certuser=Cert|machuser=Cert},server=Server,pipe=PipeName[,password=Password]  
ssl:proto=Protocol,{certuser=Cert|machuser=Cert},server=Server,port=Socket[,password=Password]  
ssl:proto=Protocol,{certuser=Cert|machuser=Cert},clicon=Server,port=Socket[,password=Password]
```

Alternatively, you can use the **Browse** button to locate active debugging servers. See [File | Connect to Remote Session](#) for details.

The parameters in the preceding commands have the following possible values:

Debugger

This does not have to be the same debugger as the one used by the debugging client -- WinDbg, KD, and CDB are all interchangeable for purposes of remote debugging through the debugger.

Server

This is the network name or IP address of the computer on which the debugging server was created. The two initial backslashes (\) are optional on the command line, but are not permitted in the WinDbg dialog box.

pipe= PipeName

If NPIPE or SPIPE protocol is used, *PipeName* is the name that was given to the pipe when the server was created.

If you are not logged on to the client computer with an account that has access to the server computer, you must provide a user name and password. On the client computer, in a Command Prompt window, enter the following command.

```
net use \\Server\ipc$ /user:UserName
```

where *Server* is the name of the server computer, and *UserName* is the name of an account that has access to the server computer.

When you are prompted, enter the password for *UserName*.

After this command succeeds, you can activate a debugging client by using the **-remote** command-line option or by using the WinDbg graphical interface.

Note You might need to enable file and printer sharing on the server computer. In Control Panel, navigate to **Network and Internet > Network and Sharing Center > Advanced sharing settings**. Select **Turn on file and printer sharing**.

port= Socket

If TCP or SSL protocol is used, *Socket* is the same socket port number that was used when the server was created.

clicon

Specifies that the debugging server will try to connect to the client through a reverse connection. The client must use **clicon** if and only if the server is using **clicon**. In most cases, the debugging client is started before the debugging server when a reverse connection is used.

port= COMPort

If COM protocol is used, *COMPort* specifies the COM port to be used. The prefix "COM" is optional -- for example, both "com2" and "2" are acceptable.

baud= BaudRate

If COM protocol is used, *BaudRate* should match the baud rate chosen when the server was created.

channel= COMChannel

If COM protocol is used, *COMChannel* should match the channel number chosen when the server was created.

proto= Protocol

If SSL or SPIPE protocol is used, *Protocol* should match the secure protocol used when the server was created.

Cert

If SSL or SPIPE protocol is used, you should use the identical **certuser=Cert** or **machuser= Cert** parameter that was used when the server was created.

password= Password

If a password was used when the server was created, *Password* must be supplied in order to create the debugging client. It must match the original password. Passwords are case-sensitive. If the wrong password is supplied, the error message will specify "Error 0x80004005." Passwords must be twelve characters or less in length.

ipversion=6

(Debugging Tools for Windows 6.6.07 and earlier only) Forces the debugger to use IP version 6 rather than version 4 when using TCP to connect to the Internet. In Windows Vista and later versions, the debugger attempts to auto-default to IP version 6, making this option unnecessary.

Command-line options used to start new debugging sessions (like **-p**) cannot be used by the debugging client, but only by the server. Configuration options (like **-n**) will work from either the client or the server.

Client and Server Examples

5/26/2017 • 2 min to read • [Edit Online](#)

Suppose one person is running an application on a computer named \\BOX17. This application has problems, but the debugging technician is at a different site.

The first person sets up a debugging server using CDB on \\BOX17. The target application has a process ID of 122. TCP protocol is chosen, with a socket port number of 1025. The server is started by entering the following command in an elevated Command Prompt window (Run as Administrator):

```
E:\Debugging Tools for Windows> cdb -server tcp:port=1025 -p 122
```

On the other computer, the technician decides to use WinDbg as the debugging client. It can be started with this command:

```
G:\Debugging Tools> windbg -remote tcp:server=BOX17,port=1025
```

Here is another example. In this case, NPIPE protocol is chosen, and CDB is used instead of WinDbg. The first user chooses a pipe name. This can be any alphanumeric string -- in this example, "MainPipe". The first user opens an elevated Command Prompt window (Run as Administrator) and starts a debugging server by entering this command:

```
E:\Debugging Tools for Windows> cdb -server npipe:pipe=MainPipe -v winmine.exe
```

The technician is logged on to the client computer with an account that does not have access to the server computer. But the technician knows the username and password for an account that does have access to the server computer. The username for that account is Contoso. The technician enters the following command:

```
net use \\BOX17\ipc$ /user:Contoso
```

When prompted, the technician enters the password for the Contoso account.

The technician is not sure what name was used for the named pipe, so she queries BOX17 for available debugging servers.

```
G:\Debugging Tools> cdb -QR \\BOX17
Servers on \\BOX17:
Debugger Server - npipe:Pipe=MainPipe
Remote Process Server - npipe:Pipe=AnotherPipe
```

Two pipes are shown. However, only one is a debugging server -- the other is a process server, and we are not interested in that. So **MainPipe** must be the correct name. The technician uses the following command to start the debugging client:

```
G:\Debugging Tools> cdb -remote npipe:server=BOX17,pipe=MyPipe
```

Using a Secure Server

Here is an example of a secure server. This server uses secure sockets layer with an S-Channel protocol of TLS1. The debugger will look for the certificate in the machine store. The certificate is specified by its hexadecimal thumbprint.

```
D:\> cdb -server "ssl:proto=tls1,machuser=ab 38 f7 ae 13 20 ac da 05 14 65 60 30 83 7b 83 09 2c d2 34,port=1234" notepad.exe
```

[Send comments about this topic to Microsoft](#)

Controlling a Remote Debugging Session

5/26/2017 • 3 min to read • [Edit Online](#)

Once the remote session has been started, commands can be entered into either the debugging server or the debugging client. If there are multiple clients, any of them can enter commands. Once ENTER is pressed, the command is transmitted to the debugging server and executed.

Whenever one user enters a command, all users will see the command itself and its output. If this command was issued from a debugging client, all other users will see an identification, preceding the command, of which user issued the command. Commands issued from the debugging server do not have this prefix.

After a command is executed by one user, other users who are connected through KD or CDB will not see a new command prompt. On the other hand, users of WinDbg will see the prompt in the bottom panel of the Debugger Command window continuously, even when the debugger engine is running. Neither of these should be a cause for alarm; any user can enter a command at any time, and the engine will execute these commands in the order they were received.

Actions made through the WinDbg interface will also be executed by the debugging server.

Communication Between Users

Whenever a new debugging client connects to the session, all other users will see a message that this client has connected. No message is displayed when a client disconnects.

The [.clients \(List Debugging Clients\)](#) command will list all clients currently connected to the debugging session.

The [.echo \(Echo Comment\)](#) command is useful for sending messages from one user to another.

WinDbg Workspaces

When WinDbg is being used as a debugging client, its workspace will only save values set through the graphical interface. Changes made through the Debugger Command window will not be saved. (This guarantees that only changes made by the local client will be reflected, since the Debugger Command window will accept input from all clients as well as the debugging server.)

File Paths

The symbol path, executable image path, and extension DLL path are all interpreted as file paths relative to the Debugging Tools for Windows installation folder on the debugging server.

When WinDbg is used as a debugging client, it has its own *local source path* as well. All source-related commands will access the source files on the local computer. Therefore, the proper paths have to be set on any client or server that will use source commands.

This multiple-path system allows a debugging client to use source-related commands without actually sharing the source files with other clients or with the server. This is useful if there are private or confidential source files which one of the users has access to.

Cancelling the Debugging Server

The [.endsrv \(End Debugging Server\)](#) command can be used to terminate a debugging server. If the debugger has established multiple debugging servers, you can cancel some of them while leaving others running.

Terminating a server will prevent any future clients from attaching to it. It will not cut off any clients that are currently attached through the server.

Exiting the Debugger and Terminating the Session

To exit from one debugging client without terminating the server, you must issue a command from that specific client. If this client is KD or CDB, use the **CTRL+B** key to exit. If you are using a script to run KD or CDB, use **.remote_exit (Exit Debugging Client)**. If this client is WinDbg, choose **Exit** from the **File** menu to exit.

To terminate the entire session and exit the debugging server, use the **q (Quit)** command. This command can be entered from any server or client, and it will terminate the entire session for all users.

Controlling the User-Mode Debugger from the Kernel Debugger

5/26/2017 • 1 min to read • [Edit Online](#)

You can redirect the input and output from a user-mode debugger to a kernel debugger. This redirection enables the kernel debugger to control a specific user-mode debugging session that is occurring on the target computer.

You can use either KD or WinDbg as the kernel debugger. Note that many of the familiar features of WinDbg are not available in this scenario. For example, you cannot use the Locals window, the Disassembly window, or the Call Stack window, and you cannot step through source code. This is because WinDbg is only acting as a viewer for the debugger (NTSD or CDB) running on the target computer.

You can use either CDB or NTSD as the user-mode debugger. NTSD is the better choice, because it requires minimal resources from the processor and operating system of the computer whose application is being debugged. In fact, when NTSD is started under the control of the kernel debugger, no NTSD window is created. With NTSD, you can perform user-mode debugging through the serial port early in the boot phase and late into shutdown.

Note The [.shell](#) command is not supported when the output of a user-mode debugger is redirected to the kernel debugger.

This section includes the following:

- [Starting the Debugging Session](#) describes how to begin a session where the user-mode debugger is controlled from the kernel debugger.
- [Switching Modes](#) describes the four different modes that are involved, and how to alternate between them.
- [When to Use This Technique](#) describes scenarios where this technique is particularly useful.
- [Combining This Method with Remote Debugging](#) describes how to control the user-mode debugger from a kernel debugger, and use it as a debugging server at the same time. This combination can be useful if your user-mode symbols are located on a symbol server.

[Send comments about this topic to Microsoft](#)

Starting the Debugging Session

5/26/2017 • 1 min to read • [Edit Online](#)

In this documentation of how to [control user-mode debugging from the kernel debugger](#), *target application* refers to the user-mode application that is being debugged, *target computer* refers to the computer that contains the target application and the NTSD or CDB process, and *host computer* refers to the computer that contains the kernel debugger.

To begin using this technique, you must do the following. You can do steps 1 and 2 in either order.

1. Start NTSD or CDB on the target computer, with the -d command-line option.

For example, you can attach to a running process by using the following syntax.

ntsd -d [-y UserSymbolPath] -p PID

Or, you can start a new process as the target by using the following syntax.

ntsd -d [-y UserSymbolPath] ApplicationName

If you are installing this as a postmortem debugger, you would use the following syntax.

ntsd -d [-y UserSymbolPath]

For more information about this step, see [Debugging a User-Mode Process Using CDB](#).

2. Start WinDbg or KD on the host computer, as if you were going to debug the target computer, but do not actually break in to the target computer. To use WinDbg, use the following syntax.

windbg [-y KernelSymbolPath] [-k ConnectionOptions]

For more information about this step, see [Live Kernel-Mode Debugging Using WinDbg](#).

Note If you use WinDbg as the kernel debugger, many of the familiar features of WinDbg are not available in this scenario. For example, you cannot use the Locals window, the Disassembly window, or the Call Stack window, and you cannot step through source code. This is because WinDbg is only acting as a viewer for the debugger (NTSD or CDB) running on the target computer.

3. If you have not set the user-mode symbol path, set it from the Input> prompt. If you have not set the kernel-mode symbol path, set it from the kd> prompt. For information on how to access these prompts and to switch between modes, see [Switching Modes](#).

If you use CDB, the Command Prompt window that is associated with CDB remains locked and unavailable while debugging continues. If you use NTSD, no additional window is created, even though NTSD has a process ID associated with it on the target computer.

If you want to run the user-mode debugger from the kernel debugger while also using it as a debugging server, see [Combining This Method with Remote Debugging](#).

[Send comments about this topic to Microsoft](#)

Switching Modes

5/26/2017 • 3 min to read • [Edit Online](#)

When you [control user-mode debugging from the kernel debugger](#), you encounter four different modes, and can switch between them in a variety of ways.

Note In describing this scenario, *target application* refers to the user-mode application that is being debugged, *target computer* refers to the computer that contains the target application and the CDB or NTSD process, and *host computer* refers to the computer that contains the kernel debugger.

The following four modes will be encountered:

User-mode debugging

The target computer and target application are frozen. The user-mode debugging prompt appears in the [Debugger Command window](#) of the kernel debugger. In WinDbg, the prompt in the lower panel of the WinDbg window displays `Input>`. You can enter commands at this prompt, as if they are entered during user-mode debugging, to analyze the target application's state or cause it to run or step through its execution. Symbol files, extension DLLs, and other files that the debugger accesses will be those files on the target computer, not the host computer.

Target application execution

The target computer is running, the target application is running, and the debugger is waiting. This mode is the same as letting the target run in ordinary debugging.

Sleep mode

The target computer is running, but the target application is frozen, and both debuggers are frozen. This mode is useful if you have to do something on the target computer but you do not want to change the state of the debugging session.

Kernel-mode debugging

The target computer and the target application are frozen. The kernel-mode debugging prompt `kd>` appears in the [Debugger Command window](#) of the kernel debugger. This mode is the typical kernel-mode debugging state.

The session begins in user-mode debugging mode. The following actions and events cause the mode to change:

- To switch from user-mode debugging to target application execution, use the [g \(Go\)](#) command at the `Input>` prompt.
- To temporarily switch from user-mode debugging to target application execution and then return to user-mode debugging, use a step, trace, or other temporary execution command. For a list of such commands, see [Controlling the Target](#).
- To switch from user-mode debugging to sleep mode, use the [.sleep \(Pause Debugger\)](#) command. This command is timed. When the time expires, the system returns to user-mode debugging.
- To switch from user-mode debugging to kernel-mode debugging, use the [.breakin \(Break to the Kernel Debugger\)](#) command. Note that [.breakin](#) might fail with an access denied error if the calling process does not have administrator rights. In this case, switch to KD by issuing a short [.sleep](#) command and pressing **CTRL+C**.
- You can switch from target application execution to user-mode debugging only in certain environments. If the target computer is running Microsoft Windows XP or a later version of the Windows operating system, you can use the [!bpid](#) extension command. If you are using CDB (not NTSD), you can activate the CDB window on the target computer and press **CTRL+C**.

- If the target application hits a breakpoint, encounters an exception, encounters some other controlled event, or ends, the system switches from target application execution to user-mode debugging. You should plan such events in advance, especially when you are using NTSD. For more information about these events, see [Using Breakpoints](#) and [Controlling Exceptions and Events](#).
- To switch from target application execution to kernel-mode debugging, press CTRL+C in the KD window, press CTRL+BREAK or click **Break** on the **Debug** menu in the WinDbg window, or press SYSRQ or ALT+SYSRQ on the target computer keyboard. (If your kernel debugger is KD and if you press CTRL+C at the same time that the kernel debugger is communicating with the user-mode debugger, the user-mode debugger might capture you pressing CTRL+C.)
- If the debugger encounters a kernel error or if you use the Breakin.exe tool, the system switches from target application execution to kernel-mode debugging.
- To switch from sleep mode to user-mode debugging, wait for the sleep time to expire, start a new CDB process on the target computer by using the -wake **command-line option**, or use the **.wake (Wake Debugger)** command in a different copy of CDB or NTSD on the target computer.
- To switch out of kernel-mode debugging, use the **g (Go)** command at the `kd>` prompt. This command returns to user-mode debugging or target application execution (whichever of the two was the most recently-used state).

[Send comments about this topic to Microsoft](#)

When to Use This Technique

5/26/2017 • 1 min to read • [Edit Online](#)

There are several situations in which it is useful, or even necessary, to [control user-mode debugging from the kernel debugger](#):

- When you need to perform user-mode debugging, but also need control over the Windows kernel that the user-mode target is running on or need to use some kernel-mode debugging features to analyze the problem.
- When your user-mode target is a Windows process such as CSRSS or WinLogon. For a detailed description of how to debug these targets, see [Debugging CSRSS](#) and [Debugging WinLogon](#).
- When your user-mode target is a service application. For a detailed description of how to debug these targets, see [Debugging a Service Application](#).

[Send comments about this topic to Microsoft](#)

Combining This Method with Remote Debugging

5/31/2017 • 3 min to read • [Edit Online](#)

It is sometimes useful to [control the user-mode debugger from the kernel debugger](#) and use the user-mode debugger as a [debugging server](#) at the same time.

For example, this configuration is useful when your user-mode symbols are located on a symbol server. In the standard configuration for controlling the user-mode debugger from a kernel debugger, the interaction of the two debuggers can lead to tiny lapses in synchronization, and these lapses can prevent symbol server authentication. The more complex configuration described here can avoid this problem.

Note In describing this scenario, *target application* refers to the user-mode application that is being debugged, *target computer* refers to the computer that contains the target application and the CDB or NTSD process, and *host computer* refers to the computer that contains the kernel debugger.

To use this technique, you must do the following:

1. Start NTSD or CDB on the target computer, with the -ddefer and -server command-line options, specifying the desired transport options. The -server option must be the first parameter on the command line.

For example, you can attach to a running process by using the following syntax.

```
ntsd -server ServerTransport -ddefer [-y UserSymbolPath] -p PID
```

Or, you can start a new process as the target by using the following syntax.

```
ntsd -server ServerTransport -ddefer [-y UserSymbolPath] ApplicationName
```

If you are installing this as a postmortem debugger, you would use the following syntax. Note that you must manually edit the registry to install a postmortem debugger that includes the -server parameter; for details, see [Enabling Postmortem Debugging](#).

```
ntsd -server ServerTransport -ddefer [-y UserSymbolPath]
```

For information about the available transport options, see [Activating a Debugging Server](#).

2. Start WinDbg or KD on the host computer, as if you were going to debug the target computer, but do not actually break in to the target computer. To use WinDbg, use the following syntax.

```
windbg [-y KernelSymbolPath] [-k ConnectionOptions]
```

For more information about this step, see [Live Kernel-Mode Debugging Using WinDbg](#)

3. Start WinDbg or CDB as a debugging client, with the same transport options used to start the server. This debugging client can be run on either the host computer or on a third computer.

```
cdb -remote ClientTransport
```

For more information about this step, see [Activating a Debugging Client](#).

4. Once the debuggers are running and the `Input>` prompt appears in the kernel debugger, use the [.sleep \(Pause Debugger\)](#) command to pause the debuggers and let the target computer run for a few seconds. This gives the target computer time to process the remote transport protocol, establishing the connection between the user-mode remote server and the remote client.

If you use CDB as the user-mode debugger, the Command Prompt window that is associated with CDB remains locked and unavailable while debugging continues. If you use NTSD, no additional window is created, even though NTSD has a process ID associated with it on the target computer.

The four modes and the methods of switching between them described in the topic [Switching Modes](#) apply in this combination scenario, with the following differences:

- There are two different user-mode debugging modes. When the target computer is running, the debugging server is controlled by the debugging client as in any other remote debugging session; this is called *remote-controlled user-mode debugging*. When the kernel-mode debugger is broken in to the target computer and the `Input>` prompt is showing, the user-mode debugger is controlled by the kernel debugger; this is called *kernel-controlled user-mode debugging*.
- These two modes are never available at the same time. When the kernel debugger is broken in to the target computer, even though the user-mode debugger may be active, the target computer is unable to process the remote transport protocol, and therefore the user-mode debugger will not be able to receive remote input across this connection.
- If your user-mode symbols are located on a symbol server, any debugger commands that require symbol access should be issued while in remote-controlled user-mode debugging mode.
- To switch from kernel-controlled user-mode debugging to remote-controlled user-mode debugging, use the [.sleep \(Pause Debugger\)](#) command. When the user-mode debugger wakes from the sleep command, it will be in remote-controlled user-mode debugging mode.
- To switch from remote-controlled user-mode debugging to kernel-mode debugging, enter any command from the `Input>` prompt. If this prompt is not visible, switch to kernel-mode debugging, and then use the [g \(Go\)](#) command at the `kd>` prompt.

Internally, a user-mode debugger started with -ddefer gives first priority to input from the debugging client, and second priority to input from the kernel debugger. However, there can never be a conflict between simultaneous inputs, because when the kernel debugger has broken in to the target computer, the remote connection is unavailable.

Remote Debugging Through Remote.exe

5/26/2017 • 1 min to read • [Edit Online](#)

Remote debugging through remote.exe involves running the debugger on the remote computer and running the remote.exe tool on the local computer.

The remote computer and the local computer can be running any Windows operating system.

Note Since remote.exe only works for console applications, it cannot be used to remotely control WinDbg.

This section includes:

[The Remote.exe Utility](#)

[Starting a Remote.exe Session](#)

[Remote.exe Batch Files](#)

[Send comments about this topic to Microsoft](#)

The Remote.exe Utility

5/26/2017 • 1 min to read • [Edit Online](#)

The remote.exe utility is a versatile server/client tool that allows you to run command-line programs on remote computers.

Remote.exe provides remote network access by means of named pipes to applications that use STDIN and STDOUT for input and output. Users at other computers on a network, or connected by a direct-dial modem connection, can either view the remote session or enter commands themselves.

This utility has a large number of uses. For example, when you are developing software, you can compile code with the processor and resources of a remote computer while you perform other tasks on your computer. You can also use remote.exe to distribute the processing requirements for a particular task across several computers.

Please note that remote.exe does no security authorization, and will permit anyone running Remote.exe Client to connect to your Remote.exe Server. This leaves the account under which the Remote.exe Server was run open to anyone who connects.

[Send comments about this topic to Microsoft](#)

Starting a Remote.exe Session

5/31/2017 • 2 min to read • [Edit Online](#)

There are two ways to start a remote.exe session with KD or CDB. Only the second of these methods works with NTSD.

Customizing Your Command Prompt Window

The Remote.exe Client and Remote.exe Server run in Command Prompt windows.

To prepare for the remote session, you should customize this window to increase its usability. Open a Command Prompt window. Right-click the title bar and select **Properties**. Select the **Layout** tab. Go to the section titled "Screen Buffer Size" and type **90** in the **Width** box and a value between **4000** and **9999** in the **Height** box. This enables scroll bars in the remote session on the kernel debugger.

Change the values for the height and width of the "Windows Size" section if you want to alter the shape of the command prompt. Select the **Options** tab. Enable the **Edit Options** quickedit mode and insert mode. This allows you to cut and paste information in the command prompt session. Click **OK** to apply the changes. Select the option to apply the changes to all future sessions when prompted.

Starting the Remote.exe Server: First Method

The general syntax for starting a Remote.exe Server is as follows:

```
remote /s "Command_Line" Unique_Id [/f Foreground_Color] [/b Background_Color]
```

This can be used to start KD or CDB on the remote computer, as in the following examples:

```
remote /s "KD [options]" MyBrokenBox  
remote /s "CDB [options]" MyBrokenApp
```

This starts the Remote.exe Server in the Command Prompt window, and starts the debugger.

You cannot use this method to start NTSD directly, because the NTSD process runs in a different window than the one in which it was invoked.

Starting the Remote.exe Server: Second Method

There is an alternate method that can start a Remote.exe Server. This method involves first starting the debugger, and then using the **.remote (Create Remote.exe Server)** command to start the server.

Since the **.remote** command is issued after the debugger has started, this method works equally well with KD, CDB, and NTSD.

Here is an example. First, start the debugger in the normal fashion:

```
KD [options]
```

Once the debugger is running, use the **.remote** command:

```
.remote MyBrokenBox
```

This results in a KD process that is also a Remote.exe Server with an ID of "MyBrokenBox", exactly as in the first method.

One advantage of this method is that you do not have to decide in advance if you intend to use remote debugging. If you are debugging with one of the console debuggers and then decide that you would prefer someone in a remote location to take over, you can use the **.remote** command and then they can connect to your session.

Starting the Remote.exe Client

The general syntax for starting a Remote.exe Client is as follows:

```
remote /c ServerNetBIOSName Unique_ID [/l Lines_to_Get] [/f Foreground_Color] [/b Background_Color]
```

For example, if the "MyBrokenBox" session, described above, was started on a local host computer whose network name was "Server2", you can connect to it with the command:

```
remote /c server2 MyBrokenBox
```

Anyone on the network with appropriate permission can connect to this debug session, as long as they know your machine name and the session ID.

Issuing Commands

Commands are issued through the Remote.exe Client and are sent to the Remote.exe Server. You can enter any command into the client as if you were directly entering it into the debugger.

To exit from the remote.exe session on the Remote.exe Client, enter the **@Q** command. This leaves the Remote.exe Server and the debugger running.

To end the server session, enter the **@K** command on the Remote.exe Server.

[Send comments about this topic to Microsoft](#)

Remote.exe Batch Files

5/26/2017 • 1 min to read • [Edit Online](#)

As a more detailed example of remote debugging with remote.exe, assume the following about a local host computer in a three-computer kernel debugging scenario:

- Debugging needs to take place over a null-modem cable on COM2.
- The symbol files are in the folder c:\winnt\symbols.
- A log file called debug.log is created in **c:\temp**.

The log file holds a copy of everything you see on the Debug screen during your debug session. All input from the person doing the debugging, and all output from the kernel debugger on the target system, is written to that log file.

A sample batch file for running a debugging session on the local host is:

```
set _NT_DEBUG_PORT=COM2
set _NT_DEBUG_BAUD_RATE=19200
set _NT_SYMBOL_PATH=c:\winnt\symbols
set _NT_LOG_FILE_OPEN=c:\temp\debug.log
remote /s "KD -v" debug
```

Note If this batch file is not in the same directory as Remote.exe, and Remote.exe is not in a directory listed in the system path, then you should give the full path to the utility when invoking Remote.exe in this batch file.

After this batch file is run, anyone with a Windows computer that is networked to the local host computer can connect to the debug session by using the following command:

```
remote /c computername debug
```

where *computername* is the NetBIOS name of the local host computer.

[Send comments about this topic to Microsoft](#)

Process Servers (User Mode)

5/26/2017 • 1 min to read • [Edit Online](#)

Remote debugging through a process server involves running a small application called a *process server* on the server computer. Then a user-mode debugger is started on the client computer. Since this debugger will be doing all of the actual processing, it is called the *smart client*.

The Debugging Tools for Windows package includes a process server called DbgSrv (dbgsrv.exe) for use in user mode.

The two computers do not have to be running the same version of Windows; they can be running any version of Windows. However, the debugger binaries used on the client and the DbgSrv binary used on the server must be from the same release of the Debugging Tools for Windows package. This method cannot be used for dump-file debugging.

To set up this remote session, the process server is set up first, and then the smart client is activated. Any number of smart clients can operate through a single process server -- these debugging sessions will remain separate and will not interfere with each other. If a debugging session is ended, the process server will continue to run and can be used for new debugging sessions.

In this section

- [Activating a Process Server](#)
- [Searching for Process Servers](#)
- [Activating a Smart Client](#)
- [Process Server Examples](#)
- [Controlling a Process Server Session](#)

[Send comments about this topic to Microsoft](#)

Activating a Process Server

5/31/2017 • 7 min to read • [Edit Online](#)

The process server that is included in Debugging Tools for Windows is called DbgSrv (dbgsrv.exe). To activate a process server, open an elevated Command Prompt window (Run as Administrator), and enter the **dbgsrv** command.

Note You can activate a process server without having elevated privileges, and debugging clients will be able to connect to the server. However, clients will not be able to discover a process server unless it was activated with elevated privileges. For information about how to discover debugging servers, see [Searching for Process Servers](#).

DbgSrv supports several transport protocols: named pipe (NPIPE), TCP, COM port, secure pipe (SPIPE), and secure sockets layer (SSL).

```
dbgsrv -t npipe:pipe=PipeName[,hidden][,password=Password][,IcfEnable] [[-sifeo Executable] -c[s] AppCmdLine]
[-x | -pc]

dbgsrv -t tcp:port=Socket[,hidden][,password=Password][,ipversion=6][,IcfEnable] [[-sifeo Executable] -c[s]
AppCmdLine] [-x | -pc]

dbgsrv -t tcp:port=Socket,clicon=Client[,password=Password][,ipversion=6] [[-sifeo Executable] -c[s]
AppCmdLine] [-x | -pc]

dbgsrv -t com:port=COMPort,baud=BaudRate,channel=COMChannel[,hidden][,password=Password] [[-sifeo Executable]
-c[s] AppCmdLine] [-x | -pc]

dbgsrv -t spipe:proto=Protocol,{certuser=Cert|machuser=Cert},pipe=PipeName[,hidden][,password=Password] [[-sifeo Executable]
-c[s] AppCmdLine] [-x | -pc]

dbgsrv -t ssl:proto=Protocol,{certuser=Cert|machuser=Cert},port=Socket[,hidden][,password=Password] [[-sifeo Executable]
-c[s] AppCmdLine] [-x | -pc]

dbgsrv -t ssl:proto=Protocol,{certuser=Cert|machuser=Cert},port=Socket,clicon=Client[,password=Password] [[-sifeo Executable]
-c[s] AppCmdLine] [-x | -pc]
```

The parameters in the previous commands have the following possible values:

pipe= PipeName

When NPIPE or SPIPE protocol is used, *PipeName* is a string that will serve as the name of the pipe. Each pipe name should identify a unique process server. If you attempt to reuse a pipe name, you will receive an error message. *PipeName* must not contain spaces or quotation marks. *PipeName* can include a numerical **printf**-style format code, such as **%x** or **%d**. The process server will replace this with the process ID of DbgSrv. A second such code will be replaced with the thread ID of DbgSrv.

Note You might need to enable file and printer sharing on the computer that is running the process server. In Control Panel, navigate to **Network and Internet > Network and Sharing Center > Advanced sharing settings**. Select **Turn on file and printer sharing**.

port= Socket

When TCP or SSL protocol is used, *Socket* is the socket port number.

It is also possible to specify a range of ports separated by a colon. DbgSrv will check each port in this range to see if it is free. If it finds a free port and no error occurs, the process server will be created. The smart client will have to specify the actual port being used to connect to the server. To determine the actual port, use any of the methods described in [Searching for Process Servers](#); when this process server is displayed, the port will be followed by

two numbers separated by a colon. The first number will be the actual port used; the second can be ignored. For example, if the port was specified as **port=51:60**, and port 53 was actually used, the search results will show "port=53:60". (If you are using the **clicon** parameter to establish a reverse connection, the smart client can specify a range of ports in this manner, while the process server must specify the actual port used.)

clicon= *Client*

When TCP or SSL protocol is used and the **clicon** parameter is specified, a *reverse connection* will be opened. This means that the process server will try to connect to the smart client, instead of letting the client initiate the contact. This can be useful if you have a firewall that is preventing a connection in the usual direction. *Client* specifies the network name or IP address of the computer on which the smart client exists or will be created. The two initial backslashes (\) are optional.

Since the process server is looking for one specific client, you cannot connect multiple clients to the server if you use this method. If the connection is refused or is broken you will have to restart the process server. A reverse-connection process server will not appear when someone uses the **-QR** command-line option to display all active servers.

Note When **clicon** is used, it is best to start the smart client before the process server is created, although the usual order (server before client) is also permitted.

port= *COMPort*

When COM protocol is used, *COMPort* specifies the COM port to be used. The prefix "COM" is optional -- for example, both "com2" and "2" are acceptable.

baud= *BaudRate*

When COM protocol is used, *BaudRate* specifies the baud rate at which the connection will run. Any baud rate that is supported by the hardware is permitted.

channel= *COMChannel*

If COM protocol is used, *COMChannel* specifies the COM channel to be used in communicating with the debugging client. This can be any value between 0 and 254, inclusive. You can use a single COM port for multiple connections using different channel numbers. (This is different from the use of a COM ports for a debug cable -- in that situation you cannot use channels within a COM port.)

proto= *Protocol*

If SSL or SPIPE protocol is used, *Protocol* specifies the Secure Channel (S-Channel) protocol. This can be any one of the strings *tls1*, *pct1*, *ssl2*, or *ssl3*.

Cert

If SSL or SPIPE protocol is used, *Cert* specifies the certificate. This can either be the certificate name or the certificate's thumbprint (the string of hexadecimal digits given by the certificate's snapin). If the syntax **certuser=Cert** is used, the debugger will look up the certificate in the system store (the default store). If the syntax **machuser=Cert** is used, the debugger will look up the certificate in the machine store. The specified certificate must support server authentication.

hidden

Prevents the process server from appearing when someone uses the **-QR** command-line option to display all active servers.

password= *Password*

Requires a smart client to supply the specified password in order to connect to the process server. *Password* can be any alphanumeric string, up to twelve characters in length.

Warning Using a password with TCP, NPIPE, or COM protocol only offers a small amount of protection, because the password is not encrypted. When a password is used with SSL or SPIPE protocol, it is encrypted. If you want to establish a secure remote session, you must use SSL or SPIPE protocol.

ipversion=6

(Debugging Tools for Windows 6.6.07 and earlier only) Forces the debugger to use IP version 6 rather than version 4 when using TCP to connect to the Internet. In Windows Vista and later versions, the debugger attempts to auto-default to IP version 6, making this option unnecessary.

IcfEnable

(Windows XP and later versions only) Causes the debugger to enable the necessary port connections for TCP or named pipe communication when the Internet Connection Firewall is active. By default, the Internet Connection Firewall disables the ports used by these protocols. When **IcfEnable** is used with a TCP connection, the debugger causes Windows to open the port specified by the *Socket* parameter. When **IcfEnable** is used with a named pipe connection, the debugger causes Windows to open the ports used for named pipes (ports 139 and 445). The debugger does not close these ports after the connection terminates.

-sifeo Executable

Suspends the Image File Execution Option (IFEO) value for the given image. *Executable* should include the file name of the executable image, including the file name extensions. The **-sifeo** option allows DbgSrv to be set as the IFEO debugger for an image created by the **-c** option, without causing recursive invocation due to the IFEO setting. This option can be used only if **-c** is used.

-c

Causes DbgSrv to create a new process. You can use this to create a process that you intend to debug. This is similar to spawning a new process from the debugger, except that this process will not be debugged when it is created. To debug this process, determine its PID and use the **-p** option when starting the smart client to debug this process.

s

Causes the newly-created process to be immediately suspended. If you are using this option, it is recommended that you use CDB as your smart client, and that you start the smart client with the **-pb** command-line option, in conjunction with **-p PID**. If you include the **-pb** option on the command line, the process will resume when the debugger attaches to it; otherwise you can resume the process with the **~*m** command.

AppCmdLine

Specifies the full command line of the process to be created. *AppCmdLine* can be either a Unicode or ASCII string, and can include any printable character. All text that appears after the **-c[s]** parameter will be taken to form the string *AppCmdLine*.

-x

Causes the remainder of the command line to be ignored. This option is useful if you are launching DbgSrv from an application that may append unwanted text to its command line.

-pc

Causes the remainder of the command line to be ignored. This option is useful if you are launching DbgSrv from an application that may append unwanted text to its command line. A syntax error results if **-pc** is the final element on the DbgSrv command line. Aside from this restriction, **-pc** is identical to **-x**.

You can start any number of process servers on one computer. However, this is generally unnecessary, since one process server can be used by any number of smart clients (each engaged in a different debugging session).

[Send comments about this topic to Microsoft](#)

Searching for Process Servers

5/31/2017 • 1 min to read • [Edit Online](#)

You can use KD or CDB with the **-QR** command-line option to obtain a list of available process servers that are running on a network server computer.

This list may include servers that no longer exist but which were not shut down properly -- connecting to one of these generates an error message. The list will also include debugging servers and KD connection servers. The server type will be indicated in each case.

The syntax for this is as follows:

```
Debugger -QR \\Server
```

Debugger can be either KD or CDB -- the display will be the same in either case. The two backslashes (\\\) preceding *Server* are optional.

In WinDbg, you can use the **Connect to Remote Stub Server** dialog box to browse a list of available process servers. See [File | Connect to Remote Stub](#) for more details.

Note For a process server to be discoverable, it must be activated with elevated privileges. For more information, see [Activating a Process Server](#).

Note

If you are not logged on to the client computer with an account that has access to the server computer, you might need to provide a user name and password. On the client computer, in a Command Prompt window, enter the following command.

net use \\Server\ipc\$ /user:UserName where *Server* is the name of the server computer, and *UserName* is the name of an account that has access to the server computer.

When you are prompted, enter the password for *UserName*.

After this command succeeds, you can discover process servers (running on the server computer) by using **-QR** or **Connect to Remote Stub**.

[Send comments about this topic to Microsoft](#)

Activating a Smart Client

5/31/2017 • 4 min to read • [Edit Online](#)

Once the DbgSrv process server has been activated, you can create a smart client on another computer and begin a debugging session.

There are two ways to start a smart client: by starting CDB or WinDbg with the `-premote` [command-line option](#), or by using the WinDbg graphical interface.

The protocol of the smart client must match the protocol of the process server. The general syntax for starting a smart client depends on the protocol used. The following options exist:

```
Debugger -premote npipe:server=Server,pipe=PipeName[,password=Password] [Options]  
Debugger -premote tcp:server=Server,port=Socket[,password=Password][,ipversion=6] [Options]  
Debugger -premote tcp:clicon=Server,port=Socket[,password=Password][,ipversion=6] [Options]  
Debugger -premote com:port=COMPort,baud=BaudRate,channel=COMChannel[,password=Password] [Options]  
Debugger -premote spipe:proto=Protocol,  
{certuser=Cert|machuser=Cert},server=Server,pipe=PipeName[,password=Password] [Options]  
Debugger -premote ssl:proto=Protocol,  
{certuser=Cert|machuser=Cert},server=Server,port=Socket[,password=Password] [Options]  
Debugger -premote ssl:proto=Protocol,  
{certuser=Cert|machuser=Cert},clicon=Server,port=Socket[,password=Password] [Options]
```

To use the graphical interface to connect to a process server, WinDbg must be in dormant mode -- it must either have been started with no command-line parameters, or it must have ended the previous debugging session.

Select the **File | Connect to Remote Stub** menu command. When the **Connect to Remote Stub Server** dialog box appears, enter one of the following strings into the **Connection string** text box:

```
npipe:server=Server,pipe=PipeName[,password=Password]  
tcp:server=Server,port=Socket[,password=Password][,ipversion=6]  
tcp:clicon=Server,port=Socket[,password=Password][,ipversion=6]  
com:port=COMPort,baud=BaudRate,channel=COMChannel[,password=Password]  
spipe:proto=Protocol,{certuser=Cert|machuser=Cert},server=Server,pipe=PipeName[,password=Password]  
ssl:proto=Protocol,{certuser=Cert|machuser=Cert},server=Server,port=Socket[,password=Password]  
ssl:proto=Protocol,{certuser=Cert|machuser=Cert},clicon=Server,port=Socket[,password=Password]
```

Alternatively, you can use the **Browse** button to locate active process servers. See [File | Connect to Remote Stub](#) for details.

The parameters in the preceding commands have the following possible values:

Debugger

This can be CDB or WinDbg.

Server

This is the network name or IP address of the computer on which the process server was created. The two initial backslashes (\) are optional on the command line, but are not permitted in the WinDbg dialog box.

pipe= PipeName

If NPIPE or SPIPE protocol is used, *PipeName* is the name that was given to the pipe when the process server was created.

If you are not logged on to the client computer with an account that has access to the server computer, you must provide a user name and password. On the client computer, in a Command Prompt window, enter the following command.

```
net use \\Server\ipc$ /user:UserName
```

where *Server* is the name of the server computer, and *UserName* is the name of an account that has access to the server computer.

When you are prompted, enter the password for *UserName*.

After this command succeeds, you can activate a smart client by using the **-premove** command-line option or by using the WinDbg graphical interface.

Note You might need to enable file and printer sharing on the server computer. In Control Panel, navigate to **Network and Internet > Network and Sharing Center > Advanced sharing settings**. Select **Turn on file and printer sharing**.

port= Socket

If TCP or SSL protocol is used, *Socket* is the same socket port number that was used when the process server was created.

clicon

Specifies that the process server will try to connect to the smart client through a reverse connection. The client must use **clicon** if and only if the server is using **clicon**. In most cases, the smart client is started before the process server when a reverse connection is used.

port= COMPort

If COM protocol is used, *COMPort* specifies the COM port to be used. The prefix "COM" is optional -- for example, both "com2" and "2" are acceptable.

baud= BaudRate

If COM protocol is used, *BaudRate* should match the baud rate chosen when the process server was created.

channel= COMChannel

If COM protocol is used, *COMChannel* should match the channel number chosen when the process server was created.

proto= Protocol

If SSL or SPIPE protocol is used, *Protocol* should match the secure protocol used when the process server was created.

Cert

If SSL or SPIPE protocol is used, you should use the identical **certuser=Cert** or **machuser=Cert** parameter that was used when the process server was created.

password= Password

If a password was used when the process server was created, *Password* must be supplied in order to create the smart client. It must match the original password. Passwords are case-sensitive. If the wrong password is supplied, the error message will specify "Error 0x80004005."

ipversion=6

(Debugging Tools for Windows 6.6.07 and earlier only) Forces the debugger to use IP version 6 rather than version 4 when using TCP to connect to the Internet. In Windows Vista and later versions, the debugger attempts to auto-default to IP version 6, making this option unnecessary.

Options

Any additional command-line parameters can be placed here. See [Command-Line Options](#) for a full list. If you are using CDB, this must specify the process you wish to debug. If you are using WinDbg, you can specify the process on the command line or through the graphical interface.

Since the process server simply acts as a gateway for the smart client, the additional *Options* will be the same as those you would use if you were starting a user-mode debugger on the same machine as the target application.

If you are using the **-premote** option with [.attach \(Attach to Process\)](#) or [.create \(Create Process\)](#), the parameters are the same as those listed above.

[Send comments about this topic to Microsoft](#)

Process Server Examples

5/26/2017 • 1 min to read • [Edit Online](#)

Suppose one person is running an application on a computer named \\BOX17. This application has problems, but the debugging technician is at a different site.

The first person sets up a process server using DbgSrv on \\BOX17. The target application has a process ID of 122. TCP protocol is chosen, with a socket port number of 1025. The server is started with the following command:

```
E:\Debugging Tools for Windows> dbgsrv -t tcp:port=1025
```

On the other computer, the technician starts WinDbg as a smart client with this command:

```
G:\Debugging Tools> windbg -premote tcp:server=BOX17,port=1025 -p 122
```

Here is another example. In this case, NPIPE protocol is chosen, and CDB is used instead of WinDbg. The first user chooses a pipe name. This can be any alphanumeric string -- in this example, "AnotherPipe". The first user opens an elevated Command Prompt window (Run as Administrator) and starts a debugging server by entering this command:

```
E:\Debugging Tools for Windows> dbgsrv -t npipe:pipe=AnotherPipe
```

The technician is logged on to the client computer with an account that does not have access to the server computer. But the technician knows the username and password for an account that does have access to the server computer. The username for that account is Contoso. The technician enters the following command:

```
net use \\BOX17\ipc$ /user:Contoso
```

When prompted, the technician enters the password for the Contoso account.

The technician is not sure what name was used for the named pipe, so she queries BOX17 for process servers:

```
G:\Debugging Tools> cdb -QR \\BOX17
Servers on \\BOX17:
Debugger Server - npipe:Pipe=MainPipe
Remote Process Server - npipe:Pipe=AnotherPipe
```

Two pipes are shown. However, only one is a process server -- the other is a debugging server, and we are not interested in that. So **AnotherPipe** must be the correct name. The technician enters the following command to start the smart client:

```
G:\Debugging Tools> cdb -premote npipe:server=BOX17,pipe=AnotherPipe -v sol.exe
```

For a more complicated example using a process server, see [Symbols in the Middle](#).

[Send comments about this topic to Microsoft](#)

Controlling a Process Server Session

5/26/2017 • 1 min to read • [Edit Online](#)

Once the remote session has been started, the smart client can be used as if it were debugging a target application on a single machine. All commands will behave as they would in this situation, except that paths are relative to the smart client's computer.

Using WinDbg as a Smart Client

After WinDbg is started as a smart client for a user-mode process server, it will remain attached to the process server permanently. If the debugging session is ended, the [File | Attach to a Process](#) menu command or the [.tlist \(List Process IDs\)](#) command will display all processes running on the computer running the process server. WinDbg can attach to any of these processes.

The [File | Open Executable](#) command cannot be used. A new process can only be spawned if it is included on the WinDbg command line.

In this situation, WinDbg will not be able to debug processes on the computer where it is running, nor will it be able to start a kernel debugging session.

Ending the Session

CDB or WinDbg can exit or end the debugging session in the normal fashion. See [Ending a Debugging Session in WinDbg](#) for details. The process server will remain in operation and can be re-used as many times as desired. (It can also be used by for any number of simultaneous debugging sessions.)

The process server can be terminated from either computer. To terminate it from the smart client, use the [.endpsrv \(End Process Server\)](#) command. To terminate the process server from the computer it is running on, use Task Manager to end the dbgsrv.exe process.

[Send comments about this topic to Microsoft](#)

KD Connection Servers (Kernel Mode)

5/26/2017 • 1 min to read • [Edit Online](#)

Kernel-mode remote debugging through a KD connection server involves running a small application called a *KD connection server* on the server. Then a kernel-mode debugger is started on the client. Since this debugger will be doing all of the actual processing, it is called the *smart client*.

The Debugging Tools for Windows package includes a KD connection server called KdSrv (kdsrv.exe).

The two computers do not have to be running the same version of Windows; they can be running any version of Windows. However, the debugger binaries used on the client and the KdSrv binary used on the server must be from the same release of the Debugging Tools for Windows package. This method cannot be used for dump-file debugging.

To set up this remote session, the KD connection server is set up first, and then the smart client is activated. Any number of smart clients can operate through a single KD connection server, but they must each be connected to a different kernel debugging session.

This section includes:

[Activating a KD Connection Server](#)

[Searching for KD Connection Servers](#)

Activating a KD Connection Server

5/31/2017 • 5 min to read • [Edit Online](#)

The KD connection server that is included in Debugging Tools for Windows is called KdSrv (kdsrv.exe). To activate a KD connection server, open an elevated Command Prompt window (Run as Administrator), and enter the **kdsrv** command.

Note You can activate a KD connection server without having elevated privileges, and debugging clients will be able to connect to the server. However, clients will not be able to discover a KD connection server unless it was activated with elevated privileges. For information about how to discover debugging servers, see [Searching for KD Connection Servers](#).

KdSrv supports several transport protocols: named pipe (NPIPE), TCP, COM port, secure pipe (SPIPE), and secure sockets layer (SSL).

The syntax for the KdSrv command line depends on the protocol used. The following options exist:

```
kdsrv -t npipe:pipe=PipeName[,hidden][,password=Password][,IcfEnable]  
kdsrv -t tcp:port=Socket[,hidden][,password=Password][,ipversion=6][,IcfEnable]  
kdsrv -t tcp:port=Socket,clicon=Client[,password=Password][,ipversion=6]  
kdsrv -t com:port=COMPort,baud=BaudRate,channel=COMChannel[,hidden][,password=Password]  
kdsrv -t spipe:proto=Protocol,{certuser=Cert|machuser=Cert},pipe=PipeName[,hidden][,password=Password]  
kdsrv -t ssl:proto=Protocol,{certuser=Cert|machuser=Cert},port=Socket[,hidden][,password=Password]  
kdsrv -t ssl:proto=Protocol,{certuser=Cert|machuser=Cert},port=Socket,clicon=Client[,password=Password]
```

The parameters in the previous commands have the following possible values:

pipe= PipeName

When NPIPE or SPIPE protocol is used, *PipeName* is a string that will serve as the name of the pipe. Each pipe name should identify a unique process server. If you attempt to reuse a pipe name, you will receive an error message. *PipeName* must not contain spaces or quotation marks. *PipeName* can include a numerical **printf**-style format code, such as **%x** or **%d**. This will be replaced by the process ID of KdSrv. A second such code will be replaced by the thread ID of KdSrv.

port= Socket

When TCP or SSL protocol is used, *Socket* is the socket port number.

It is also possible to specify a range of ports separated by a colon. KdSrv will check each port in this range to see if it is free. If it finds a free port and no error occurs, the KD connection server will be created. The smart client will have to specify the actual port being used to connect to the server. To determine the actual port, use any of the methods described in [Searching for KD Connection Servers](#); when this KD connection server is displayed, the port will be followed by two numbers separated by a colon. The first number will be the actual port used; the second can be ignored. For example, if the port was specified as **port=51:60**, and port 53 was actually used, the search results will show "port=53:60". (If you are using the **clicon** parameter to establish a reverse connection, the smart client can specify a range of ports in this manner, while the KD connection server must specify the actual port used.)

cicon= *Client*

When TCP or SSL protocol is used and the **cicon** parameter is specified, a *reverse connection* will be opened. This means that the KD connection server will try to connect to the smart client, instead of letting the client initiate the contact. This can be useful if you have a firewall that is preventing a connection in the usual direction. *Client* specifies the network name or IP address of the computer on which the smart client exists or will be created. The two initial backslashes (\) are optional.

Since the KD connection server is looking for one specific client, you cannot connect multiple clients to the server if you use this method. If the connection is refused or is broken you will have to restart the process server. A reverse-connection KD connection server will not appear when someone uses the **-QR** command-line option to display all active servers.

Note When **cicon** is used, it is best to start the smart client before the KD connection server is created, although the usual order (server before client) is also permitted.

port= *COMPort*

When COM protocol is used, *COMPort* specifies the COM port to be used. The prefix "COM" is optional -- for example, both "com2" and "2" are acceptable.

baud= *BaudRate*

When COM protocol is used, *BaudRate* specifies the baud rate at which the connection will run. Any baud rate that is supported by the hardware is permitted.

channel= *COMChannel*

If COM protocol is used, *COMChannel* specifies the COM channel to be used in communicating with the debugging client. This can be any value between 0 and 254, inclusive. You can use a single COM port for multiple connections using different channel numbers. (This is different from the use of a COM ports for a debug cable -- in that situation you cannot use channels within a COM port.)

proto= *Protocol*

If SSL or SPIPE protocol is used, *Protocol* specifies the Secure Channel (S-Channel) protocol. This can be any one of the strings tls1, pct1, ssl2, or ssl3.

Cert

If SSL or SPIPE protocol is used, *Cert* specifies the certificate. This can either be the certificate name or the certificate's thumbprint (the string of hexadecimal digits given by the certificate's snapin). If the syntax **certuser=***Cert* is used, the debugger will look up the certificate in the system store (the default store). If the syntax **machuser=***Cert* is used, the debugger will look up the certificate in the machine store. The specified certificate must support server authentication.

hidden

Prevents the KD connection server from appearing when someone uses the **-QR** command-line option to display all active servers.

password= *Password*

Requires a smart client to supply the specified password in order to connect to the KD connection server. *Password* can be any alphanumeric string, up to twelve characters in length.

Warning Using a password with TCP, NPIPE, or COM protocol only offers a small amount of protection, because the password is not encrypted. When a password is used with SSL or SPIPE protocol, it is encrypted. If you want to establish a secure remote session, you must use SSL or SPIPE protocol.

ipversion=6

(Debugging Tools for Windows 6.6.07 and earlier only) Forces the debugger to use IP version 6 rather than version 4 when using TCP to connect to the Internet. In Windows Vista and later versions, the debugger attempts to auto-default to IP version 6, making this option unnecessary.

IcfEnable

(Windows XP and later versions only) Causes the debugger to enable the necessary port connections for TCP or named pipe communication when the Internet Connection Firewall is active. By default, the Internet Connection Firewall disables the ports used by these protocols. When **IcfEnable** is used with a TCP connection, the debugger causes Windows to open the port specified by the *Socket* parameter. When **IcfEnable** is used with a named pipe connection, the debugger causes Windows to open the ports used for named pipes (ports 139 and 445). The debugger does not close these ports after the connection terminates.

[Send comments about this topic to Microsoft](#)

Searching for KD Connection Servers

5/31/2017 • 1 min to read • [Edit Online](#)

You can use KD or CDB with the **-QR** command-line option to obtain a list of available KD connection servers that are running on a network server.

This list may include servers that no longer exist but which were not shut down properly -- connecting to one of these generates an error message. The list will also include debugging servers and user-mode process servers. The server type will be indicated in each case.

The syntax for this is as follows:

```
Debugger -QR \\Server
```

Debugger can be either KD or CDB -- the display will be the same in either case. The two backslashes (\\\) preceding *Server* are optional.

In WinDbg, you can use the **Connect to Remote Stub Server** dialog box to browse a list of available KD connection servers. See [File | Connect to Remote Stub](#) for more details.

Note For a KD connection server to be discoverable, it must be activated with elevated privileges. For more information, see [Activating a KD Connection Server](#).

Note

If you are not logged on to the client computer with an account that has access to the server computer, you might need to provide a user name and password. On the client computer, in a Command Prompt window, enter the following command.

net use \\Server\ipc\$ /user:UserName where *Server* is the name of the server computer, and *UserName* is the name of an account that has access to the server computer.

When you are prompted, enter the password for *UserName*.

After this command succeeds, you can discover KD connection servers (running on the server computer) by using **-QR** or **Connect to Remote Stub**.

[Send comments about this topic to Microsoft](#)

Activating a Smart Client (Kernel Mode)

5/31/2017 • 4 min to read • [Edit Online](#)

Once the KD connection server has been activated, you can create a smart client on another computer and begin a debugging session.

There are two ways to start a smart client: by starting KD or WinDbg with the kernel protocol **kdsrv**, or by using the WinDbg graphical interface.

You need to specify the remote transfer protocol used by the KD connection server. You can also specify the protocol for the actual kernel connection between the KD connection server and the target computer, or you can use the default.

The general syntax for starting a smart client depends on the protocol used. The following options exist:

```
Debugger -k kdsrv:server=@{npipe:server=Server,pipe=PipeName[,password=Password]},trans=@{ConnectType}  
[Options]  
  
Debugger -k kdsrv:server=@{tcp:server=Server,port=Socket[,password=Password]  
[,ipversion=6]},trans=@{ConnectType} [Options]  
  
Debugger -k kdsrv:server=@{tcp:cicon=Server,port=Socket[,password=Password]  
[,ipversion=6]},trans=@{ConnectType} [Options]  
  
Debugger -k  
kdsrv:server=@{com:port=COMPort,baud=BaudRate,channel=COMChannel[,password=Password]},trans=@{ConnectType}  
[Options]  
  
Debugger -k kdsrv:server=@{spipe:proto=Protocol,  
{certuser=Cert|machuser=Cert},server=Server,pipe=PipeName[,password=Password]},trans=@{ConnectType} [Options]  
  
Debugger -k kdsrv:server=@{ssl:proto=Protocol,  
{certuser=Cert|machuser=Cert},server=Server,port=Socket[,password=Password]},trans=@{ConnectType} [Options]  
  
Debugger -k kdsrv:server=@{ssl:proto=Protocol,  
{certuser=Cert|machuser=Cert},cicon=Server,port=Socket[,password=Password]},trans=@{ConnectType} [Options]
```

To use the graphical interface to connect to a KD connection server, WinDbg must be in dormant mode -- it must either have been started with no command-line parameters, or it must have ended the previous debugging session. Select the **File | Connect to Remote Stub** menu command. When the **Connect to Remote Stub Server** dialog box appears, enter one of the following strings into the **Connection string** text box:

```
npipe:server=Server,pipe=PipeName[,password=Password]  
  
tcp:server=Server,port=Socket[,password=Password][,ipversion=6]  
  
tcp:cicon=Server,port=Socket[,password=Password][,ipversion=6]  
  
com:port=COMPort,baud=BaudRate,channel=COMChannel[,password=Password]  
  
spipe:proto=Protocol,{certuser=Cert|machuser=Cert},server=Server,pipe=PipeName[,password=Password]  
  
ssl:proto=Protocol,{certuser=Cert|machuser=Cert},server=Server,port=Socket[,password=Password]  
  
ssl:proto=Protocol,{certuser=Cert|machuser=Cert},cicon=Server,port=Socket[,password=Password]
```

Alternatively, you can use the **Browse** button to locate active KD connection servers. See [File | Connect to Remote](#)

[Stub](#) for details.

The parameters in the preceding commands have the following possible values:

Debugger

This can be KD or WinDbg.

Server

This is the network name or IP address of the computer on which the KD connection server was created. The two initial backslashes (\) are optional on the command line, but are not permitted in the WinDbg dialog box.

pipe= PipeName

If NPIPE or SPIPE protocol is used, *PipeName* is the name that was given to the pipe when the KD connection server was created.

If you are not logged on to the client computer with an account that has access to the server computer, you must provide a user name and password. On the client computer, in a Command Prompt window, enter the following command.

```
net use \\Server\ipc$ /user:UserName
```

where *Server* is the name of the server computer, and *UserName* is the name of an account that has access to the server computer.

When you are prompted, enter the password for *UserName*.

After this command succeeds, you can activate a smart client by using **-k kdsrv** or by using the WinDbg graphical interface.

port= Socket

If TCP or SSL protocol is used, *Socket* is the same socket port number that was used when the KD connection server was created.

clicon

Specifies that the KD connection server will try to connect to the smart client through a reverse connection. The client must use **clicon** if and only if the server is using **clicon**. In most cases, the smart client is started before the KD connection server when a reverse connection is used.

port= COMPort

If COM protocol is used, *COMPort* specifies the COM port to be used. The prefix "COM" is optional -- for example, both "com2" and "2" are acceptable.

baud= BaudRate

If COM protocol is used, *BaudRate* should match the baud rate chosen when the KD connection server was created.

channel= COMChannel

If COM protocol is used, *COMChannel* should match the channel number chosen when the KD connection server was created.

proto= Protocol

If SSL or SPIPE protocol is used, *Protocol* should match the secure protocol used when the KD connection server was created.

Cert

If SSL or SPIPE protocol is used, you should use the identical **certuser=Cert** or **machuser=Cert** parameter that was used when the KD connection server was created.

password= Password

If a password was used when the KD connection server was created, *Password* must be supplied in order to create

the smart client. It must match the original password. Passwords are case-sensitive. If the wrong password is supplied, the error message will specify "Error 0x80004005."

ipversion=6

(Debugging Tools for Windows 6.6.07 and earlier only) Forces the debugger to use IP version 6 rather than version 4 when using TCP to connect to the Internet. In Windows Vista and later versions, the debugger attempts to auto-default to IP version 6, making this option unnecessary.

trans=@{ ConnectType }

Tells the debugger how to connect to the target. The following kernel connection protocols are permitted:

```
com:port=ComPort,baud=BaudRate
1394:channel=1394Channel[,symlink=1394Protocol]
usb2:targetname=String
com:pipe,port=\\VMHost\\pipe\\PipeName[, resets=0][,reconnect]
com:modem
```

For information about these protocols, see [Getting Set Up for Debugging](#). You can omit any of the parameters for these protocols -- for example, you can say **trans=@{com:}** -- and the debugger will default to the values specified by the environment variables on the computer where KdSrv is running.

Options

Any additional command-line parameters can be placed here. See [Command-Line Options](#) for a full list.

Since the KD connection server simply acts as a gateway for the smart client, the additional *Options* will be the same as those you would use if you were starting a kernel debugger on computer where KdSrv is running. The exception to this is any option that specifies a path or filename will be taken as a path on the computer where the smart client is running.

[Send comments about this topic to Microsoft](#)

KD Connection Server Examples

5/26/2017 • 1 min to read • [Edit Online](#)

Suppose a debugging technician is not present at the site where the computer to be debugged is located. The debugging technician asks someone at this site to connect this target computer to some other computer with a debug cable.

Let this other computer be at IP address 127.0.0.42. The debug cable connects COM1 on this computer to whichever port has been debug-enabled on the target computer. The KD connection server is started with this command:

```
E:\Debugging Tools for Windows> kdsrv -t tcp:port=1027
```

Then at the other location, the technician starts WinDbg as a smart client with this command:

```
G:\Debugging Tools> windbg -k kdsrv:server=@{tcp:server=127.0.0.42,port=1027},trans=@{com:port=com1,baud=57600}-y SymbolPath
```

The symbol path will be relative to the computer where the smart client is running.

Here is another example. In this case, NPIPE protocol is chosen, and KD is used instead of WinDbg. The first user chooses a pipe name. This can be any alphanumeric string -- in this example, "KernelPipe". The first user opens an elevated Command Prompt window (Run as Administrator) and starts a debugging server by entering these commands:

```
E:\Debugging Tools for Windows> set _NT_DEBUG_PORT=com1
E:\Debugging Tools for Windows> kdsrv -t npipe:pipe=KernelPipe
```

The technician is logged on to the client computer with an account that does not have access to the server computer. But the technician knows the username and password for an account that does have access to the server computer. The username for that account is Contoso. The technician enters the following command:

```
net use \\BOX17\ipc$ /user:Contoso
```

When prompted, the technician enters the password for the Contoso account.

The technician is not sure what name was used for the named pipe, so she queries 127.0.0.42 for KD connection servers:

```
G:\Debugging Tools> cdb -QR 127.0.0.42
Servers on 127.0.0.42:
Debugger Server - npipe:Pipe=MainPipe
Remote Process Server - npipe:Pipe=AnotherPipe
Remote Kernel Debugger Server - npipe:Pipe=KernelPipe
```

Three pipes are shown. However, only one is a KD connection server -- the others are a debugging server and a user-mode process server. The technician enters the following command can to start the smart client:

```
G:\Debugging Tools> kd -k kdsrv:server=@{npipe:server=127.0.0.42,pipe=KernelPipe},trans=@{com:baud=57600} -y  
SymbolPath
```

Notice that although the baud rate is specified, the port is not. This causes the debugger to default to the port specified by `_NT_DEBUG_PORT` on the computer where `KdSrv` is running.

[Send comments about this topic to Microsoft](#)

Controlling a KD Connection Server Session

5/26/2017 • 1 min to read • [Edit Online](#)

Once the remote session has been started, the smart client can be used as if it were debugging the target computer from the computer where the KD connection server is running. All commands will behave as they would in this situation, except that paths are relative to the smart client's computer.

Using WinDbg as a Smart Client

After WinDbg is started as a smart client for a KD connection server, you can use the [Debug | Stop Debugging](#) command to end the debugging session. At that point, WinDbg will enter dormant mode and will no longer be connected to the KD connection server. All subsequent debugging will be done on the computer where WinDbg is running. You cannot reattach to the KD connection serve by using [File | Kernel Debug](#) -- this can only be done from the command line.

Ending the Session

KD or WinDbg can exit or end the debugging session in the normal fashion. See [Ending a Debugging Session in WinDbg](#)

for details. The KD connection server will remain in operation and can be re-used as many times as desired. (It can also be used by for any number of simultaneous debugging sessions.)

The KD connection server can be terminated from either computer. To terminate it from the smart client, use the [.endpsrv \(End Process Server\)](#) command. To terminate the KD connection server from the computer it is running on, use Task Manager to end the kdsrv.exe process.

[Send comments about this topic to Microsoft](#)

Repeaters

5/26/2017 • 1 min to read • [Edit Online](#)

A *repeater* is a lightweight proxy server that runs on a computer and relays data between two other computers. The repeater does not process the data in any way. The two other computers barely notice the repeater; from their perspective it seems as if they are directly connected to each other.

The processes running on these two other computers are called the *server* and the *client*. There is not any fundamental difference between them from the repeater's point of view, except that in most cases the server is started first, then the repeater, and finally the client.

The Debugging Tools for Windows package includes a repeater called DbEngPrx (dbengprx.exe).

This section includes:

[Activating a Repeater](#)

[Using a Repeater](#)

[Repeater Examples](#)

[Send comments about this topic to Microsoft](#)

Activating a Repeater

5/31/2017 • 7 min to read • [Edit Online](#)

To activate the repeater connection, you will usually first start the server, then start the repeater, then start the client.

It is also possible to start the repeater first and then the server. But unless you are using the **clicon** parameter to establish a reverse connection, the client must always be started last.

Step One: Starting the Server

The server can be a debugging server, a process server, or a KD connection server. You start this as you normally would, except that the transport protocol settings will be used to connect to the repeater, not the client. For details, see [Activating a Debugging Server](#), [Activating a Process Server](#), or [Activating a KD Connection Server](#).

If you use a password when creating the server, this password will be required when the client attaches, but not when the repeater is created.

If you use the **hidden** parameter, the server will be hidden as usual. The repeater itself is always hidden.

Step Two: Starting the Repeater

The repeater that is included in Debugging Tools for Windows is called DbEngPrx (dbengprx.exe).

DbEngPrx understands the following transport protocols: named pipe (NPIPE), TCP, and COM port.

If your client and server are using secure sockets layer (SSL) protocol, you should use TCP protocol for the repeater. If your client and server are using secure pipe (SPIPE) protocol, you should use NPIPE protocol for the repeater. The repeater will pass on whatever data it receives -- it does not interpret, encrypt, or decrypt any information. All encryption and decryption will be done by the client and the server.

The syntax for the DbEngPrx command line is as follows:

dbengprx [-p] -c ClientTransport -s ServerTransport

The parameters in the previous commands have the following possible values:

-p

Causes DbEngPrx to continue existing even after all connections to it are dropped.

ClientTransport

Specifies the protocol settings to be used in connecting to the server. The protocol should match that used when the server was created. The protocol syntaxes are as follows:

```
npipe:server=Server,pipe=PipeName[,password=Password]
tcp:server=Server,port=Socket[,password=Password][,ipversion=6]
tcp:clicon=Server,port=Socket[,password=Password][,ipversion=6]
com:port=COMPort,baud=BaudRate,channel=COMChannel[,password=Password]
```

The protocol parameters have the following meanings:

Server

This is the network name or IP address of the computer on which the server was created. The two initial backslashes (\) are optional.

pipe= PipeName

If NPIPE or SPIPE protocol is used, *PipeName* is the name that was given to the pipe when the server was created.

port= Socket

If TCP or SSL protocol is used, *Socket* is the same socket port number that was used when the server was created.

clicon

Specifies that the server will try to connect to the repeater through a reverse connection. *ClientTransport* must use **clicon** if and only if the server is using **clicon**. In most cases, the repeater is started before the server when a reverse connection is used.

port= COMPort

If COM protocol is used, *COMPort* specifies the COM port to be used. The prefix "COM" is optional -- for example, both "com2" and "2" are acceptable.

baud= BaudRate

If COM protocol is used, *BaudRate* should match the baud rate chosen when the server was created.

channel= COMChannel

If COM protocol is used, *COMChannel* should match the channel number chosen when the server was created.

password= Password

If a password was used when the server was created, *Password* must be supplied in order to create the debugging client. It must match the original password. Passwords are case-sensitive. If the wrong password is supplied, the error message will specify "Error 0x80004005."

ipversion=6

(Debugging Tools for Windows 6.6.07 and earlier only) Forces the debugger to use IP version 6 rather than version 4 when using TCP to connect to the Internet. In Windows Vista and later versions, the debugger attempts to auto-default to IP version 6, making this option unnecessary.

ServerTransport

Specifies the protocol settings that will be used when the client connects to the repeater. The possible protocol syntaxes are:

```
npipe:pipe=PipeName[,hidden][,password=Password][,IcfEnable]  
tcp:port=Socket[,hidden][,password=Password][,IcfEnable]  
tcp:port=Socket,clicon=Client[,password=Password]  
com:port=COMPort,baud=BaudRate,channel=COMChannel[,hidden][,password=Password]
```

The protocol parameters have the following meanings:

pipe= PipeName

When NPIPE or SPIPE protocol is used, *PipeName* is a string that will serve as the name of the pipe. Each pipe name should identify a unique repeater. If you attempt to reuse a pipe name, you will receive an error message. *PipeName* must not contain spaces or quotation marks. *PipeName* can include a numerical **printf**-style format code, such as **%x** or **%d**. The repeater will replace this with the process ID of DbEngPrx. A second such code will be replaced with the thread ID of DbEngPrx.

port= Socket

When TCP or SSL protocol is used, *Socket* is the socket port number.

It is also possible to specify a range of ports separated by a colon. DbEngPrx will check each port in this range to see if it is free. If it finds a free port and no error occurs, the repeater will be created. The client will have to specify the actual port being used to connect to the repeater. To determine the actual port, search for the repeater; when this repeater is displayed, the port will be followed by two numbers separated by a colon. The first number will be

the actual port used; the second can be ignored. For example, if the port was specified as **port=51:60**, and port 53 was actually used, the search results will show "port=53:60". (If you are using the **clicon** parameter to establish a reverse connection, the client can specify a range of ports in this manner, while the repeater must specify the actual port used.)

clicon=Client

When TCP or SSL protocol is used and the **clicon** parameter is specified, a *reverse connection* will be opened. This means that the repeater will try to connect to the client, instead of letting the client initiate the contact. This can be useful if you have a firewall that is preventing a connection in the usual direction. *Client* specifies the network name or IP address of the computer on which the client exists or will be created. The two initial backslashes (\) are optional.

Since the repeater is looking for one specific client, you cannot connect multiple clients to the repeater if you use this method. If the connection is refused or is broken you will have to restart the repeater.

When **clicon** is used, it is best to start the client before the repeater is created, although the usual order (repeater before client) is also permitted.

port= COMPort

When COM protocol is used, *COMPort* specifies the COM port to be used. The prefix "COM" is optional -- for example, both "com2" and "2" are acceptable. You cannot use the same COM port in the *ClientTransport* and the *ServerTransport*.

baud= BaudRate

When COM protocol is used, *BaudRate* specifies the baud rate at which the connection will run. Any baud rate that is supported by the hardware is permitted. If you are using COM protocol in both the *ClientTransport* and the *ServerTransport* you may specify different baud rates, but naturally the slower rate will be the limit on how fast the client and server can communicate with each other.

channel= COMChannel

If COM protocol is used, *COMChannel* specifies the COM channel to be used in communicating with the client. This can be any value between 0 and 254, inclusive. You can use a single COM port for multiple connections using different channel numbers. (This is different from the use of a COM ports for a debug cable -- in that situation you cannot use channels within a COM port.)

hidden

Prevents the server from appearing when another debugger displays all active servers.

password= Password

Requires a client to supply the specified password in order to connect to the debugging session. *Password* can be any alphanumeric string.

IcfEnable

(Windows XP and later versions only) Causes the debugger to enable the necessary port connections for TCP or named pipe communication when the Internet Connection Firewall is active. By default, the Internet Connection Firewall disables the ports used by these protocols. When **IcfEnable** is used with a TCP connection, the debugger causes Windows to open the port specified by the *Socket* parameter. When **IcfEnable** is used with a named pipe connection, the debugger causes Windows to open the ports used for named pipes (ports 139 and 445). The debugger does not close these ports after the connection terminates.

Step Three: Starting the Client

The client should be a debugging client or a smart client -- whichever corresponds to your server type. For details, see [Activating a Debugging Client](#), [Activating a Smart Client](#), or [Activating a Smart Client \(Kernel Mode\)](#).

If the server rejects the connection (for example, if you supply an incorrect password), both the repeater and the client will be shut down. You will have to restart both of them to reestablish contact with the server.

[Send comments about this topic to Microsoft](#)

Using a Repeater

5/26/2017 • 1 min to read • [Edit Online](#)

A repeater connection obeys very simple rules:

- Any communication that the server and client intend for each other passes through the repeater without alteration.
- Any action that the server performs with respect to the transport connection affects the repeater (and only indirectly affects the client).
- Any action that the client performs with respect to the transport connection affects the repeater (and only indirectly affects the server).

This means that any debugging commands, debugger output, control keys, and file access will take place exactly as if the client and server were directly connected. The repeater will be invisible to all these commands.

Actions that terminate the connection itself will affect the repeater. For example, if you issue a **qq (Quit)** command from the client, the server will shut down and will send a shutdown signal to the transport. This will cause the repeater to exit (unless it was started with the **-p** option). As another example, the **.clients (List Debugging Clients)** command will list the client's computer name, but it will show the connection protocol used to connect the server with the repeater.

If the server is shut down, the repeater will automatically exit (unless it was started with the **-p** option). When the repeater shuts down, this will cause a debugging client to exit as well, although a smart client will not. If for some reason you need to terminate the repeater directly, you can use Task Manager or the kill.exe tool.

[Send comments about this topic to Microsoft](#)

Repeater Examples

5/26/2017 • 1 min to read • [Edit Online](#)

Let us suppose you have three computers, \\BOXA, \\BOXB, and \\BOXC, and you wish to use them as the server, the repeater, and the client, respectively.

You can start a debugging server on \\BOXA, using process 122 as the target, in the following manner:

```
E:\Debugging Tools for Windows> cdb -server tcp:port=1025,password=wrought -p 122
```

Then you can start a repeater on \\BOXB as follows:

```
C:\Misc> dbengprx -c tcp:server=BOXA,port=1025 -s npipe:pipe=MyPipe
```

Finally, start a debugging client on \\BOXC in the following manner:

```
G:\Debugging Tools> windbg -remote npipe:server=BOXB,pipe=MyPipe,password=wrought
```

Here is another example. Your symbols are at the remote location, 127.0.0.30. So you decide to use a process server on the computer where the target is, 127.0.0.10. You put a repeater at 127.0.0.20.

You also decide to use reverse connections. So you begin by starting the client on 127.0.0.30:

```
G:\Debugging Tools> windbg -premote tcp:clicon=127.0.0.20,port=1033 notepad.exe
```

Then start the repeater on 127.0.0.20:

```
C:\Misc> dbengprx -c tcp:clicon=127.0.0.10,port=1025 -s tcp:port=1033,clicon=127.0.0.10
```

And finally start the process server on 127.0.0.10:

```
E:\Debugging Tools for Windows> dbgsrv -t tcp:port=1025,clicon=127.0.0.20
```

For a more complicated example using repeaters, see [Two Firewalls](#).

Advanced Remote Debugging Scenarios

5/26/2017 • 1 min to read • [Edit Online](#)

This section includes:

[Debugging Targets on Multiple Computers](#)

[Symbols in the Middle](#)

[Two Firewalls](#)

[Send comments about this topic to Microsoft](#)

Debugging Targets on Multiple Computers

5/26/2017 • 1 min to read • [Edit Online](#)

The debugger can debug multiple dump files or live user-mode applications at the same time. See [Debugging Multiple Targets](#) for details.

You can debug multiple live targets even if the processes are on different systems. Simply start a process server on each system, and then use the **-premote** parameter with [.attach \(Attach to Process\)](#) or [.create \(Create Process\)](#) to identify the proper process server.

The *current* or *active* system is the system currently being debugged. If you use the **.attach** or **.create** command again without specifying the **-premote** parameter, the debugger will attach to, or create, a process on the current system.

For details on how to control such a debugging session, see [Debugging Multiple Targets](#).

[Send comments about this topic to Microsoft](#)

Symbols in the Middle

5/26/2017 • 1 min to read • [Edit Online](#)

In this scenario, you have three computers. The first has the target application, the second has the symbols, and the third has the technician.

Since the smart client behaves like a regular debugger in every way, it can be used as a debugging server at the same time. This allows you to link three machines together with the smart client in the middle.

First, you start a process server on the computer \\BOXA:

```
dbgsrv -t npipe:pipe=FarPipe
```

The middle machine, named \\BOXB, starts the debugger with both the **-premove** and **-server** parameters.

Suppose the PID of the target application is 400 and the symbol path is G:\\MySymbols:

```
cdb -server npipe:pipe=NearPipe -premove npipe:server=BOXA,pipe=FarPipe -v -y g:\\mysymbols -p 400
```

Then a debugging client on a third machine can be started as follows:

```
windbg -remote npipe:server=BOXB,pipe=NearPipe
```

The third machine is then used to control the debugging, while the second machine is where the actual processing is done and the symbols are accessed.

[Send comments about this topic to Microsoft](#)

Two Firewalls

5/31/2017 • 1 min to read • [Edit Online](#)

In this scenario, you need to perform kernel debugging on a computer in Building A. Your technician is located in Building C, and he or she has access to symbols there. However, both buildings have firewalls that will not allow incoming connections.

You need to set up a repeater at a neutral site -- say, Building B. Then you can connect A outward to B, and connect C outward to B.

There will be four computers involved in this scenario:

- The target computer, located in Building A.
- The local host computer, located in Building A. This computer will run a KD connection server. It will be connected to the target computer by a debug cable or 1394 cable, and will connect outward to the repeater. Let this computer's IP address be 127.0.10.10.
- The computer in Building B. This will run the repeater. Let its IP address be 127.0.20.20.
- The computer in Building C where the technician is located. This computer will run WinDbg as a smart client. Let its IP address be 127.0.30.30.

First, make sure the target computer is configured for debugging and is attached to the local host computer. In this example, a 1394 cable is used.

Second, start the repeater on 127.0.20.20:

```
dbengprx -p -s tcp:port=9001 -c tcp:port=9000,clicon=127.0.10.10
```

Third, start the KD connection server on 127.0.10.10 in Building A as follows:

```
kdsrv -t tcp:port=9000,clicon=127.0.20.20,password=longjump
```

Finally, start the smart client on 127.0.30.30 in Building C. (This can actually be done before or after starting the server in Building A.)

```
windbg -k kdsrv:server=@{tcp:server=127.0.20.20,port=9001,password=longjump},trans=@{1394:channel=9} -y SymbolPath
```

Five-Computer Scenario

This scenario can be made even more complicated if you suppose that the symbols are on one computer in Building C, but the technician is at a different computer.

Suppose that 127.0.30.30 has the symbols, as before, and that its local name is \\BOXC. The smart client can be started with the same command as above but with an additional **-server** parameter. Since no one will be using this machine, it will take less processing time if you use KD instead of WinDbg:

```
kd -server npipe:pipe=randomname -k  
kdsrv:server=@{tcp:server=127.0.20.20,port=9001,password=longjump},trans=@{1394:channel=9} -y SymbolPath
```

Then the technician, elsewhere in the building, can start a debugging client as follows:

```
windbg -remote npipe:server=\\BOXC,pipe=randomname
```

Notice that the password must be supplied by the first non-repeater in the chain (the smart client on \\BOXC), not by the final debugger in the chain.

[Send comments about this topic to Microsoft](#)

Remote Debugging on Workgroup Computers

5/26/2017 • 2 min to read • [Edit Online](#)

You can perform remote debugging with computers that are joined to a workgroup. First configure the computer that will run the debugging server. Then activate the debugging server. After the debugging server is activated, you can connect to the server from a debugging client.

Configuring the debugging server computer

- Create a local administrator account, and log on using that account.
- Enable file and printer sharing for your active network. For example if your active network is Private, enable file and printer sharing for Private networks.

You can use Control Panel to enable file and printer sharing. For example, here are the steps in Windows 8.

1. Open Control Panel.
 2. Click **Network and Internet** and then **Network and Sharing Center**. Under **View your active networks**, note the type of network (for example, Private) that is active.
 3. Click **Change advanced sharing settings**. For your active network type, select **Turn on network discovery** and **Turn on file and printer sharing**.
- Start the remote registry service by following these steps.
 1. In a Command Prompt window or in the Run box, enter **services.msc**.
 2. Right click **Remote Registry**, and choose **Start**.
 - Turn off the ForceGuest feature by following these steps.
 1. In a Command Prompt window or in the Run box, enter **regedit**.
 2. In Registry Editor, set this value to 0.

HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\LSA\ForceGuest

Activating the debugging server

You can activate the debugging server through the debugger or by using a process server or a KD connection server. For more information, see the following topics.

- [Activating a Debugging Server](#)
- [Activating a Process Server](#)
- [Activating a KD Connection Server](#)

Activating the debugging client

There are several ways to activate a debugging client. For more information, see the following topics.

- [Activating a Debugging Client](#)
- [Activating a Smart Client](#)
- [Activating a Smart Client \(Kernel Mode\)](#)
- [Searching for Process Servers](#)
- [Searching for KD Connection Servers](#)

Note

If you are using a named pipe to connect a debugging client to a debugging server, you must provide the user name and password of an account that has access to the computer running the debugging server. Use one, but not both, of the following options.

- Log on to the debugging client computer with an account that shares the user name and password of an account on the debugging server computer.
- On the debugging client computer, in a Command Prompt window, enter the following command.

```
net use \\Server\ipc$ /user:UserName
```

where *Server* is the name of the server computer, and *UserName* is the name of an account that has access to the server computer.

When you are prompted, enter the password for *UserName*.

Debugging Tools for Windows: New for Windows 8

5/26/2017 • 1 min to read • [Edit Online](#)

Beginning with Windows 8, you can develop, build, and debug both kernel-mode and user-mode components all from Microsoft Visual Studio. There is added support for debugging over a network connection or a USB 3.0 connection and improved support for debugging optimized code and inline functions. For more information, see these topics:

- [Debugging Using Visual Studio](#)
- [Setting Up a Network Connection Manually](#)
- [Setting Up a USB 3.0 Connection Manually](#)
- [Debugging Optimized Code and Inline Functions](#)

Two new sets of debugger extension commands are included:

- [USB 3.0 Extensions](#)
- [RCDRKD Extensions](#)

In addition to Visual Studio, you can use the Windows debugger to debug Windows apps. The Debugging Tools for Windows package includes, [PLMDebug.exe](#), that enables you to take manual control of suspending, resuming, debugging, and terminating Windows app.

Sos.dll is a component that is used for debugging managed code. The Windows 8 Debugging Tools for Windows package does not include sos.dll. For information about how to get sos.dll, see [Getting the SOS Debugging Extension \(sos.dll\)](#).

Debugging Tools For Windows8 Release Notes

5/26/2017 • 1 min to read • [Edit Online](#)

Channel number for 1394 debugging in Visual Studio

If you use Microsoft Visual Studio to perform kernel-mode debugging over a 1394 cable, set the channel to a decimal integer between 1 and 62 inclusive. Do not set the channel to 0 when you first set up debugging. Because the default channel value is 0, the software assumes there is no change and does not update the settings. If you must use channel 0, first use an alternate channel (1 through 62) and then switch to channel 0.

Inline function debugging is on by default

In Windows 8, debugging of inline functions is turned on by default. The command **.inline 0** turns off inline function debugging, and the command **.inline 1** turns on inline function debugging.

Invalid port number in configuration page for network debugging

Issue: If an invalid port number is entered in the configuration page for kernel-mode network debugging, the configuration succeeds but the debugger on the host computer cannot connect to the target computer.

Workaround: Make sure the port number is valid. Valid port numbers range from 49152–65535. Also, your company might have restrictions on which ports can be used for network debugging. To ensure that a valid port number is entered, please check your internal IP Security Policy.

Use of **.remote** tool in command line

Issue: The use of **.remote** tool in the command line crashes the interface as it creates old style remote.exe using npipe.

Workaround: Use the **.server** command instead.

Design features for Visual Studio

- Automatic provisioning of a machine includes both user mode and kernel mode bootstrapping, regardless of which one is chosen. This requires two restarts for provisioning and takes between 8–20 minutes.
- Support for attaching only one process at a time.
- During a debugging session in Windows Debugger Extension for Visual Studio, exceptions are managed using the command line.

Global design features

- User must run in an elevated context in order to install the USB 3.0 XHCI filter driver. If the user is not running elevated, the PnP manager returns an error message that does not inform the user that elevation is the problem.
- If kernel debugging is enabled, the device used for kernel debugging should not be removed from the system while the device is still turned on. If the device is removed, the system will hang and will need to be restarted.

Debugging Windows XP and Windows Vista

5/26/2017 • 1 min to read • [Edit Online](#)

To use WinDbg to debug Windows XP or Windows Vista, get the Windows 7 Debugging Tools for Windows package, which is included in the [Microsoft Windows Software Development Kit \(SDK\) for Windows 7 and .NET Framework 4.0](#).

If you want to download only Debugging Tools for Windows, install the SDK, and, during the installation, select the **Debugging Tools for Windows** box and clear all the other boxes.

Note You might have to uninstall Microsoft Visual C++ 2010 Redistributable components before you install the SDK. For more information, see [the Microsoft Support website](#).

Debugging Tools (WinDbg, KD, CDB, NTSD) for Windows XP and Windows Vista

The Windows 7 Debugging Tools for Windows can run on x86-based or x64-based processors, and they can debug code that's running on x86-based or x64-based processors. Sometimes the debugger and the code being debugged run on the same computer, but other times the debugger and the code being debugged run on separate computers. In either case, the computer that's running the debugger is called the *host computer*, and the computer that is being debugged is called the *target computer*. Use the Windows 7 Debugging Tools for Windows when the target computer is running one of these operating systems.

Windows XP	Windows Server 2003
Windows Vista	Windows Server 2008

If the target computer is running a more recent version of Windows, get the current [Debugging Tools for Windows](#).

[Send comments about this topic to Microsoft](#)

Debugging Using Visual Studio

5/26/2017 • 1 min to read • [Edit Online](#)

Starting with Windows Driver Kit (WDK) 8, the driver development environment and the Windows debuggers are integrated into Microsoft Visual Studio. In this integrated environment, most of the tools you need for coding, building, packaging, testing, debugging, and deploying a driver are available in the Visual Studio user interface.

To get the integrated environment, first install Visual Studio, and then install the Windows Driver Kit (WDK). For more information, see [Windows Driver Kit \(WDK\)](#).

Important This feature is not available in Windows 10, version 1507 and later versions of the WDK.

Typically kernel-mode debugging requires two computers. The debugger runs on the *host computer*, and the code being debugged runs on the *target computer*. The target computer is also called the *test computer*. You can do user-mode debugging on a single computer, but in some cases you might want to debug a user-mode process that is running on a separate target computer.

In the Visual Studio environment, you can configure target computers for kernel-mode and user-mode debugging. You can establish a kernel-mode debugging session. You can attach to a user-mode process or launch and debug a user mode process on the host computer or a target computer. You can analyze dump files. In Visual Studio you can sign, deploy, install, and load a driver on a target computer.

These topics show you how to use Visual Studio to perform several of the tasks involved in debugging a driver.

[Send comments about this topic to Microsoft](#)

Debugging a User-Mode Process Using Visual Studio

5/26/2017 • 2 min to read • [Edit Online](#)

In Microsoft Visual Studio, you can use the Windows User Mode Debugger to attach to a running process or to spawn and attach to a new process. The process can run on the same computer that is running the debugger, or it can run on a separate computer.

The procedures shown in this topic require that you have the Windows Driver Kit integrated into Visual Studio. To get the integrated environment, first install Visual Studio, and then install the Windows Driver Kit (WDK). For more information, see [Windows Driver Kit \(WDK\)](#).

Attaching to a running process on the same computer

1. In Visual Studio, from the **Tools** menu, choose **Attach to Process**.
2. In the **Attach to Process** dialog box, set **Transport** to **Windows User Mode Debugger**, and set **Qualifier** to **localhost**.
3. In the **Available Processes** list, select the process that you want to attach to.
4. Click **Attach**.

Noninvasive debugging

If you want to debug a running process and interfere only minimally in its execution, you should debug the process [noninvasively](#).

Spawning a new process on the same computer

1. In Visual Studio, from the **Tools** menu, choose **Launch Under Debugger**.
2. In the **Launch Under Debugger** dialog box, enter the path to the executable file. You can also enter arguments and a working directory.
3. Click **Launch**.

Processes that the debugger creates (also known as spawned processes) behave a little differently than processes that the debugger does not create.

Instead of using the standard heap API, processes that the debugger creates use a special debug heap. You can force a spawned process to use the standard heap instead of the debug heap by using the `_NO_DEBUG_HEAP` environment variable.

Also, because the target application is a child process of the debugger, it inherits the debugger's permissions. This permission might enable the target application to perform certain actions that it could not perform otherwise. For example, the target application might be able to affect protected processes.

Attaching to a running process on a separate computer

Sometimes the debugger and the code being debugged run on separate computers. The computer that runs the debugger is called the *host computer*, and the computer that runs the code being debugged is called the *target computer*. You can configure a target computer from Visual Studio on the host computer. Configuring the target computer is also called *provisioning* the target computer. For more information, see [Provision a computer for driver deployment and testing \(WDK 8.1\)](#).

After you have provisioned a target computer, you can use Visual Studio on the host computer to attach to a process running on the target computer.

1. On the host computer, in Visual Studio, from the **Tools** menu, choose **Attach to Process**.
2. In the **Attach to Process** dialog box, set **Transport** to **Windows User Mode Debugger**, and set **Qualifier** to the name of the target computer.
3. In the **Available Processes** list, select the process that you want to attach to.
4. Click **Attach**.

Note

If you are using separate host and target computers, do not install Visual Studio and the WDK on the target computer. Debugging is not supported if Visual Studio and the WDK are installed on the target computer.

Source Code Debugging in Visual Studio

5/26/2017 • 1 min to read • [Edit Online](#)

The procedures shown in this topic require that you have the Windows Driver Kit integrated into Visual Studio. To get the integrated environment, first install Microsoft Visual Studio, and then install the Windows Driver Kit (WDK). For more information, see [Windows Driver Development](#).

To use source debugging, you must have your compiler or linker create symbol files (.pdb files) when the binaries are built. These symbol files show the debugger how the binary instructions correspond to the source lines. Also, the debugger must be able to access the actual source files. For more information, see [Source Path](#).

When you break in to the target computer, or when code running on the target computer hits a breakpoint, Visual Studio displays source code if it can find the source file. You can step through the source code by choosing one of the **Step** commands from the **Debug** menu. You can also set breakpoints by clicking in the left column of the source window. The following screen shot shows a source code window in the Visual Studio debugger.

Configuring Exceptions and Events in Visual Studio

5/26/2017 • 1 min to read • [Edit Online](#)

You can configure the Windows Debugger to react to specified exceptions and events in a pre-determined way. For each exception, you can set the break status and the handling status. For each event, you can set the break status.

The procedures shown in this topic require that you have the Windows Driver Kit integrated into Visual Studio. To get the integrated environment, first install Microsoft Visual Studio, and then install the Windows Driver Kit (WDK). For more information, see [Windows Driver Development](#).

You can configure the break status or the handling status by entering the following commands in the Debugger Immediate Window. If the Debugger Immediate Window is not already open, from the **Debug** menu, choose **Windows>Immediate**.

- [sxe](#)
- [sxd](#)
- [sxn](#)
- [sxi](#)

For a detailed discussion of exceptions and events, see [Controlling Exceptions and Events](#).

Keeping a Log File in Visual Studio

5/26/2017 • 1 min to read • [Edit Online](#)

The Windows Debugger can write a log file that records the debugging session. This log file contains all of the commands that you type and the responses from the debugger. In Microsoft Visual Studio, you can open, append, and close log files by entering commands in the Debugger Immediate Window.

The procedures shown in this topic require that you have the Windows Driver Kit integrated into Visual Studio. To get the integrated environment, first install Visual Studio, and then install the Windows Driver Kit (WDK). For more information, see [Windows Driver Development](#).

If the Debugger Immediate Window is not already open, from the **Debug** menu, choose **Windows>Immediate**.

Opening a New Log File

To open a new log file, enter the **.logopen (Open Log File)** command. If you use the **/t** option, the date and time are appended to your specified file name. If you use the **/u** option, the log file is written in Unicode instead of in ASCII.

Appending to an Existing Log File

To append text to an existing log file, enter the **.logappend (Append Log File)** command. If you are appending to a Unicode log file, you must use the **/u** option.

Closing a Log File

To close an open log file, enter the **.logclose (Close Log File)** command.

Checking Log File Status

To determine the log file status, enter the **.logfile (Display Log File Status)** command.

Setting Up Kernel-Mode Debugging in Visual Studio

5/26/2017 • 1 min to read • [Edit Online](#)

You can use Microsoft Visual Studio to set up and perform kernel-mode debugging of Windows. To use Visual Studio for kernel-mode debugging, you must have the Windows Driver Kit (WDK) integrated with Visual Studio. For information about how to install the integrated environment, see [Windows Driver Development](#).

Important This feature is not available in Windows 10, version 1507 and later versions of the WDK.

As an alternative to using Visual Studio to set up kernel-mode debugging, you can do the setup manually. For more information, see [Setting Up Kernel-Mode Debugging Manually](#).

Kernel-mode debugging typically requires two computers. The debugger runs on the *host computer*, and the code being debugged runs on the *target computer*.

Setting Up Kernel-Mode Debugging over a Network Cable in Visual Studio

5/31/2017 • 7 min to read • [Edit Online](#)

You can use Microsoft Visual Studio to set up and perform kernel-mode debugging over an Ethernet network. To use Visual Studio for kernel-mode debugging, you must have the Windows Driver Kit (WDK) integrated with Visual Studio. For information about how to install the integrated environment, see [Windows Driver Development](#).

As an alternative to using Visual Studio to set up Ethernet debugging, you can do the setup manually. For more information, see [Setting Up Kernel-Mode Debugging over a Network Cable Manually](#).

Debugging over an Ethernet network has the following advantages compared to debugging over other types of cable:

- The host and target computers can be anywhere on the local network.
- It is easy to debug many target computers from one host computer.
- Network cable is inexpensive and readily available.
- Given any two computers, it is likely that they will both have Ethernet adapters. It is less likely that they will both have serial ports or both have 1394 ports.

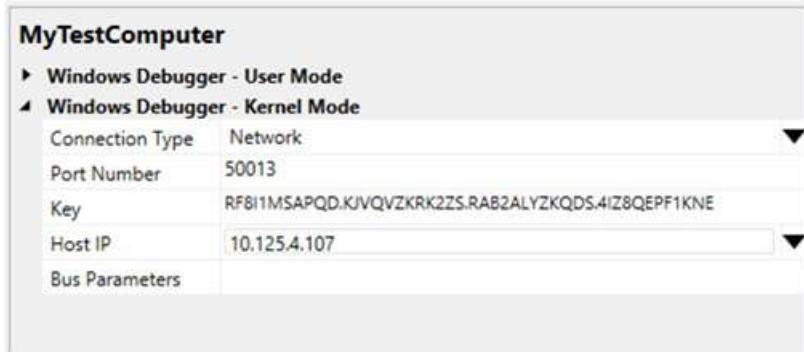

The computer that runs the debugger is called the *host computer*, and the computer that is being debugged is called the *target computer*. The host computer must be running Windows XP or later, and the target computer must be running Windows 8 or later.

Supported network adapters

The host computer can use any wired or wireless network adapter, but the target computer must use a network adapter that is supported by Debugging Tools for Windows. For a list of supported network adapters, see [Supported Ethernet NICs for Network Kernel Debugging in Windows 8.1](#).

Configuring the host and target computer

1. Connect the network adapter of the target computer to a network hub or switch using standard CAT5 (or higher-level) network cable. Do not use a crossover cable, and do not use a crossover port in your hub or switch. Connect the network adapter of the host computer to a network hub or switch using a standard cable or a wireless connection.
2. Begin configuring your host and target computers as described in [Provision a computer for driver deployment and testing \(WDK 8.1\)](#).
3. On the host computer, in Visual Studio, when you come to the Computer Configuration dialog box, select **Provision computer and choose debugger settings**.
4. For **Connection Type**, choose **Network**.

For **Port Number**, accept the default value or fill in a value of your choice. You can choose any number from 49152 through 65535. The port that you choose will be opened for exclusive access by the debugger running on the host computer. Take care to choose a port number that is not used by any other applications that run on the host computer.

Note The range of port numbers that can be used for network debugging might be limited by your company's network policy. There is no way to tell from the host computer what the limitations are. To determine whether your company's policy limits the range of ports that can be used for network debugging, check with your network administrators.

For **Key**, we strongly recommend that you use the automatically generated default value. However, you can enter your own key if you prefer. For more information, see [Creating your own key](#creating-your-own-key) later in this topic. For **Host IP**, accept the default value. This is the IP address of your host computer.

If your target computer has only one network adapter, you can leave **Bus Parameters** empty. If there is more than one network adapter on the target computer, use Device Manager on the target computer to determine the PCI bus, device, and function numbers for the adapter you want to use for debugging. For **Bus Parameters**, enter ***b*. *d*. *f*** where ***b***, ***d***, and ***f*** are the bus number, device number, and function number of the adapter.

1. The configuration process takes several minutes and might automatically reboot the target computer once or twice. When the process is complete, click **Finish**.

Caution If your target computer is in a docking station, and you have network debugging enabled for a network adapter that is part of the docking station, do not remove the computer from the docking station. If you need to remove the target computer from the docking station, disable kernel debugging first. To disable kernel debugging on the target computer, open a Command Prompt window as Administrator and enter the command **bcdedit /debug off**. Reboot the target computer.

Note If you intend to install the Hyper-V role on the target computer, see [Setting Up Network Debugging of a Virtual Machine Host](#).

Verifying dbgsettings on the Target Computer

On the target computer, open a Command Prompt window as Administrator, and enter these commands:

bcdedit /dbgsettings

bcdedit /enum

```
...
key RF8...KNE
debugtype NET
hostip 10.125.5.10
port 50001
dhcp Yes
...
busparams 0.29.7
...
```

Verify that *debugtype* is NET and *port* is the port number you specified in Visual Studio on the host computer. Also verify that *key* is the key that was automatically generated (or you specified) in Visual Studio.

If you entered **Bus Parameters** in Visual Studio, verify that *busparams* matches the bus parameters you specified.

If you do not see the value you entered for **Bus Parameters**, enter this command:

```
bcdedit /set "{dbgsettings}" busparams b.d.f
```

where *b*, *d*, and *f* are the bus, device, and function numbers of the network adapter on the target computer that you have chosen to use for debugging.

For example:

```
bcdedit /set "{dbgsettings}" busparams 0.29.7
```

Starting the Debugging Session

1. On the host computer, in Visual Studio, on the **Tools** menu, choose **Attach to Process**.
2. For **Transport**, choose **Windows Kernel Mode Debugger**.
3. For **Qualifier**, select the name of the target computer that you previously configured.
4. Click **Attach**.

Allowing the debugger through the firewall

When you first attempt to establish a network debugging connection, you might be prompted to allow the debugging application (Microsoft Visual Studio) through the firewall. Client versions of Windows display the prompt, but Server versions of Windows do not display the prompt. Respond to the prompt by checking the boxes for all three network types: domain, private, and public. If you do not get the prompt, or if you did not check the boxes when the prompt was available, you must use Control Panel to allow access through the firewall. Open **Control Panel > System and Security**, and click **Allow an app through Windows Firewall**. In the list of applications, use the check boxes to allow Visual Studio through the firewall. Restart Visual Studio.

Creating Your Own Key

To keep the target computer secure, packets that travel between the host and target computers must be encrypted. We strongly recommend that you use an automatically generated encryption key (provided by the Visual Studio configuration wizard) when you configure the target computer). However, you can choose to create your own key. Network debugging uses a 256-bit key that is specified as four 64-bit values, in base 36, separated by periods. Each 64-bit value is specified by using up to 13 characters. Valid characters are the letters a through z and the digits 0 through 9. Special characters are not allowed. The following list gives examples of valid (although not strong) keys:

- 1.2.3.4
- abc.123.def.456
- dont.use.previous.keys

Troubleshooting Tips for Debugging over a Network Cable

Debugging application must be allowed through firewall

Your debugger (WinDbg or KD) must have access through the firewall. You can use Control Panel to allow access through the firewall. Open **Control Panel > System and Security**, and click **Allow an app through Windows Firewall**. In the list of applications, use the check boxes to allow Visual Studio through the firewall. Restart Visual Studio.

Port number must be in range allowed by network policy

The range of port numbers that can be used for network debugging might be limited by your company's network policy. To determine whether your company's policy limits the range of ports that can be used for network debugging, check with your network administrator.

Use the following procedure if you need to change the port number.

1. On the host computer, in Visual Studio, on the **Driver** menu, choose **Test > Configure Computers**.
2. Select the name of your test computer, and click **Next**.
3. Select **Provision computer and choose debugger settings**. Click **Next**.
4. For **Port Number**, enter a number that is in the range allowed by your network administrator. Click **Next**.
5. The reconfiguration process takes a few minutes and automatically reboots the target computer. When the process is complete, click **Next** and **Finish**.

Specify busparams if target computer has multiple network adapters

If your target computer has more than one network adapter, you must specify the bus, device, and function numbers of the network adapter that you intend to use for debugging. To specify the bus parameters, open Device Manager, and locate the network adapter that you want to use for debugging. Open the property page for the network adapter, and make a note of the bus number, device number, and function number. In an elevated Command Prompt Window, enter the following command, where *b*, *d*, and *f* are the bus, device and function numbers in decimal format:

```
bcddedit -set "{dbgsettings}" busparams b.d.f
```

Reboot the target computer.

Setting Up Kernel-Mode Debugging over a 1394 Cable in Visual Studio

5/31/2017 • 4 min to read • [Edit Online](#)

You can use Microsoft Visual Studio to set up and perform kernel-mode debugging over a 1394 (Firewire) cable. To use Visual Studio for kernel-mode debugging, you must have the Windows Driver Kit (WDK) integrated with Visual Studio. For information about how to install the integrated environment, see [Windows Driver Development](#).

As an alternative to using Visual Studio to set up 1394 debugging, you can do the setup manually. For more information, see [Setting Up Kernel-Mode Debugging over a 1394 Cable Manually](#).

The computer that runs the debugger is called the *host computer*, and the computer that is being debugged is called the *target computer*. The host and target computers must each have a 1394 adapter.

Configuring the host and target computers

1. Connect a 1394 cable to the 1394 controllers that you have chosen for debugging on the host and target computers.
2. Begin configuring your host and target computers as described in [Provision a computer for driver deployment and testing \(WDK 8.1\)](#).
3. On the host computer, in Visual Studio, when you get to the Computer Configuration dialog, select **Provision computer and choose debugger settings**.
4. For **Connection Type**, choose **Firewire**.

For **Channel**, enter a decimal number of your choice from 1 through 62.

Note Do not set the channel to 0 when you first set up debugging. Because the default channel value is 0, the software assumes there is no change and does not update the settings. If you must use channel 0, first use an alternate channel (1 through 62) and then switch to channel 0.

If you have more than one 1394 controller on the target computer, enter a **Bus Parameters** value of ***b*.d*.f***, where ***b***, ***d***, and ***f*** are the bus, device, and function numbers for the 1394 controller that you intend to use for debugging on the target computer. The bus, device, and function numbers must be in decimal format (example: 4.4.0).

1. The configuration process takes several minutes and might automatically reboot the target computer once or twice. When the process is complete, click **Finish**.

Verifying dbgsettings on the Target Computer

On the target computer, open a Command Prompt window as Administrator, and enter this command:

bcdedit /dbgsettings

bcdedit /enum

```
...
debugtype      1394
debugport      1
baudrate      115200
channel        1
...
busparams      4.0.0
...
```

Verify that *debugtype* is 1394 and *channel* is the channel number you specified in Visual Studio on the host computer. You can ignore the values of *debugport* and *baudrate*; they do not apply to debugging over 1394.

If you entered **Bus Parameters** in Visual Studio, verify that *busparams* matches the bus parameters you specified.

If you do not see the value you entered for **Bus Parameters**, enter this command:

```
bcdedit /set "{dbgsettings}" busparams b.d.f
```

where *b*, *d*, and *f* are the bus, device, and function numbers of the 1394 controller on the target computer that you have chosen to use for debugging.

For example:

```
bcdedit /set "{dbgsettings}" busparams 4.4.0
```

Starting a Debugging Session for the First Time

1. On the host computer, open Visual Studio as Administrator.
2. On the **Tools** menu, choose **Attach to Process**.
3. For **Transport**, choose **Windows Kernel Mode Debugger**.
4. For **Qualifier**, select the name of the target computer that you previously configured.
5. Click **Attach**.

At this point, the 1394 debug driver gets installed on the host computer. This is why it is important to run Visual Studio as Administrator. After the 1394 debug driver is installed, you do not need to run as Administrator for subsequent debugging sessions.

Starting a Debugging Session

1. On the host computer, in Visual Studio, on the **Tools** menu, choose **Attach to Process**.
2. For **Transport**, choose **Windows Kernel Mode Debugger**.
3. For **Qualifier**, select the name of the target computer that you previously configured.
4. Click **Attach**.

Troubleshooting Tips for Debugging over a 1394 Cable

Most 1394 debugging problems are caused by using multiple 1394 controllers in either the host or target computer. Using multiple 1394 controllers in the host computer is not supported. The 1394 debug driver, which runs on the host, can communicate only with the first 1394 controller enumerated in the registry. If you have a 1394 controller built into the motherboard and a separate 1394 card, either remove the card or disable (by using Device Manager) the built-in controller.

The target computer can have multiple 1394 controllers, although this is not recommended. If your target computer has a 1394 controller on the motherboard, use that controller for debugging, if possible. If there is an additional 1394 card, you should remove the card and use the onboard controller. Another solution is to disable the onboard 1394 controller in the BIOS settings of the computer.

If you decide to have multiple 1394 controllers enabled on the target computer, you must specify bus parameters so that the debugger knows which controller to claim for debugging. To specify the bus parameters, Open Device Manager, and locate the 1394 controller that you want to use for debugging. Open the property page for the controller, and make a note of the bus number, device number, and function number. In an elevated Command Prompt Window, enter the following command, where *b*, *d*, and *f* are the bus, device and function numbers in decimal format:

```
bcdedit /set "{dbgsettings}" busparams b.d.f
```

Reboot the target computer.

Setting Up Kernel-Mode Debugging over a USB 3.0 Cable in Visual Studio

5/31/2017 • 5 min to read • [Edit Online](#)

You can use Microsoft Visual Studio to set up and perform kernel-mode debugging over a USB 3.0 cable. To use Visual Studio for kernel-mode debugging, you must have the Windows Driver Kit (WDK) integrated with Visual Studio. For information about how to install the integrated environment, see [Windows Driver Development](#).

As an alternative to using Visual Studio to set up USB 3.0 debugging, you can do the setup manually. For more information, see [Setting Up Kernel-Mode Debugging over a USB 3.0 Cable Manually](#).

The computer that runs the debugger is called the *host computer*, and the computer that is being debugged is called the *target computer*.

Debugging over a USB 3.0 connection requires the following hardware:

- A USB 3.0 debug cable. This is an A-A crossover cable that has only the USB 3.0 lines and no Vbus.
- On the host computer, an xHCI (USB 3.0) host controller
- On the target computer, an xHCI (USB 3.0) host controller that supports debugging

Identifying a Debug Port on the Target Computer

1. On the target computer, launch the UsbView tool. The UsbView tool is included in Debugging Tools for Windows.
2. In UsbView, locate all of the xHCI host controllers.
3. In UsbView, expand the nodes of the xHCI host controllers. Look for an indication that a port on the host controller supports debugging.

```
[Port1]

Is Port User Connectable: yes
Is Port Debug Capable: yes
Companion Port Number: 3
Companion Hub Symbolic Link Name: USB#ROOT_HUB30#5&32bab638&0&0#\...
Protocols Supported:
  USB 1.1: no
  USB 2.0: no
  USB 3.0: yes
```

4. Make a note of the bus, device, and function numbers for the xHCI controller that you intend to use for debugging. UsbView displays these numbers. In the following example, the bus number is 48, the device number is 0, and the function number is 0.

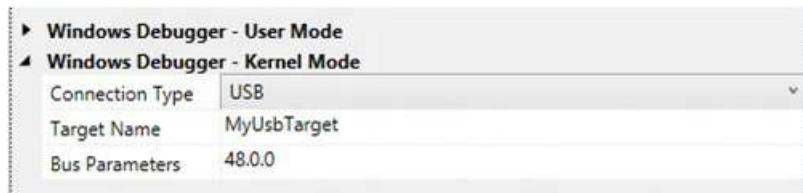

```
USB xHCI Compliant Host Controller
...
DriverKey: {36fc9e60-c465-11cf-8056-444553540000}\0020
...
Bus.Device.Function (in decimal): 48.0.0
```

5. After you have identified an xHCI controller that supports debugging, the next step is to locate the physical

USB connector that is associated with a port on the xHCI controller. To find the physical connector, plug any USB 3.0 device into any USB connector on the target computer. Refresh UsbView to see where your device is located. If UsbView shows your device connected to the xHCI host controller, then you have found a physical USB connector that you can use for USB 3.0 debugging.

Configuring the host and target computers

1. Begin configuring your host and target computers as described in [Provision a computer for driver deployment and testing \(WDK 8.1\)](#).
2. On the host computer, in Visual Studio, when you come to the Computer Configuration dialog box, select **Provision computer and choose debugger settings**.
3. For **Connection Type**, choose **USB**.

For **Target Name**, enter a string to represent the target computer. This string does not have to be the official name of the target computer; it can be any string that you create as long as it meets these restrictions:

- The maximum length of the string is 24 characters.
- The only characters in the string are the hyphen (-), the underscore(_), the digits 0 through 9, and the letters A through Z (upper or lower case).

If you have more than one USB host controller on the target computer, enter a **Bus Parameters** value of *b.d.f*, where *b*, *d*, and *f* are the bus, device, and function numbers for the USB host controller that you intend to use for debugging on the target computer. The bus, device, and function numbers must be in decimal format (example: 48.0.0).

4. The configuration process takes several minutes and might automatically reboot the target computer once or twice. When the process is complete, click **Finish**.

Verifying dbgsettings on the Target Computer

On the target computer, open a Command Prompt window as Administrator, and enter these commands:

bcdedit /dbgsettings

bcdedit /enum

...	
targetname	MyUsbTarget
debugtype	USB
debugport	1
baudrate	115200
...	
busparams	48.0.0

Verify that *debugtype* is USB and *targetname* is the name you specified in Visual Studio on the host computer. You can ignore the values of *debugport* and *baudrate*; they do not apply to debugging over USB.

If you entered **Bus Parameters** in Visual Studio, verify that *busparams* matches the bus parameters you specified.

If you do not see the value you entered for **Bus Parameters**, enter this command:

```
bcdedit /set "{dbgsettings}" busparams b.d.f
```

where *b*, *d*, and *f* are the bus, device, and function numbers of the xHCI controller on the target computer that you have chosen to use for debugging.

Example:

```
bcdedit /set "{dbgsettings}" busparams 48.0.0
```

Reboot the target computer.

Starting a Debugging Session for the First Time

1. Connect a Universal Serial Bus (USB) 3.0 debug cable to the USB 3.0 ports that you have chosen for debugging on the host and target computers.
2. On the host computer, open Visual Studio as Administrator.
3. On the **Tools** menu, choose **Attach to Process**.
4. For **Transport**, choose **Windows Kernel Mode Debugger**.
5. For **Qualifier**, select the name of the target computer that you previously configured.
6. Click **Attach**.

At this point, the USB debug driver gets installed on the host computer. This is why it is important to run Visual Studio as Administrator. After the USB debug driver is installed, you do not need to run as Administrator for subsequent debugging sessions.

Starting a Debugging Session

1. On the host computer, in Visual Studio, on the **Tools** menu, choose **Attach to Process**.
2. For **Transport**, choose **Windows Kernel Mode Debugger**.
3. For **Qualifier**, select the name of the target computer that you previously configured.
4. Click **Attach**.

Troubleshooting tips for debugging over USB 3.0

In some cases, power transitions can interfere with debugging over USB 3.0. If you have this problem, disable selective suspend for the xHCI host controller (and its root hub) that you are using for debugging.

1. In Device Manager, navigate to the node for the xHCI host controller. Right click the node, and choose **Properties**. If there is a **Power Management** tab, open the tab, and clear the **Allow the computer to turn off this device to save power** check box.
2. In Device Manager, navigate to the node for the root hub of the xHCI host controller. Right click the node, and choose **Properties**. If there is a **Power Management** tab, open the tab, and clear the **Allow the computer to turn off this device to save power** check box.

When you have finished using the xHCI host controller for debugging, enable selective suspend for the xHCI host controller.

[Setting Up Kernel-Mode Debugging in Visual Studio](#)

[Send comments about this topic to Microsoft](#)

Setting Up Kernel-Mode Debugging over a USB 2.0 Cable in Visual Studio

5/31/2017 • 5 min to read • [Edit Online](#)

You can use Microsoft Visual Studio to set up and perform kernel-mode debugging over a USB 2.0 cable. To use Visual Studio for kernel-mode debugging, you must have the Windows Driver Kit (WDK) integrated with Visual Studio. For information about how to install the integrated environment, see [Windows Driver Development](#).

As an alternative to using Visual Studio to set up USB 2.0 debugging, you can do the setup manually. For more information, see [Setting Up Kernel-Mode Debugging over a USB 2.0 Cable Manually](#).

The computer that runs the debugger is called the *host computer*, and the computer that is being debugged is called the *target computer*.

Debugging over a USB 2.0 connection requires the following hardware:

- A Universal Serial Bus (USB) 2.0 debug cable. This cable is not a standard USB 2.0 cable, because it has an extra hardware component that makes it compatible with the USB2 Debug Device Functional Specification. You can find these cables by doing an Internet search for "USB 2.0 debug cable".
- On the host computer, an EHCI (USB 2.0) host controller
- On the target computer, an EHCI (USB 2.0) host controller that supports debugging

Identifying a Debug Port on the Target Computer

1. On the target computer, launch the UsbView tool. The UsbView tool is included in Debugging Tools for Windows.
2. In UsbView, locate all of the host controllers that are compatible with the EHCI specification. For example, you could look for controllers that are listed as Enhanced.
3. In UsbView, expand the nodes of the EHCI host controllers. Look for an indication that a host controller supports debugging, and look for the number of the debug port. For example, UsbView displays this output for an EHCI host controller that supports debugging on port 1.

```
XXX XXX XXX USB2 Enhanced Host Controller - 293A
...
Debug Port Number: 1
Bus.Device.Function (in decimal): 0.29.7
```

Note Many EHCI host controllers support debugging on port 1, but some EHCI host controllers support debugging on port 2.

4. Make a note of the bus, device, and function numbers for the EHCI controller that you intend to use for debugging. UsbView displays these number. In the preceding example, the bus number is 0, the device number is 29, and the function number is 7.
5. After you have identified the EHCI controller and the port number that supports debugging, the next step is to locate the physical USB connector that is associated with the correct port number. To find the physical connector, plug any USB 2.0 device into any USB connector on the target computer. Refresh UsbView to see where your device is located. If UsbView shows your device connected to the EHCI host controller and port that you identified as the debug port, then you have found a physical USB connector that you can use for

debugging. It could be that there is no external physical USB connector that is associated with a debug port on an EHCI controller. In that case, you can look for a physical USB connector inside the computer. Perform the same steps to determine whether the internal USB connector is suitable for kernel debugging. If you cannot find a physical USB connector (either external or internal) that is associated with a debug port, then you cannot use the computer as a target for debugging over a USB 2.0 cable.

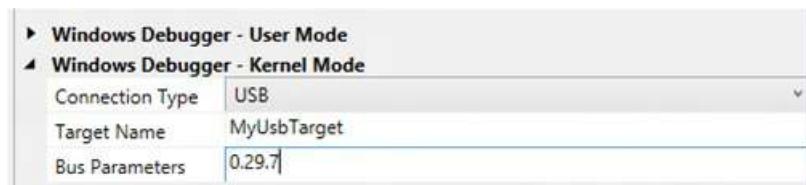

Note See [this remark](#) for an exception.

Connecting the USB debug cable

1. Verify that the host computer is not configured to be the target of USB debugging. (If necessary, open a Command Prompt window as Administrator, enter **bcdedit /debug off**, and reboot.)
2. On the host computer, use UsbView to find the EHCI host controllers and ports that support debugging. If possible, plug one end of the USB 2.0 debug cable into an EHCI port (on the host computer) that does not support debugging. Otherwise, plug the cable into any EHCI port on the host computer.
3. Plug the other end of the USB 2.0 debug cable into the connector that you identified previously on the target computer.

Configuring the host and target computers

1. Begin configuring your host and target computers as described in [Provision a computer for driver deployment and testing \(WDK 8.1\)](#).
2. On the host computer, in Visual Studio, when you come to the Computer Configuration dialog box, select **Provision computer and choose debugger settings**.
3. For **Connection Type**, choose **USB**.

For **Target Name**, enter a string to represent the target computer. This string does not have to be the official name of the target computer; it can be any string that you create as long as it meets these restrictions:

- The maximum length of the string is 24 characters.
- The only characters in the string are the hyphen (-), the underscore(_), the digits 0 through 9, and the letters A through Z (upper or lower case).

If you have more than one USB host controller on the target computer, enter a **Bus Parameters** value of *b.d.f*, where *b*, *d*, and *f* are the bus, device, and function numbers for the USB host controller that you intend to use for debugging on the target computer. The bus, device, and function numbers must be in decimal format (example: 0.29.7).

4. The configuration process takes several minutes and might automatically reboot the target computer once or twice. When the process is complete, click **Finish**.

Verifying dbgsettings on the Target Computer

On the target computer, open a Command Prompt window as Administrator, and enter these commands:

bcdedit /dbgsettings

bcdedit /enum

```
...
targetname      MyUsbTarget
debugtype       USB
debugport       1
baudrate        115200
...
busparams      0.29.7
...
```

Verify that *debugtype* is USB and *targetname* is the name you specified in Visual Studio on the host computer. You can ignore the values of *debugport* and *baudrate*; they do not apply to debugging over USB.

If you entered **Bus Parameters** in Visual Studio, verify that *busparams* matches the bus parameters you specified.

If you do not see the value you entered for **Bus Parameters**, enter this command:

```
bcdedit /set "{dbgsettings}" busparams b.d.f
```

where *b*, *d*, and *f* are the bus, device, and function numbers of the EHCI controller on the target computer that you have chosen to use for debugging.

Example:

```
bcdedit /set "{dbgsettings}" busparams 0.29.7
```

Reboot the target computer.

Starting a Debugging Session for the First Time

1. Connect a USB 2.0 debug cable to the USB 2.0 ports that you have chosen for debugging on the host and target computers.
2. On the host computer, open Visual Studio as Administrator.
3. On the **Tools** menu, choose **Attach to Process**.
4. For **Transport**, choose **Windows Kernel Mode Debugger**.
5. For **Qualifier**, select the name of the target computer that you previously configured.
6. Click **Attach**.

At this point, the USB debug driver gets installed on the host computer. This is why it is important to run Visual Studio as Administrator. After the USB debug driver is installed, you do not need to run as Administrator for subsequent debugging sessions.

Starting a Debugging Session

1. On the host computer, in Visual Studio, on the **Tools** menu, choose **Attach to Process**.
2. For **Transport**, choose **Windows Kernel Mode Debugger**.
3. For **Qualifier**, select the target name that you entered during configuration.
4. Click **Attach**.

Setting Up Kernel-Mode Debugging over a Serial Cable in Visual Studio

5/26/2017 • 3 min to read • [Edit Online](#)

You can use Microsoft Visual Studio to set up and perform kernel-mode debugging over a null-modem cable. Null-modem cables are serial cables that have been configured to send data between two serial ports. They are available at most computer stores. Do not confuse null-modem cables with standard serial cables. Standard serial cables do not connect serial ports to each other. For information about how null-modem cables are wired, see [Null-Modem Cable Wiring](#).

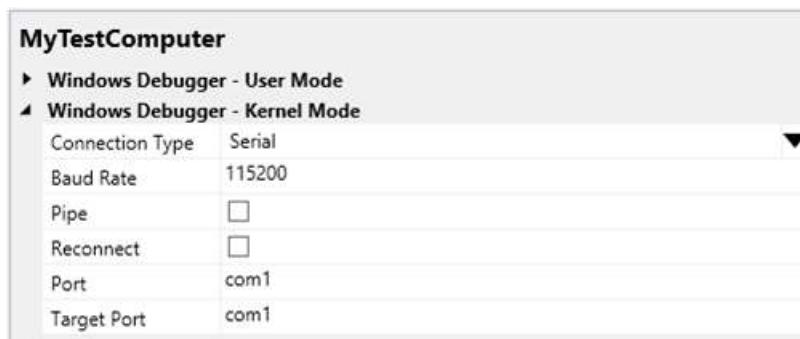

To use Visual Studio for kernel-mode debugging, you must have the Windows Driver Kit (WDK) integrated with Visual Studio. For information about how to install the integrated environment, see [Windows Driver Development](#).

As an alternative to using Visual Studio to set up serial debugging, you can do the setup manually. For more information, see [Setting Up Kernel-Mode Debugging over a Serial Cable Manually](#).

The computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*.

Configuring the host and target computers

1. Begin configuring your host and target computer as described in [Provision a computer for driver deployment and testing \(WDK 8.1\)](#).
2. On the host computer, in Visual Studio, when you come to the Computer Configuration dialog box, select **Provision computer and choose debugger settings**.
3. For **Connection Type**, choose **Serial**.

For **Baud Rate**, accept the default value or enter the baud rate you want to use. For **Port**, enter the name of the COM port that you want to use for debugging on the host computer. For **Target Port**, enter the name of the COM port that you want to use for debugging on the target computer.

4. The configuration process takes several minutes and might automatically reboot the target computer once or twice. When the process is complete, click **Finish**.

Starting the Debugging Session

1. Connect the null-modem cable to the COM ports that you have chosen for debugging on the host and target computers.
2. On the host computer, in Visual Studio, on the **Tools** menu, choose **Attach to Process**.
3. For **Transport**, choose **Windows Kernel Mode Debugger**.

4. For **Qualifier**, select the name of the target computer that you previously configured.

5. Click **Attach**.

Troubleshooting Tips for Debugging over a Serial Cable

Specify correct COM ports and baud rate

Determine the numbers of the COM ports you are using for debugging on the host and target computers. For example, suppose you have your null-modem cable connected to COM1 on the host computer and COM2 on the target computer. Also suppose you have chosen a baud rate of 115200.

1. On the host computer, in Visual Studio, on the **Driver** menu, choose **Test > Configure Computers**.
2. Select the name of your test computer, and click **Next**.
3. Select **Provision computer and choose debugger settings**. Click **Next**.
4. If you are using COM1 on the host computer, for **Port**, enter com1. If you are using COM2 on the target computer, for **Target Port**, enter com2.
5. If you have chosen to use a baud rate of 115200, for **Baud Rate**, enter 115200.

You can double check the COM port and baud rate settings on the target computer by opening a Command Prompt window as Administrator, and entering **bcdedit /dbgsettings**. If you are using COM2 on the target computer and a baud rate of 115200, the output of **bcdedit** should show `debugport 2` and `baudrate 115200`.

Null Modem Cable Wiring

The following tables show how null-modem cables are wired.

9-pin connector

CONNECTOR 1	CONNECTOR 2	SIGNALS
2	3	Tx - Rx
3	2	Rx - Tx
7	8	RTS - CTS
8	7	CTS - RTS
4	1+6	DTR - (CD+DSR)
1+6	4	(CD+DSR) - DTR
5	5	Signal ground

25-pin connector

CONNECTOR 1	CONNECTOR 2	SIGNALS
2	3	Tx - Rx
3	2	Rx - Tx
4	5	RTS - CTS

CONNECTOR 1	CONNECTOR 2	SIGNALS
5	4	CTS - RTS
6	20	DSR - DTR
20	6	DTR - DSR
7	7	Signal ground

Signal Abbreviations

ABBREVIATION	SIGNAL
Tx	Transmit data
Rx	Receive data
RTS	Request to send
CTS	Clear to send
DTR	Data terminal ready
DSR	Data set ready
CD	Carrier detect

Setting Up Kernel-Mode Debugging using Serial over USB in Visual Studio

5/26/2017 • 3 min to read • [Edit Online](#)

The [Sharks Cove development board](#) supports serial debugging over a USB cable.

To use Microsoft Visual Studio for kernel-mode debugging, you must have the Windows Driver Kit (WDK) integrated with Visual Studio. For information about how to install the integrated environment, see [Windows Driver Kit \(WDK\)](#).

As an alternative to using Visual Studio to set up serial debugging over a USB cable, you can do the setup manually. For more information, see [Setting Up Kernel-Mode Debugging using Serial over USB Manually](#).

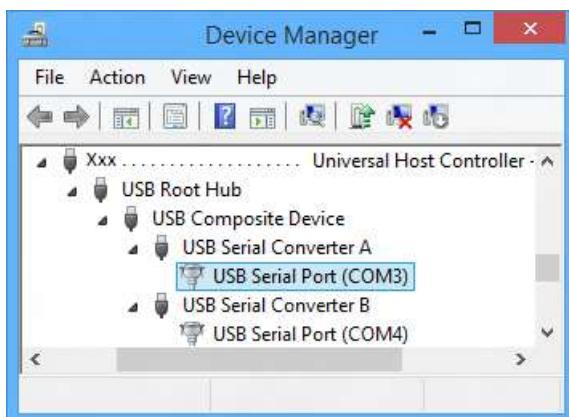

The computer that runs the debugger is called the *host computer*, and the computer being debugged is called the *target computer*. In this topic, the Sharks Cove board is the target computer.

Setting up a Host Computer for debugging the Sharks Cove board

1. On the host computer, open Device Manager. On the **View** menu, choose **Devices by Type**.
2. On the Sharks Cove board, locate the debug connector. This is the micro USB connector shown in the following picture.

3. Use a USB 2.0 cable to connect the host computer to the debug connector on the Sharks Cove board.
4. On the host computer, in Device Manager, two COM ports will get enumerated. Select the lowest numbered COM port. On the **View** menu, choose **Devices by Connection**. Verify that the COM port is listed under one of the USB host controllers.

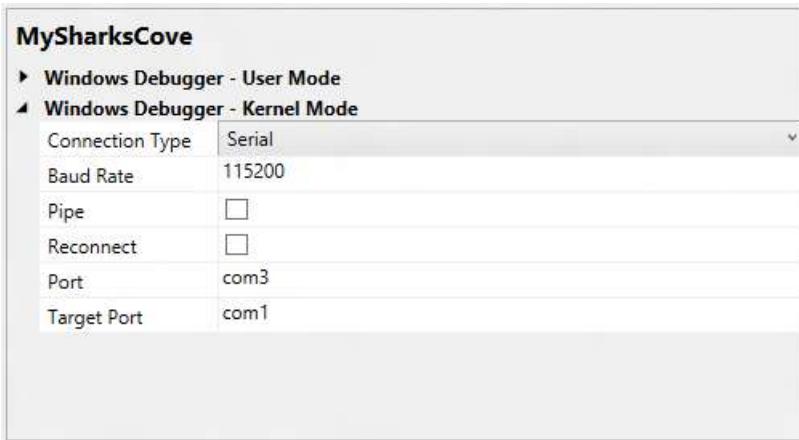

Make a note of the COM port number. This is the lowest COM port number that shows under the USB host

controller node. For example, in the preceding screen shot, the lowest COM port number under the USB host controller is COM3. You will need this COM port number later when you start a debugging session. If the driver is not already installed for the COM port, right click the COM port node, and choose **Update Driver**. Then select **Search automatically for updated driver software**. You will need an internet connection for this.

Configuring the host and target computers

In these steps, the Sharks Cove board is the target computer.

1. Begin configuring your host and target computer as described in [Provision a computer for driver deployment and testing \(WDK 8.1\)](#).
2. On the host computer, in Visual Studio, when you come to the Computer Configuration dialog box, select **Provision computer and choose debugger settings**.
3. For **Connection Type**, choose **Serial**.

For **Baud Rate**, enter 115200. For **Port**, enter the name of the COM port that you noted previously in Device Manager (for example, com3). For **Target Port**, enter com1.

4. The configuration process takes several minutes and might automatically reboot the target computer once or twice. When the process is complete, click **Finish**.

Starting the Debugging Session

1. On the host computer, in Visual Studio, on the **Tools** menu, choose **Attach to Process**.
2. For **Transport**, choose **Windows Kernel Mode Debugger**.
3. For **Qualifier**, select the name of the target computer that you previously configured.
4. Click **Attach**.

Troubleshooting Tips for Serial Debugging over a USB Cable

Specify correct COM port on both host and target

On the target computer (Sharks Cove board), verify that you are using COM1 for debugging. Open a Command Prompt window as Administrator, and enter **bcdedit /dbgsettings**. The output of **bcdedit** should show `debugport 1`.

On the host computer, verify that you are using the COM port that you noted earlier in Device Manager.

1. On the host computer, in Visual Studio, on the **Driver** menu, choose **Test > Configure Computers**.
2. Select the name of your test computer, and click **Next**.
3. Select **Provision computer and choose debugger settings**. Click **Next**.
4. Verify that the correct COM port number is listed for **Port**.

Baud rate must be the same on host and target

The baud rate must be 115200 on both the host and target computers.

On the target computer (Sharks Cove board), open a Command Prompt window as Administrator, and enter **bcdedit /dbgsettings**. The output of **bcdedit** should show `baudrate 115200`.

On the host computer, verify that you are using a baud rate of 115200.

1. On the host computer, in Visual Studio, on the **Driver** menu, choose **Test > Configure Computers**.
2. Select the name of your test computer, and click **Next**.
3. Select **Provision computer and choose debugger settings**. Click **Next**.
4. Verify that the **Baud Rate** is 115200.

Setting Up Kernel-Mode Debugging of a Virtual Machine in Visual Studio

5/26/2017 • 2 min to read • [Edit Online](#)

You can use Microsoft Visual Studio to set up and perform kernel-mode debugging of a virtual machine. The virtual machine can be located on the same physical computer as the debugger or on a different computer that is connected to the same network. To use Visual Studio for kernel-mode debugging, you must have the Windows Driver Kit (WDK) integrated with Visual Studio. For information about how to install the integrated environment, see [Windows Driver Development](#).

As an alternative to using Visual Studio to set up debugging of a virtual machine, you can do the setup manually. For more information, see [Setting Up Kernel-Mode Debugging of a Virtual Machine Manually](#).

The computer that runs the debugger is called the *host computer*, and the virtual machine that is being debugged is called the *target virtual machine*.

Configuring the Target Virtual Machine

1. In the virtual machine, in an elevated Command Prompt window, enter the following commands.

```
bcdedit /debug on
```

```
bcdedit /dbgsettings serial debugport:n baudrate:115200
```

where *n* is the number of a COM port on the virtual machine.

2. Reboot the virtual machine.
3. In the virtual machine, configure the COM port to map to a named pipe. The debugger will connect through this pipe. For more information about how to create this pipe, see your virtual machine's documentation.

Configuring the Host Computer

The host computer can be the same physical computer that is running the virtual machine, or it can be a separate computer.

1. On the host computer, in Visual Studio, on the **Driver** menu, choose **Test > Configure Computer**.
2. Click **Add New Computer**.
3. For **Computer name**, enter the name of the physical computer that is running the target virtual machine.
4. Select **Manually configure debuggers and do not provision**, and click **Next**.
5. For **Connection Type**, select **Serial**.
6. Check **Pipe**, and check **Reconnect**.
7. If the debugger is running on the same computer as the virtual machine, enter the following for **Pipe name**:
`\\.\pipe\PipeName.`

If the debugger is running on a different computer from the virtual machine, enter the following for **Pipe name**:

```
\\VMHost\pipe\PipeName
```

where, *VMHost* is the name of the physical computer that is running the target virtual machine, and

PipeName is the name of the pipe that you associated with the COM port on the target virtual machine.

8. Click **Next**. Click **Finish**.

Starting the Debugging Session

1. On the host computer, in Visual Studio, on the **Tools** menu, choose **Attach to Process**.
2. For **Transport**, choose **Windows Kernel Mode Debugger**.
3. For **Qualifier**, select the name of the physical computer that is running the target virtual machine.
4. Click **Attach**.

Generation 2 Virtual Machines

By default, COM ports are not presented in generation 2 virtual machines. You can add COM ports through PowerShell or WMI. For the COM ports to be displayed in the Hyper-V Manager console, they must be created with a path.

To enable kernel debugging using a COM port on a generation 2 virtual machine, follow these steps:

1. Disable Secure Boot by entering this PowerShell command:

```
Set-VMFirmware -Vmname VmName -EnableSecureBoot Off
```

where *VmName* is the name of your virtual machine.

2. Add a COM port to the virtual machine by entering this PowerShell command:

```
Set-VMComPort -VMName VmName 1 \\.\pipe\PipeName
```

For example, the following command configures the first COM port on virtual machine TestVM to connect to named pipe TestPipe on the local computer.

```
Set-VMComPort -VMName TestVM 1 \\.\pipe\TestPipe
```

For more information, see [Generation 2 Virtual Machine Overview](#).

Using Breakpoints

5/26/2017 • 1 min to read • [Edit Online](#)

A *breakpoint* is a location in executable code at which the operating system stops execution and breaks into the debugger. This allows you to analyze the target and issue debugger commands.

This section includes the following topics:

[Methods of Controlling Breakpoints](#)

[Breakpoint Syntax](#)

[Unresolved Breakpoints \(bu Breakpoints\)](#)

[Processor Breakpoints \(ba Breakpoints\)](#)

[Initial Breakpoint](#)

[User Space and System Space](#)

[Risks Entailed When Setting Breakpoints](#)

[Send comments about this topic to Microsoft](#)

Methods of Controlling Breakpoints

5/31/2017 • 3 min to read • [Edit Online](#)

You can specify the location of a breakpoint by virtual address, module and routine offsets, or source file and line number (when in source mode). If you put a breakpoint on a routine without an offset, the breakpoint is activated when that routine is entered.

There are several additional kinds of breakpoints:

- A breakpoint can be associated with a certain thread.
- A breakpoint can enable a fixed number of passes through an address before it is triggered.
- A breakpoint can automatically issue certain commands when it is triggered.
- A breakpoint can be set on non-executable memory and watch for that location to be read or written to.

If you are debugging more than one process in user mode, the collection of breakpoints depends on the current process. To view or change a process' breakpoints, you must select the process as the current process. For more information about the current process, see [Controlling Processes and Threads](#).

Debugger Commands for Controlling and Displaying Breakpoints

To control or display breakpoints, you can use the following methods:

- Use the [bl \(Breakpoint List\)](#) command to list existing breakpoints and their current status.
- Use the [.bpcmds \(Display Breakpoint Commands\)](#) command to list all breakpoints along with the commands that were used to create them.
- Use the [bp \(Set Breakpoint\)](#) command to set a new breakpoint.
- Use the [bu \(Set Unresolved Breakpoint\)](#) command to set a new breakpoint. Breakpoints that are set with **bu** are called unresolved breakpoints; they have different characteristics than breakpoints that are set with **bp**. For complete details, see [Unresolved Breakpoints \(bu Breakpoints\)](#).
- Use the [bm \(Set Symbol Breakpoint\)](#) command to set new breakpoints on symbols that match a specified pattern. A breakpoint set with **bm** will be associated with an address (like a **bp** breakpoint) if the **/d** switch is included; it will be unresolved (like a **bu** breakpoint) if this switch is not included.
- Use the [ba \(Break on Access\)](#) command to set a *processor breakpoint*, also known as a *data breakpoint*. These breakpoints can be triggered when the memory location is written to, when it is read, when it is executed as code, or when kernel I/O occurs. For complete details, see [Processor Breakpoints \(ba Breakpoints\)](#).
- Use the [bc \(Breakpoint Clear\)](#) command to permanently remove one or more breakpoints.
- Use the [bd \(Breakpoint Disable\)](#) command to temporarily disable one or more breakpoints.
- Use the [be \(Breakpoint Enable\)](#) command to re-enable one or more disabled breakpoints.
- Use the [br \(Breakpoint Rerumber\)](#) command to change the ID of an existing breakpoint.
- Use the [bs \(Update Breakpoint Command\)](#) command to change the command associated with an existing breakpoint.
- Use the [bsc \(Update Conditional Breakpoint\)](#) command to change the condition under which an

existing conditional breakpoint occurs.

In Visual Studio and WinDbg, there are several user interface elements that facilitate controlling and displaying breakpoints. See [Setting Breakpoints in Visual Studio](#) and [Setting Breakpoints in WinDbg](#).

Each breakpoint has a decimal number called the breakpoint ID associated with it. This number identifies the breakpoint in various commands.

Breakpoint Commands

You can include a command in a breakpoint that is automatically executed when the breakpoint is hit. For example, the following command breaks at MyFunction+0x47, writes a dump file, and then resumes execution.

```
0:000> bu MyFunction+0x47 ".dump c:\mydump.dmp; g"
```

Note If you are controlling the user-mode debugger from the kernel debugger, do not use **g (Go)** in the breakpoint command string. The serial interface might be unable to keep up with this command, and you will be unable to break back into CDB. For more information about this situation, see [Controlling the User-Mode Debugger from the Kernel Debugger](#).

Number of Breakpoints

In kernel mode, you can use a maximum of 32 software breakpoints. In user mode, you can use any number of software breakpoints.

The number of processor breakpoints that are supported depends on the target processor architecture.

Conditional Breakpoints

You can set a breakpoint that is triggered only under certain conditions. For more information about these kinds of breakpoints, see [Setting a Conditional Breakpoint](#).

[Send comments about this topic to Microsoft](#)

Breakpoint Syntax

5/31/2017 • 2 min to read • [Edit Online](#)

The following syntax elements can be used when creating a [breakpoint](#), either through the Debugger Command window or through the WinDbg graphical interface.

Addresses in Breakpoints

Breakpoints support many kinds of address syntax, including virtual addresses, function offsets, and source line numbers. For example, you can use any of the following commands to set breakpoints:

```
0:000> bp 0040108c
0:000> bp main+5c
0:000> bp `source.c:31`
```

For more information about this syntax, see [Numerical Expression Syntax](#), [Source Line Syntax](#), and the individual command topics.

Breakpoints on Methods

If you want to put a breakpoint on the *MyMethod* method in the *MyClass* class, you can use two different syntaxes:

- In MASM expression syntax, you can indicate a method by a double colon or by a double underscore.

```
0:000> bp MyClass::MyMethod
0:000> bp MyClass__MyMethod
```

- In C++ expression syntax, you must indicate a method by a double colon.

```
0:000> bp @@( MyClass::MyMethod )
```

If you want to use a more complex breakpoint command, you should use MASM expression syntax. For more information about expression syntax, see [Evaluating Expressions](#).

Breakpoints Using Complicated Text

To set a breakpoint on complicated functions, including functions that contain spaces, as well as a member of a C++ public class, enclose the expression in parentheses. For example, use **bp (??MyPublic)** or **bp (operator new)**.

A more versatile technique is to use the @!"chars" syntax. This is a special escape in the MASM evaluator that enables you to provide arbitrary text for symbol resolution. You must start with the three symbols @!" and end with a quotation mark (""). Without this syntax, you cannot use spaces, angle brackets (<, >), or other special characters in symbol names in the MASM evaluator. This syntax is exclusively for names, and not parameters. Templates and overloads are the primary sources of symbols that require this quote notation. You can also set the **bu** command by using the @!"chars" syntax, as the following code example shows.

```
0:000> bu @!"ExecutableName!std::pair<unsigned int, std::basic_string<unsigned short, std::char_traits<unsigned short>, std::allocator<unsigned short> >::operator="
```

In this example, *ExecutableName* is the name of an executable file.

This escape syntax is more useful for C++ (for example, overloaded operators) instead of C because there are no

spaces (or special characters) in C function names. However, this syntax is also important for a lot of managed code because of the considerable use of overloads in the .NET Framework.

To set a breakpoint on arbitrary text in C++ syntax, use **bu @@c++(text)** for C++-compatible symbols.

Breakpoints in Scripts

Breakpoint IDs do not have to be referred to explicitly. Instead, you can use a numerical expression that resolves to an integer that corresponds to a breakpoint ID. To indicate that the expression should be interpreted as a breakpoint, use the following syntax.

```
b?[[Expression]]
```

In this syntax, the square brackets are required, and *Expression* stands for any numerical expression that resolves to an integer that corresponds to a breakpoint ID.

This syntax allows debugger scripts to programmatically select a breakpoint. In the following example, the breakpoint changes depending on the value of a user-defined pseudo-register.

```
b?[@$t0]
```

Breakpoint Pseudo-Registers

If you want to refer to a breakpoint address in an expression, you can use a [pseudo-register](#) with the **\$bpNumber** syntax, where *Number* is the breakpoint ID. For more information about this syntax, see [Pseudo-Register Syntax](#).

[Send comments about this topic to Microsoft](#)

Unresolved Breakpoints (bu Breakpoints)

5/26/2017 • 2 min to read • [Edit Online](#)

If a [breakpoint](#) is set for a routine name that has not been loaded, the breakpoint is called a *deferred*, *virtual*, or *unresolved* breakpoint. (These terms are used interchangeably.) Unresolved breakpoints are not associated with any specific load of a module. Every time that a new application is loaded, it is checked for this routine name. If this routine appears, the debugger computes the actual coded address of the virtual breakpoint and enables the breakpoint.

If you set a breakpoint by using the **bu** command, the breakpoint is automatically considered unresolved. If this breakpoint is in a loaded module, the breakpoint is still enabled and functions normally. However, if the module is later unloaded and reloaded, this breakpoint does not vanish. On the other hand, a breakpoint that you set with **bp** is immediately resolved to an address.

There are three primary differences between **bp** breakpoints and **bu** breakpoints:

- A **bp** breakpoint location is always converted to an address. If a module change moves the code at which a **bp** breakpoint was set, the breakpoint remains at the same address. On the other hand, a **bu** breakpoint remains associated with the symbolic value (typically a symbol plus an offset) that was used, and it tracks this symbolic location even if its address changes.
- If a **bp** breakpoint address is found in a loaded module, and if that module is later unloaded, the breakpoint is removed from the breakpoint list. On the other hand, **bu** breakpoints persist after repeated unloads and loads.
- Breakpoints that you set with **bp** are not saved in WinDbg [workspaces](#). Breakpoints that are set with **bu** are saved in workspaces.

Controlling Address Breakpoints and Unresolved Breakpoints

Address breakpoints can be created with the [bp \(Set Breakpoint\)](#) command, or the [bm \(Set Symbol Breakpoint\)](#) command when the **/d** switch is included. Unresolved breakpoints can be created with the [bu \(Set Unresolved Breakpoint\)](#) command, or the [bm](#) command when the **/d** switch is not included. Commands that disable, enable, and modify breakpoints apply to all kinds of breakpoints. Commands that display a list of breakpoints include all breakpoints, and indicate the type of each. For a listing of these commands, see [Methods of Controlling Breakpoints](#).

The WinDbg **Breakpoints** dialog box displays all breakpoints, indicating unresolved breakpoints with the notation "u". This dialog box can be used to modify any breakpoint. The **Command** text box on this dialog box can be used to create any type of breakpoint; if the type is omitted, an unresolved breakpoint is created. For details, see [Edit | Breakpoints](#). When you set a breakpoint by using the mouse in the WinDbg [Disassembly window](#) or [Source window](#), the debugger creates an unresolved breakpoint.

[Send comments about this topic to Microsoft](#)

Processor Breakpoints (ba Breakpoints)

5/26/2017 • 6 min to read • [Edit Online](#)

Breakpoints that are controlled by the processor at the request of the debugger are known as *processor breakpoints* or *data breakpoints*. Breakpoints that are controlled directly by the debugger are known as *software breakpoints*.

Note Although the term *data breakpoint* is commonly used as a synonym for *processor breakpoint*, this term can be misleading. There are two fundamental types of breakpoints: processor breakpoints, which are controlled by the processor, and software breakpoints, which are controlled by the debugger. Processor breakpoints are usually set on program data -- this is the reason they are called "data breakpoints" -- but they can also be set on executable code. Software breakpoints are usually set on executable code, but they can also be set on program data. Unfortunately, it is common in debugging literature to refer to processor breakpoints as "data breakpoints", even when they are set on executable code.

Processor Breakpoints

A processor breakpoint is triggered when a specific memory location is accessed. There are four types of processor breakpoints, corresponding to the kind of memory access that triggers it:

BREAKPOINT TYPE	ACTION
e (execute)	Triggered when the processor retrieves an instruction from the specified address.
r (read/write)	Triggered when the processor reads or writes memory at the specified address.
w (write)	Triggered when the processor writes memory at the specified address.
i (i/o)	Triggered when the I/O port at the specified Address is accessed.

Each processor breakpoint has a size associated with it. For example, a **w** (write) processor breakpoint could be set at the address 0x70001008 with a size of four bytes. This would monitor the block of addresses from 0x70001008 to 0x7000100B, inclusive. If this block of memory is written to, the breakpoint will be triggered.

It can happen that the processor performs an operation on a memory region that overlaps with, but is not identical to, the specified region. In the example given in the preceding paragraph, a single write operation that includes the range 0x70001000 to 0x7000100F, or a write operation that includes only the byte at 0x70001009, would be an overlapping operation. In such a situation, whether the breakpoint is triggered is processor-dependent. For details of how this situation is handled on a specific processor, consult the processor architecture manual and look for "debug register" or "debug control register". To take one specific processor type as an example, on an x86 processor, a read or write breakpoint is triggered whenever the accessed range overlaps the breakpoint range.

Similarly, if an **e** (execute) breakpoint is set on the address 0x00401003, and then a two-byte instruction spanning the addresses 0x00401002 and 0x00401003 is executed, the result is processor-dependent. Again, consult the processor architecture manual for details.

The processor distinguishes between breakpoints set by a user-mode debugger and breakpoints set by a kernel-mode debugger. A user-mode processor breakpoint does not affect any kernel-mode processes. A kernel-mode processor breakpoint might or might not affect a user-mode process, depending on whether the user-mode code is using the debug register state and whether there is a user-mode debugger that is attached.

To apply the current process' existing data breakpoints to a different register context, use the [.apply_dbp \(Apply Data Breakpoint to Context\)](#) command.

On a multiprocessor computer, each processor breakpoint applies to all processors. For example, if the current processor is 3 and you use the command `ba e1 MyAddress` to put a breakpoint at **MyAddress**, any processor -- not only processor 3 -- that executes at that address triggers the breakpoint. This holds for software breakpoints as well.

Software Breakpoints

Software breakpoints, unlike processor breakpoints, are controlled by the debugger. When the debugger sets a software breakpoint at some location, it temporarily replaces the contents of that memory location with a break instruction. The debugger remembers the original contents of this location, so that if this memory is displayed in the debugger, the debugger will show the original contents of that memory location, not the break instruction. When the target process executes the code at this location, the break instruction causes the process to break into the debugger. After you have performed whatever actions you choose, you can cause the target to resume execution, and execution will resume with the instruction that was originally in that location.

Availability of Processor Breakpoint Types

On Windows Server 2003 with Service Pack 1 (SP1), on an Itanium-based computer that uses WOW64 to emulate x86, processor breakpoints do not work with the **e** (execute) option but they do work with the **r** (read/write) and **w** (write) options.

The **i** (i/o) option is available only during kernel-mode debugging, with a target computer that is running Windows XP or a later version of Windows on an x86-based processor.

Not all data sizes can be used with all processor breakpoint types. The permitted sizes depend on the processor of the target computer. For details, see [ba \(Break on Access\)](#).

Limitations of Software Breakpoints and Processor Breakpoints

It is possible to specify a data address rather than a program address when using the **bp** or **bm /a** commands. However, even if a data location is specified, these commands create software breakpoints, not processor breakpoints. When the debugger places a software breakpoint at some location, it temporarily replaces the contents of that memory location with a break instruction. This does not corrupt the executable image, because the debugger remembers the original contents of this location, and when the target process attempts to execute this code the debugger can respond appropriately. But when a software breakpoint is set in a data location, the resulting overwrite can lead to data corruption. Therefore, setting a software breakpoint on a data location is safe only if you are certain that this location will be used only as executable code.

The **bp**, **bu**, and **bm** commands set software breakpoints by replacing the processor instruction with a break instruction. Therefore these cannot be used in read-only code or any other code that cannot be overwritten. To set a breakpoint in such code, you must use [ba \(Break on Access\)](#) with the **e** (execute) option.

You cannot create multiple processor breakpoints at the same address that differ only in the command that is automatically executed when the breakpoint is triggered. However, you can create multiple breakpoints at the same address that differ in their other restrictions (for example, you can create multiple breakpoints at the same address by using the **ba** command with different values of the **/p**, **/t**, **/c**, and **/C** options).

The initial breakpoint in a user-mode process (typically set on the **main** function or its equivalent) cannot be a processor breakpoint.

The number of processor breakpoints that are supported depends on the target processor architecture.

Controlling Software Breakpoints and Processor Breakpoints

Software breakpoints can be created with the [bp \(Set Breakpoint\)](#), [bm \(Set Symbol Breakpoint\)](#), and [bu \(Set Unresolved Breakpoint\)](#) commands. Processor breakpoints can be created with the [ba \(Break on Access\)](#) command. Commands that disable, enable, and modify breakpoints apply to all kinds of breakpoints. Commands that display a list of breakpoints include all breakpoints, and indicate the type of each. For a listing of these commands, see [Methods of Controlling Breakpoints](#).

The WinDbg **Breakpoints** dialog box displays all breakpoints, indicating processor breakpoints with the notation "e", "r", "w", or "i" followed by the size of the block. This dialog box can be used to modify any breakpoint. The **Command** text box on this dialog box can be used to create any type of breakpoint. If a processor breakpoint is desired, begin the input with "ba". For details, see [Edit | Breakpoints](#). When you set a breakpoint by using the mouse in the WinDbg [Disassembly window](#) or [Source window](#), the debugger creates an unresolved software breakpoint.

Processor breakpoints are stored in the processor's debug registers. It is possible to set a breakpoint by manually editing a debug register value, but this is strongly discouraged.

Initial Breakpoint

5/26/2017 • 1 min to read • [Edit Online](#)

When the debugger starts a new target application, an initial breakpoint automatically occurs after the main image and all statically-linked DLLs are loaded before any DLL initialization routines are called.

When the debugger attaches to an existing user-mode application, an initial [breakpoint](#) occurs immediately.

The **-g** command-line option causes WinDbg or CDB to ignore the initial breakpoint. You can automatically execute a command at this point. For more information about this situation, see [Controlling Exceptions and Events](#).

If you want to start a new target and break into it when the execution of the actual application is about to begin, do not use the **-g** option. Instead, let the initial breakpoint occur. After the debugger is active, set a breakpoint on the **main** or **winmain** routine and then use the **g (Go)** command. All of the initialization procedures then run, and the application stops when execution of the main application is about to begin.

For more information about automatic breakpoints in kernel mode, see [Crashing and Rebooting the Target Computer](#).

[Send comments about this topic to Microsoft](#)

User Space and System Space

5/31/2017 • 2 min to read • [Edit Online](#)

Windows gives each user-mode application a block of virtual addresses. This is known as the *user space* of that application. The other large block of addresses, known as *system space* or *kernel space*, cannot be directly accessed by the application.

When WinDbg or CDB sets a [breakpoint](#) in user space, this breakpoint is set at the specified address in the user space of a single process. During user-mode debugging, the current process determines the meaning of virtual addresses. For more information, see [Controlling Processes and Threads](#).

In kernel mode, you can set breakpoints in user space with the **bp**, **bu**, and **ba** commands or with the **Breakpoints** dialog box. You must first use the *process context* to specify the user-mode process that owns that address space by using **.process /i** (or a process-specific breakpoint on some kernel-space function) to switch the target to the correct *process context*.

Breakpoints in user space are always associated with the process whose process context was active when the breakpoints were set. If a user-mode debugger is debugging this process and if a kernel debugger is debugging the computer that the process is running on, this breakpoint breaks into the user-mode debugger, even though the breakpoint was actually set from the kernel debugger. You can break into the system from the kernel debugger at this point, or use the [.breakin \(Break to the Kernel Debugger\)](#) command from the user-mode debugger to transfer control to the kernel debugger.

Determining the Range of User Space and System Space

If you need to determine the extent of user space and system space on the target computer, you can use the [dp \(Display Memory\)](#) command from a kernel debugger to display the Windows global variable

MmHighestUserAddress. This variable contains the address of the top of user space. Since system space addresses are always higher than user space addresses, this value allows you to determine whether any given address is in user space or in kernel space.

For example, on a 32-bit target computer with an x86 processor and standard boot parameters, this command will show the following result:

```
kd> dp nt!mmhighestuseraddress L1
81f71864 7fffffff
```

This indicates that user space ranges from the address 0x00000000 to 0x7FFFFFFF, and system space therefore ranges from 0x80000000 up to the highest possible address (which is 0xFFFFFFFF on a standard 32-bit Windows installation).

With a 64-bit target computer, different values will occur. For example, this command might show the following:

```
0: kd> dp nt!mmhighestuseraddress L1
fffff800`038b4010 000007ff`ffffffff
```

This indicates that user space ranges from 0x00000000`00000000 to 0x000007FF`FFFFFF. Therefore, system space includes all addresses from 0x00000800`00000000 upward.

For more information about Windows memory management, see *Microsoft Windows Internals* by David Solomon and Mark Russinovich (4th edition, Microsoft Press, 2005).

Risks Entailed When Setting Breakpoints

5/26/2017 • 2 min to read • [Edit Online](#)

When you are setting a [breakpoints](#) by specifying a memory address or a symbol plus an offset, you must not put this breakpoint in the middle of an instruction.

For example, consider the following disassembled code.

```
770000f1 5e          pop    esi
770000f2 5b          pop    ebx
770000f3 c9          leave
770000f4 c21000       ret    0x10
770000f7 837ddc00     cmp    dword ptr [ebp-0x24],0x0
```

The first three instructions are only one byte long. However, the fourth instruction is three bytes long. (It includes bytes 0x770000F4, 0x770000F5, and 0x770000F6.) If you want to put a breakpoint on this instruction by using the **bp**, **bu**, or **ba** command, you must specify the 0x770000F4 address.

If you put a breakpoint in the 0x770000F5 address by using the **ba** command, the processor puts a breakpoint at that location. But this breakpoint would never be triggered, because the processor considers 0x770000F4 to be the actual address of the instruction.

If you put a breakpoint in the 0x770000F5 address by using the **bp** or **bu** commands, the debugger writes a breakpoint at that location. However, this breakpoint might corrupt the target because of how the debugger creates breakpoints:

1. The debugger saves the contents of 0x770000F5 and overwrites this memory with a breakpoint instruction.
2. If you try to display this memory in the debugger, the debugger does not show the breakpoint instruction that it has written. Instead, the debugger shows the memory that "should" be there. That is, the debugger shows the original memory, or any modifications to that memory that you have made since inserting the breakpoint.
3. If you use the **BC** command to remove the breakpoint, the debugger restores the original memory to its proper location.

When you put a breakpoint at 0x770000F5, the debugger saves this byte and a break instruction is written here. However, when the application runs, it reaches the 0x770000F4 address and recognizes this address as the first byte of a multibyte instruction. The processor then tries to combine 0x770000F4, 0x770000F5, and possibly some later bytes into a single instruction. This combination can create a variety of behaviors, none of which are desirable.

Therefore, when you put breakpoints by using a **bp**, **bu**, or **ba** command, make sure that you always put the breakpoints at the proper address. If you are using the WinDbg graphical interface to add breakpoints, you do not have to be concerned about this situation because the correct address is chosen automatically.

Conditional breakpoints in WinDbg and other Windows debuggers

5/31/2017 • 6 min to read • [Edit Online](#)

Conditional breakpoints in WinDbg and other Windows debuggers are useful when you need to break in only if a specific condition is satisfied.

A conditional breakpoint is created by combining a breakpoint command with either the **j (Execute If - Else)** command or the **.if** token, followed by the **gc (Go from Conditional Breakpoint)** command. This breakpoint causes a break to occur only if a specific condition is satisfied.

The basic syntax for a conditional breakpoint using the **j** command is as follows:

```
0:000> bp Address "j (Condition) 'OptionalCommands'; 'gc' "
```

The basic syntax for a conditional breakpoint using the **.if** token is as follows:

```
0:000> bp Address ".if (Condition) {OptionalCommands} .else {gc}"
```

Conditional breakpoints are best illustrated with an example. The following command sets a breakpoint at line 143 of the Mysource.cpp source file. When this breakpoint is hit, the variable **MyVar** is tested. If this variable is less than or equal to 20, execution continues; if it is greater than 20, execution stops.

```
0:000> bp `mysource.cpp:143` "j (poi(MyVar)>0n20) ''; 'gc' "
0:000> bp `mysource.cpp:143` ".if (poi(MyVar)>0n20) {} .else {gc}"
```

The preceding command has a fairly complicated syntax that contains the following elements:

- The **bp (Set Breakpoint)** command sets breakpoints. Although the preceding example uses the **bp** command, you could also use the **bu (Set Unresolved Breakpoint)** command. For more information about the differences between **bp** and **bu**, and for a basic introduction to breakpoints, see [Using Breakpoints](#).
- Source line numbers are specified by using grave accents (`). For details, see [Source Line Syntax](#).
- When the breakpoint is hit, the command in straight quotation marks ("") is executed. In this example, this command is a **j (Execute If - Else)** command or an **.if** token, which tests the expression in parentheses.
- In the source program, **MyVar** is an integer. If you are using C++ expression syntax, **MyVar** is interpreted as an integer. However, in this example (and in the default debugger configuration), MASM expression syntax is used. In a MASM expression, **MyVar** is treated as an address. Thus, you need to use the **poi** operator to dereference it. (If your variable actually is a C pointer, you will need to dereference it twice--for example, **poi(poi(MyPtr))**.) The **On** prefix specifies that this number is decimal. For syntax details, see [MASM Numbers and Operators](#).
- The expression in parentheses is followed by two commands, surrounded by single quotation marks ('') for the **j** command and curly brackets ({}) for the **.if** token. If the expression is true, the first of these commands is executed. In this example, there is no first command, so command execution will end and control will remain with the debugger. If the expression in parentheses is false, the second command will

execute. The second command should almost always be a **gc (Go from Conditional Breakpoint)** command, because this command causes execution to resume in the same manner that was occurring before the breakpoint was hit (stepping, tracing, or free execution).

If you want to see a message each time the breakpoint is passed or when it is finally hit, you can use additional commands in the single quotation marks or curly brackets. For example:

```
0:000> bp `:143` "j (poi(MyVar)>5) '.echo MyVar Too Big'; '.echo MyVar Acceptable; gc' "
0:000> bp `:143` ".if (poi(MyVar)>5) {.echo MyVar Too Big} .else {.echo MyVar Acceptable; gc} "
```

These comments are especially useful if you have several such breakpoints running at the same time, because the debugger does not display its standard "Breakpoint *n* Hit" messages when you are using a command string in the **bp** command.

Conditional Breakpoint Based on String Comparison

In some situations you might want to break into the debugger only if a string variable matches a pattern. For example, suppose you want to break at `kernel32!CreateEventW` only if the *lpName* argument points to a string that matches the pattern "Global*". The following example shows how to create the conditional breakpoint.

```
bp kernel32!CreateEventW "$$<c:\\commands.txt"
```

The preceding **bp** command creates a breakpoint based on conditions and optional commands that are in a script file named `commands.txt`. The script file contains the following statements.

```
.if (@r9 != 0) { as /mu ${/v:EventName} @r9 } .else { ad /q ${/v:EventName} }
.if ($spat(@"${EventName}", "Global*") == 0) { gc } .else { .echo EventName }
```

The *lpName* argument passed to the **CreateEventW** function is the fourth argument, so it is stored in the *r9* register (x64 processor). The script performs the following steps:

1. If *lpName* is not NULL, use **as** and **\$()** to create an alias named *EventName*. Assign to *EventName* the null-terminated Unicode string beginning at the address pointed to by *lpName*. On the other hand, if *lpName* is NULL, use **ad** to delete any existing alias named *EventName*.
2. Use **\$spat** to compare the string represented by *EventName* to the pattern "Global*". If the string does not match the pattern, use **gc** to continue without breaking. If the string does match the pattern, break and display the string represented by *EventName*.

Note **\$spat** performs a case-insensitive match.

****Note**** The ampersand (@) character in `$spat(@"${EventName}")` specifies that the string represented by *EventName* is to be interpreted literally; that is, a backslash (\\) is treated as a backslash rather than an escape character.

Conditional Breakpoints and Register Sign Extension

You can set a breakpoint that is conditional on a register value.

The following command will break at the beginning of the **myFunction** function if the **eax** register is equal to 0xA3:

```
0:000> bp mydriver!myFunction "j @eax = 0xa3 ''; 'gc' "
0:000> bp mydriver!myFunction ".if @eax = 0xa3 {} .else {gc}"
```

However, the following similar command will not necessarily break when **eax** equals 0xC0004321:

```
0:000> bp mydriver!myFunction "j @eax = 0xc0004321 '';'gc'"  
0:000> bp mydriver!myFunction ".if @eax = 0xc0004321 {} .else {gc}"
```

The reason the preceding command will fail is that the MASM expression evaluator sign-extends registers whose high bit equals one. When **eax** has the value 0xC0004321, it will be treated as 0xFFFFFFFF`C0004321 in computations--even though **eax** will still be displayed as 0xC0004321. However, the numeral **0xc0004321** is sign-extended in kernel mode, but not in user mode. Therefore, the preceding command will not work properly in user mode. If you mask the high bits of **eax**, the command will work properly in kernel mode--but now it will fail in user mode.

You should formulate your commands defensively against sign extension in both modes. In the preceding command, you can make the command defensive by masking the high bits of a 32-bit register by using an AND operation to combine it with 0x00000000`FFFFFF and by masking the high bits of a numeric constant by including a grave accent (`) in its syntax.

The following command will work properly in user mode and kernel mode:

```
0:000> bp mydriver!myFunction "j (@eax & 0x0`ffffffff) = 0x0`c0004321 '';'gc'"  
0:000> bp mydriver!myFunction ".if (@eax & 0x0`ffffffff) = 0x0`c0004321 {} .else {gc}"
```

For more information about which numbers are sign-extended by the debugger, see [Sign Extension](#).

Conditional Breakpoints in WinDbg

In WinDbg, you can create a conditional breakpoint by clicking **Breakpoints** from the **Edit** menu, entering a new breakpoint address into the **Command** box, and entering a condition into the **Condition** box.

For example, typing **mymod!myFunc+0x3A** into the **Command** box and **myVar < 7** into the **Condition** box is equivalent to issuing the following command:

```
0:000> bu mymod!myFunc+0x3A "j(myVar<7) '.echo \"Breakpoint hit, condition myVar<7\"'; 'gc'"  
0:000> bu mymod!myFunc+0x3A ".if(myVar<7) {.echo \"Breakpoint hit, condition myVar<7\"} .else {gc}"
```

Restrictions on Conditional Breakpoints

If you are [controlling the user-mode debugger from the kernel debugger](#), you cannot use conditional breakpoints or any other breakpoint command string that contains the **gc (Go from Conditional Breakpoint)** or **g (Go)** commands. If you use these commands, the serial interface might not be able to keep up with the number of breakpoint passes, and you will be unable to break back into CDB.

[Send comments about this topic to Microsoft](#)

Executing Until a Specified State is Reached

5/26/2017 • 2 min to read • [Edit Online](#)

There are several ways to cause the target to execute until a specified state is reached.

Using a Breakpoint to Control Execution

One method is to use a breakpoint. The simplest breakpoint halts execution when the program counter reaches a specified address. A more complex breakpoint can:

- be triggered only when this address is executed by a specific thread,
- allow a specified number of passes through this address before being triggered,
- automatically issue a specified command when it is triggered, or
- watch a specified address in non-executable memory, being triggered when that memory is read or written to.

For details on how to set and control breakpoints, see [Using Breakpoints](#).

A more complicated way to execute until a specified state is reached is to use a *conditional breakpoint*. This kind of breakpoint is set at a certain address, but is only triggered if a specified condition holds. For details, see [Setting a Conditional Breakpoint](#).

Breakpoints and Pseudo-Registers

In specifying the desired state, it is often helpful to use *automatic pseudo-registers*. These are variables controlled by the debugger which allow you to reference a variety of values related to the target state.

For example, the following breakpoint uses the **\$thread** pseudo-register, which is always equal to the value of the current thread. It resolves to the value of the current thread when it is used in a command. By using **\$thread** as the argument of the **/t** parameter of the **bp (Set Breakpoint)** command, you can create a breakpoint that will be triggered every time that **NtOpenFile** is called by the thread which was active at the time you issued the **bp** command:

```
kd> bp /t @$thread nt!ntopenfile
```

This breakpoint will not be triggered when any other thread calls **NtOpenFile**.

For a list of automatic pseudo-registers, see [Pseudo-Register Syntax](#).

Using a Script File to Control Execution

Another way to execute until a specified state is reached is to create a script file that calls itself recursively, testing the desired state in each iteration.

Typically, this script file will contain the **.if** and **.else** tokens. You can use a command such as **t (Trace)** to execute a single step, and then test the condition in question.

For example, if you wish to execute until the **eax** register contains the value 0x1234, you can create a script file called **eaxstep** that contains the following line:

```
.if (@eax == 1234) { .echo 1234 } .else { t "<eaxstep" }
```

Then issue the following command from the Debugger Command window:

```
t "$<eaxstep"
```

This **t** command will execute a single step, and then execute the quoted command. This command happens to be **\$<(Run Script File)**, which runs the *eaxstep* file. The script file tests the value of **eax**, runs the **t** command, and then calls itself recursively. This continues until the **eax** register equals 0x1234, at which point the **.echo (Echo Comment)** command prints a message to the Debugger Command window, and execution stops.

For details on script files, see [Using Script Files](#) and [Using Debugger Command Programs](#).

Reading and Writing Memory

5/26/2017 • 1 min to read • [Edit Online](#)

The Windows debuggers can read and write directly into memory. This memory can be referenced by addresses or by the names of variables.

This section includes the following topics:

[Accessing Memory by Virtual Address](#)

[Accessing Memory by Physical Address](#)

[Accessing Global Variables](#)

[Accessing Local Variables](#)

[Controlling Variables Through the Watch Window](#)

[Send comments about this topic to Microsoft](#)

Accessing Memory by Virtual Address

5/26/2017 • 2 min to read • [Edit Online](#)

To access memory addresses or address ranges, you can use several commands. Visual Studio and WinDbg provide user interface elements (as well as commands) that you can use to view and edit memory. For more information, see [Viewing and Editing Memory and Registers in Visual Studio](#) and [Viewing and Editing Memory in WinDbg](#).

The following commands can read or write memory in a variety of formats. These formats include hexadecimal bytes, words (words, double words, and quad-words), integers (short, long, and quad integers and unsigned integers), floating-point numbers (10-byte, 16-byte, 32-byte, and 64-byte real numbers), and ASCII characters.

- The [d* \(Display Memory\)](#) command displays the contents of a specified memory address or range.
- The [e* \(Enter Values\)](#) command writes a value to the specified memory address.

You can use the following commands to handle more specialized data types:

- The [dt \(Display Type\)](#) command finds a variety of data types and displays data structures that have been created by the application that is being debugged. This command is highly versatile and has many variations and options.
- The [ds, dS \(Display String\)](#) command displays a STRING, ANSI_STRING, or UNICODE_STRING data structure.
- The [dl \(Display Linked List\)](#) command traces and displays a linked list.
- The [d*s \(Display Words and Symbols\)](#) command finds double-words or quad-words that might contain symbol information and then displays the data and the symbol information.
- The [!address](#) extension command displays information about the properties of the memory that is located at a specific address.

You can use the following commands to manipulate memory ranges:

- The [m \(Move Memory\)](#) command moves the contents of one memory range to another.
- The [f \(Fill Memory\)](#) command writes a pattern to a memory range, repeating it until the range is full.
- The [c \(Compare Memory\)](#) command compares the contents of two memory ranges.
- The [s \(Search Memory\)](#) command searches for a specified pattern within a memory range or searches for any ASCII or Unicode characters that exist in a memory range.
- The [.holdmem \(Hold and Compare Memory\)](#) command compares one memory range to another.

In most situations, these commands interpret their parameters in the current radix. Therefore, you should add **0x** before hexadecimal addresses if the current radix is not 16. However, the display output of these commands is typically in hexadecimal format, regardless of the current radix. (For more information about the output, see the individual command topics.) The [Memory window](#) displays integers and real numbers in decimal format and displays other formats in hexadecimal format.

To change the default radix, use the [n \(Set Number Base\)](#) command. To quickly convert numbers from one base to another, use the [? \(Evaluate Expression\)](#) command or the [.formats \(Show Number Formats\)](#) command.

When you are performing user-mode debugging, the meaning of virtual addresses is determined by the current process. When you are performing kernel-mode debugging, the meaning of virtual addresses can be controlled by the debugger. For more information, see [Process Context](#).

[Send comments about this topic to Microsoft](#)

Accessing Memory by Physical Address

5/26/2017 • 1 min to read • [Edit Online](#)

To read from a physical address, use the **!db**, **!dc**, **!dd**, **!dp**, **!du**, and **!dw** extension commands.

To write to a physical address, use the **!eb** and **!ed** extension commands.

The **fp (Fill Physical Memory)** command writes a pattern to a physical memory range, repeating it until the range is full.

When you are using WinDbg in kernel mode, you can also read or write to physical memory directly from the [Memory window](#).

To search physical memory for a piece of data or a range of data, use the **!search** extension command.

Also, for more information about physical addresses, see [Converting Virtual Addresses to Physical Addresses](#).

[Send comments about this topic to Microsoft](#)

Accessing Global Variables

5/26/2017 • 1 min to read • [Edit Online](#)

The names of global variables are stored in the symbol files that are created when an application is compiled. The debugger interprets the name of a global variable as a virtual address. Any command that accepts an address as a parameter also accepts the name of a variable. Therefore, you can use all of the commands that are described in [Accessing Memory by Virtual Address](#) to read or write global variables.

In addition, you can use the **? (Evaluate Expression)** command to display the address that is associated with any symbol.

Visual Studio and WinDbg provide user interface elements that you can use (in addition to commands) to view and edit global variables. See [Viewing and Editing Memory and Registers in Visual Studio](#) and [Viewing and Editing Global Variables in WinDbg](#).

Consider the following example. Suppose that you want to examine the `MyCounter` global variable, which is a 32-bit integer. Also suppose that the default radix is 10.

You can obtain this variable's address and then display it as follows.

```
0:000> ? MyCounter
Evaluate expression: 1244892 = 0012fedc
0:000> dd 0x0012fedc L1
0012fedc  00000052
```

The first command output tells you that the address of `MyCounter` is 0x0012FEDC. You can then use the **d* (Display Memory)** command to display one double-word at this address. (You could also use 1244892, which is the decimal version of this address. However, most C programmers prefer to use 0x0012FEDC.) The second command tells you that the value of `MyCounter` is 0x52 (decimal 82).

You could also perform these steps in the following command.

```
0:000> dd MyCounter L1
0012fedc  00000052
```

To change the value of `MyCounter` to decimal 83, use the following command.

```
0:000> ed MyCounter 83
```

This example uses decimal input, because that format seems more natural for an integer. However, the output of the **d* command** is still in hexadecimal format.

```
0:000> dd MyCounter L1 0012fedc  00000053
```

[Send comments about this topic to Microsoft](#)

Accessing Local Variables

5/26/2017 • 1 min to read • [Edit Online](#)

Local variables, like global variables, are stored in the symbol files. And as with global variables, the debugger interprets their names as addresses. They can be read and written in the same manner as global variables. However, if you need to indicate to a command that a symbol is local, precede the symbol with a dollar sign (\$) and an exclamation point (!), as in `$!var`.

Visual Studio and WinDbg provide user interface elements that you can use (in addition to commands) to view and edit local variables. For more information, see [Viewing and Editing Memory and Registers in Visual Studio](#) and [Viewing and Editing Local Variables in WinDbg](#).

You can also use the following methods to display, change, and use local variables:

- The **dv (Display Local Variables)** command displays the names and values of all local variables.
- The **!for_each_local** extension enables you to execute a single command repeatedly, once for each local variable.

However, there is one primary difference between local and global variables. When an application is executing, the meaning of local variables depends on the location of the program counter, because the scope of such variables extends only to the function in which they are defined.

The debugger interprets local variables according to the [local context](#). By default, this context matches the location of the program counter. But the debugger can change the context. For more information about the local context, see [Local Context](#).

When the local context is changed, the Locals window is immediately updated to reflect the new collection of local variables. The **dv** command also shows the new variables. All of these variable names are then interpreted correctly by the memory commands that are described earlier. You can then read or write to these variables.

[Send comments about this topic to Microsoft](#)

Controlling Variables Through the Watch Window

5/26/2017 • 1 min to read • [Edit Online](#)

In WinDbg, you can also use the Watch window to display and change global and local variables.

The Watch window can display any list of variables that you want. These variables can include global variables and local variables from any function. At any time, the Watch window displays the values of those variables that match the current function's scope. You can also change the values of these variables through the Watch window.

Unlike the Locals window, the Watch window is not affected by changes to the local context. Only those variables that are defined in the scope of the current program counter can have their values displayed or modified.

[Send comments about this topic to Microsoft](#)

Converting Virtual Addresses to Physical Addresses

5/31/2017 • 5 min to read • [Edit Online](#)

Most debugger commands use virtual addresses, not physical addresses, as their input and output. However, there are times that having the physical address can be useful.

There are two ways to convert a virtual address to a physical address: by using the **!vtop** extension, and by using the **!pte** extension.

Address Conversion Using **!vtop**

Suppose you are debugging a target computer on which the `MyApp.exe` process is running and you want to investigate the virtual address `0x0012F980`. Here is the procedure you would use with the **!vtop** extension to determine the corresponding physical address.

Converting a virtual address to a physical address using **!vtop**

1. Make sure that you are working in hexadecimal. If necessary, set the current base with the **N 16** command.
2. Determine the *byte index* of the address. This number is equal to the lowest 12 bits of the virtual address. Thus, the virtual address `0x0012F980` has a byte index of `0x980`.
3. Determine the *directory base* of the address by using the **!process** extension:

```
kd> !process 0 0
**** NT ACTIVE PROCESS DUMP ****
...
PROCESS ff779190 SessionId: 0 Cid: 04fc Peb: 7ffdf000 ParentCid: 0394
DirBase: 098fd000 ObjectTable: e1646b30 TableSize: 8.
Image: MyApp.exe
```

4. Determine the *page frame number* of the directory base. This is simply the directory base without the three trailing hexadecimal zeros. In this example, the directory base is `0x098FD000`, so the page frame number is `0x098FD`.
5. Use the **!vtop** extension. The first parameter of this extension should be the page frame number. The second parameter of **!vtop** should be the virtual address in question:

```
kd> !vtop 98fd 12f980
Pdi 0 Pti 12f
0012f980 09de9000 pfn(09de9)
```

The second number shown on the final line is the physical address of the beginning of the physical page.

6. Add the byte index to the address of the beginning of the page: $0x09DE9000 + 0x980 = 0x09DE9980$. This is the desired physical address.

You can verify that this computation was done correctly by displaying the memory at each address. The **!d*** extension displays memory at a specified physical address:

```
kd> !dc 9de9980
# 9de9980 6d206e49 726f6d65 00120079 0012f9f4 In memory.....
# 9de9990 0012f9f8 77e57119 77e8e618 ffffffff .....q.w...w....
# 9de99a0 77e727e0 77f6f13e 77f747e0 ffffffff .'.w>..w.G.w....
# 9de99b0 ....
```

The **d* (Display Memory)** command uses a virtual address as its argument:

```
kd> dc 12f980
0012f980 6d206e49 726f6d65 00120079 0012f9f4 In memory.....
0012f990 0012f9f8 77e57119 77e8e618 ffffffff .....q.w...w....
0012f9a0 77e727e0 77f6f13e 77f747e0 ffffffff .'.w>..w.G.w....
0012f9b0 ....
```

Because the results are the same, this indicates that the physical address 0x09DE9980 does indeed correspond to the virtual address 0x0012F980.

Address Conversion Using !pte

Again, assume you are investigating the virtual address 0x0012F980 belonging to the MyApp.exe process. Here is the procedure you would use with the **!pte** extension to determine the corresponding physical address:

Converting a virtual address to a physical address using !pte

1. Make sure that you are working in hexadecimal. If necessary, set the current base with the **N 16** command.
2. Determine the *byte index* of the address. This number is equal to the lowest 12 bits of the virtual address. Thus, the virtual address 0x0012F980 has a byte index of 0x980.
3. Set the **process context** to the desired process:

```
kd> !process 0 0
**** NT ACTIVE PROCESS DUMP ****
...
PROCESS ff779190 SessionId: 0 Cid: 04fc Peb: 7ffdf000 ParentCid: 0394
  DirBase: 098fd000 ObjectTable: e1646b30 TableSize: 8.
  Image: MyApp.exe

kd> .process /p ff779190
Implicit process is now ff779190
.cache forcedecodeuser done
```

4. Use the **!pte** extension with the virtual address as its argument. This displays information in two columns.

The left column describes the page directory entry (PDE) for this address; the right column describes its page table entry (PTE):

```
kd> !pte 12f980
VA 0012f980
PDE at C0300000      PTE at C00004BC
contains 0BA58067      contains 09DE9067
pfn ba58 ---DA--UWV  pfn 9de9 ---DA--UWV
```

5. Look in the last row of the right column. The notation "pfn 9de9" appears. The number 0x9DE9 is the *page frame number* (PFN) of this PTE. Multiply the page frame number by 0x1000 (for example, shift it left 12 bits). The result, 0x09DE9000, is the physical address of the beginning of the page.
6. Add the byte index to the address of the beginning of the page: 0x09DE9000 + 0x980 = 0x09DE9980. This is the desired physical address.

This is the same result obtained by the earlier method.

Converting Addresses By Hand

Although the **!ptov** and **pte** extensions supply the fastest way to convert virtual addresses to physical addresses, this conversion can be done manually as well. A description of this process will shed light on some of the details of the virtual memory architecture.

Memory structures vary in size, depending on the processor and the hardware configuration. This example is taken from an x86 system that does not have Physical Address Extension (PAE) enabled.

Using 0x0012F980 again as the virtual address, you first need to convert it to binary, either by hand or by using the **.formats (Show Number Formats)** command:

```
kd> .formats 12f980
Evaluate expression:
  Hex: 0012f980
  Decimal: 1243520
  Octal: 00004574600
  Binary: 00000000 00010010 11111001 10000000
  Chars: ....
  Time: Thu Jan 15 01:25:20 1970
  Float: low 1.74254e-039 high 0
  Double: 6.14381e-318
```

This virtual address is a combination of three fields. Bits 0 to 11 are the byte index. Bits 12 to 21 are the page table index. Bits 22 to 31 are the page directory index. Separating the fields, you have:

```
0x0012F980 = 0y 00000000 00 010010 1111 1001 10000000
```

This exposes the three parts of the virtual address:

- Page directory index = 0y0000000000 = 0x0
- Page table index = 0y0100101111 = 0x12F
- Byte index = 0y100110000000 = 0x980

You then need three additional pieces of information for your system.

- The size of each PTE. This is 4 bytes on non-PAE x86 systems.
- The size of a page. This is 0x1000 bytes.
- The PTE_BASE virtual address. On a non-PAE system, this is 0xC0000000.

Using this data, you can compute the address of the PTE itself:

```
PTE address = PTE_BASE
              + (page directory index) * PAGE_SIZE
              + (page table index) * sizeof(MMPTE)
              = 0xc0000000
              + 0x0 * 0x1000
              + 0x12F * 4
              = 0xC00004BC
```

This is the address of the PTE. The PTE is a 32-bit DWORD. Examine its contents:

```
kd> dd 0xc00004bc L1
c00004bc  09de9067
```

This PTE has value 0x09DE9067. It is made of two fields:

- The low 12 bits of the PTE are the *status flags*. In this case, these flags equal 0x067 -- or in binary, 0b000001100111. For an explanation of the status flags, see the [!pte](#) reference page.
- The high 20 bits of the PTE are equal to the *page frame number* (PFN) of the PTE. In this case, the PFN is 0x09DE9.

The first physical address on the physical page is the PFN multiplied by 0x1000 (shifted left 12 bits). The byte index is the offset on this page. Thus, the physical address you are looking for is 0x09DE9000 + 0x980 = 0x09DE9980. This is the same result obtained by the earlier methods.

Using the !analyze Extension

5/31/2017 • 10 min to read • [Edit Online](#)

The first step in debugging a crashed target computer or application is to use the **!analyze** extension command.

This extension performs a tremendous amount of automated analysis. The results of this analysis are displayed in the Debugger Command window.

You should use the **-v** option for a fully verbose display of data. For details on other options, see the **!analyze** reference page.

This topic contains:

[A User-Mode !analyze -v Example](#)

[A Kernel-Mode !analyze -v Example](#)

[The Followup Field and the triage.ini File](#)

[Additional !analyze Techniques](#)

A User-Mode !analyze -v Example

In this example, the debugger is attached to a user-mode application that has encountered an exception.

```
0:000> !analyze -v
*****
*                                         *
*             Exception Analysis          *
*                                         *
*****
Debugger SolutionDb Connection::Open failed 80004005
```

If you are connected to the internet, the debugger attempts to access a database of crash solutions maintained by Microsoft. In this case, an error message was displayed, indicating that either your machine was unable to access the internet or the web site was not working.

```
FAULTING_IP:
ntdll!PropertyLengthAsVariant+73
77f97704 cc          int     3
```

The FAULTING_IP field shows the instruction pointer at the time of the fault.

```
EXCEPTION_RECORD:  ffffffff -- (.exr fffffffffff)
ExceptionAddress: 77f97704 (ntdll!PropertyLengthAsVariant+0x00000073)
  ExceptionCode: 80000003 (Break instruction exception)
  ExceptionFlags: 00000000
NumberParameters: 3
  Parameter[0]: 00000000
  Parameter[1]: 00010101
  Parameter[2]: fffffff
```

The EXCEPTION_RECORD field shows the exception record for this crash. This information can also be viewed by using the **.exr (Display Exception Record)** command.

```
BUGCHECK_STR: 80000003
```

The BUGCHECK_STR field shows the exception code. The name is a misnomer—the term *bug check* actually signifies a kernel-mode crash. In user-mode debugging, the exception code will be displayed—in this case, 0x80000003.

```
DEFAULT_BUCKET_ID: APPLICATION_FAULT
```

The DEFAULT_BUCKET_ID field shows the general category of failures that this failure belongs to.

```
PROCESS_NAME: MyApp.exe
```

The PROCESS_NAME field specifies the name of the process that raised the exception.

```
LAST_CONTROL_TRANSFER: from 01050963 to 77f97704
```

The LAST_CONTROL_TRANSFER field shows the last call on the stack. In this case, the code at address 0x01050963 called a function at 0x77F97704. You can use these addresses with the [In \(List Nearest Symbols\)](#) command to determine what modules and functions these addresses reside in.

```
STACK_TEXT:

```

The STACK_TEXT field shows a stack trace of the faulting component.

```
FOLLOWUP_IP:
MyApp!FatalErrorBox+55
01050963 5e          pop      esi

FOLLOWUP_NAME: dbg

SYMBOL_NAME: MyApp!FatalErrorBox+55

MODULE_NAME: MyApp

IMAGE_NAME: MyApp.exe

DEBUG_FLR_IMAGE_TIMESTAMP: 383490a9
```

When [!analyze](#) determines the instruction that has probably caused the error, it displays it in the FOLLOWUP_IP field. The SYMBOL_NAME, MODULE_NAME, IMAGE_NAME, and DEBUG_FLR_IMAGE_TIMESTAMP fields show the symbol, module, image name, and image timestamp corresponding to this instruction.

```
STACK_COMMAND: .ecxr ; kb
```

The STACK_COMMAND field shows the command that was used to obtain the STACK_TEXT. You can use this command to repeat this stack trace display, or alter it to obtain related stack information.

```
BUCKET_ID: 80000003 MyApp!FatalErrorBox+55
```

The BUCKET_ID field shows the specific category of failures that the current failure belongs to. This category helps the debugger determine what other information to display in the analysis output.

```
Followup: dbg
-----

```

For information about the FOLLOWUP_NAME and the Followup fields, see [The Followup Field and the triage.ini File](#).

There are a variety of other fields that may appear:

- If control was transferred to an invalid address, then the FAULTING_IP field will contain this invalid address. Instead of the FOLLOWUP_IP field, the FAILED_INSTRUCTION_ADDRESS field will show the disassembled code from this address, although this disassembly will probably be meaningless. In this situation, the SYMBOL_NAME, MODULE_NAME, IMAGE_NAME, and DBG_FLR_IMAGE_TIMESTAMP fields will refer to the caller of this instruction.
- If the processor misfires, you may see the SINGLE_BIT_ERROR, TWO_BIT_ERROR, or POSSIBLE_INVALID_CONTROL_TRANSFER fields.
- If memory corruption seems to have occurred, the CHKIMG_EXTENSION field will specify the [!chkimg](#) extension command that should be used to investigate.

A Kernel-Mode !analyze -v Example

In this example, the debugger is attached to a computer that has just crashed.

```
kd> !analyze -v
*****
*                               *
*           Bugcheck Analysis  *
*                               *
*****
DRIVER_IRQL_NOT_LESS_OR_EQUAL (d1)
An attempt was made to access a pageable (or completely invalid) address at an
interrupt request level (IRQL) that is too high. This is usually
caused by drivers using improper addresses.
If kernel debugger is available get stack backtrace.
```

The first element of the display shows the bug check code and information about this type of bug check. Some of the text displayed may not apply to this specific instance. For more details on each bug check, see the [Bug Check Code Reference](#) section.

```
Arguments:
Arg1: 00000004, memory referenced
Arg2: 00000002, IRQL
Arg3: 00000001, value 0 = read operation, 1 = write operation
Arg4: f832035c, address which referenced memory
```

The bug check parameters are displayed next. They are each followed by a description. For example, the third parameter is 1, and the comment following it explains that this indicates that a write operation failed.

```
## Debugging Details:

WRITE_ADDRESS: 00000004 Nonpaged pool

CURRENT_IRQL: 2
```

The next few fields vary depending on the nature of the crash. In this case, we see WRITE_ADDRESS and CURRENT_IRQL fields. These are simply restating the information shown in the bug check parameters. By comparing the statement "Nonpaged pool" to the bug check text that reads "an attempt was made to access a pageable (or completely invalid) address," we can see that the address was invalid. The invalid address in this case was 0x00000004.

```
FAULTING_IP:
USBPORT!USBPORT_BadRequestFlush+7c
f832035c 894204      mov      [edx+0x4],eax
```

The FAULTING_IP field shows the instruction pointer at the time of the fault.

```
DEFAULT_BUCKET_ID: DRIVER_FAULT
```

The DEFAULT_BUCKET_ID field shows the general category of failures that this failure belongs to.

```
BUGCHECK_STR: 0xD1
```

The BUGCHECK_STR field shows the bug check code, which we have already seen. In some cases additional triage information is appended.

```
TRAP_FRAME: f8950dfc -- (.trap ffffffff8950dfc)
.trap ffffffff8950dfc
ErrCode = 00000002

f8950fe0 8052c47c 8053cf20 00000000 00002e42 nt!KiTimerExpiration+0xb0
f8950ff4 8052c16a efdefd44 00000000 00000000 nt!KiRetireDpcList+0x31
```

The STACK_TEXT field shows a stack trace of the faulting component.

```
FOLLOWUP_IP:
USBPORT!USBPORT_BadRequestFlush+7c
f832035c 894204      mov      [edx+0x4],eax
```

The FOLLOWUP_IP field shows the disassembly of the instruction that has probably caused the error.

```
FOLLOWUP_NAME:  usbtri
SYMBOL_NAME:  USBPORT!USBPORT_BadRequestFlush+7c
MODULE_NAME:  USBPORT
IMAGE_NAME:  USBPORT.SYS
DEBUG_FLR_IMAGE_TIMESTAMP:  3b7d868b
```

The SYMBOL_NAME, MODULE_NAME, IMAGE_NAME, and DBG_FLR_IMAGE_TIMESTAMP fields show the symbol, module, image, and image timestamp corresponding to this instruction (if it is valid), or to the caller of this instruction (if it is not).

```
STACK_COMMAND:  .trap ffffffff8950dfc ; kb
```

The STACK_COMMAND field shows the command that was used to obtain the STACK_TEXT. You can use this command to repeat this stack trace display, or alter it to obtain related stack information.

```
BUCKET_ID:  0xD1_W_USBPORT!USBPORT_BadRequestFlush+7c
```

The BUCKET_ID field shows the specific category of failures that the current failure belongs to. This category helps the debugger determine what other information to display in the analysis output.

```
INTERNAL SOLUTION_TEXT:  http://oca.microsoft.com/resredir.asp?sid=62&State=1
```

If you are connected to the internet, the debugger attempts to access a database of crash solutions maintained by Microsoft. This database contains links to a tremendous number of Web pages that have information about known bugs. If a match is found for your problem, the INTERNAL SOLUTION_TEXT field will show a URL that you can access for more information.

```
Followup: usbtri
-----
This problem has a known fix.
Please connect to the following URL for details:
-----
http://oca.microsoft.com/resredir.asp?sid=62&State=1
```

For information about the FOLLOWUP_NAME and the Followup fields, see [The Followup Field and the triage.ini File](#):

There are a variety of other fields that may appear:

- If control was transferred to an invalid address, then the FAULTING_IP field will contain this invalid address. Instead of the FOLLOWUP_IP field, the FAILED_INSTRUCTION_ADDRESS field will show the disassembled code from this address, although this disassembly will probably be meaningless. In this situation, the SYMBOL_NAME, MODULE_NAME, IMAGE_NAME, and DBG_FLR_IMAGE_TIMESTAMP fields will refer to the caller of this instruction.
- If the processor misfires, you may see the SINGLE_BIT_ERROR, TWO_BIT_ERROR, or POSSIBLE_INVALID_CONTROL_TRANSFER fields.
- If memory corruption seems to have occurred, the CHKIMG_EXTENSION field will specify the [!chkimg](#) extension command that should be used to investigate.
- If a bug check occurred within the code of a device driver, its name may be displayed in the BUGCHECKING_DRIVER field.

The Followup Field and the triage.ini File

In both user mode and kernel mode, the Followup field in the display will show information about the owner of the current stack frame, if this can be determined. This information is determined in the following manner:

1. When the [!analyze](#) extension is used, the debugger begins with the top frame in the stack and determines whether it is responsible for the error. If it isn't, the next frame is analyzed. This process continues until a frame that might be at fault is found.
2. The debugger attempts to determine the owner of the module and function in this frame. If the owner can be determined, this frame is considered to be at fault.
3. If the owner cannot be determined, the debugger passes to the next stack frame, and so on, until the owner is determined (or the stack is completely examined). The first frame whose owner is found in this search is considered to be at fault. If the stack is exhausted without any information being found, no Followup field is displayed.
4. The owner of the frame at fault is displayed in the Followup field. If [!analyze -v](#) is used, the FOLLOWUP_IP, SYMBOL_NAME, MODULE_NAME, IMAGE_NAME, and DBG_FLR_IMAGE_TIMESTAMP fields will refer to this frame.

For the Followup field to display useful information, you must first create a Triage.ini file containing the names of the module and function owners.

The Triage.ini file should identify the owners of all modules that could possibly have errors. You can use an informational string instead of an actual owner, but this string cannot contain spaces. If you are certain that a module will not fault, you can omit this module or indicate that it should be skipped. It is also possible to specify owners of individual functions, giving the triage process an even finer granularity.

For details on the syntax of the Triage.ini file, see [Specifying Module and Function Owners](#).

Additional !analyze Techniques

If you do not believe that the BUCKET_ID is correct, you can override the bucket choice by using [!analyze](#) with the **-D** parameter.

If no crash or exception has occurred, [!analyze](#) will display a very short text giving the current status of the target. In certain situations you may want to force the analysis to take place as if a crash had occurred. Use [!analyze -f](#) to accomplish this task.

In user mode, if an exception has occurred but you believe the underlying problem is a hung thread, set the current thread to the thread you are investigating, and then use **!analyze -hang**. This extension will perform a thread stack analysis to determine if any threads are blocking other threads.

In kernel mode, if a bug check has occurred but you believe the underlying problem is a hung thread, use **!analyze -hang**. This extension will investigate locks held by the system and scan the DPC queue chain, and will display any indications of hung threads. If you believe the problem is a kernel-mode resource deadlock, use the **!deadlock** extension along with the **Deadlock Detection** option of Driver Verifier.

You can also automatically ignore known issues. To do this, you must first create an XML file containing a formatted list of known issues. Use the **!analyze -c -loadKnownIssuesFile** extension to load this file. Then when an exception or break occurs, use the **!analyze -c** extension. If the exception matches one of the known issues, the target will resume execution. If the target does not resume executing, then you can use **!analyze -v** to determine the cause of the problem. A sample XML file can be found in the `sdk\samples\analyze_continue` subdirectory of the debugger installation directory.

Handling a Bug Check When Driver Verifier is Enabled

5/31/2017 • 3 min to read • [Edit Online](#)

Driver Verifier detects driver errors at run time. You can use Driver Verifier along with the [!analyze](#) debugger command to detect and display information about errors in your driver.

In Windows 8, Driver Verifier has been enhanced with new features, including [DDI Compliance Checking](#). Here we give an example that demonstrates DDI Compliance Checking.

Use the following procedure to get set up.

1. Establish a kernel-mode debugging session between a host and target computer.
2. Install your driver on the target computer.
3. On the target computer, open a Command Prompt window and enter the command **Verifier**. Use [Driver Verifier Manager](#) to enable Driver Verifier for your driver.
4. Reboot the target computer.

When Driver Verifier detects an error, it generates a bug check. Then Windows breaks into the debugger and displays a brief description of the error. Here is an example where Driver Verifier generates Bug Check [DRIVER_VERIFIER_DETECTED_VIOLATION \(C4\)](#).

```
Driver Verifier: Extension abort with Error Code 0x20005
Error String ExAcquireFastMutex should only be called at IRQL <= APC_LEVEL.

*** Fatal System Error: 0x0000000c4
(0x0000000000020005,0xFFFFF880000E16F50,0x0000000000000000,0x0000000000000000)

Break instruction exception - code 80000003 (first chance)

A fatal system error has occurred.
Debugger entered on first try; Bugcheck callbacks have not been invoked.

A fatal system error has occurred.

nt!DbgBreakPointWithStatus:
fffff802`a40ef930 cc          int     3
```

In the debugger, enter [!analyze -v](#) to get a detailed description of the error.

```

0: kd> !analyze -v

DRIVER_VERIFIER_DETECTED_VIOLATION (c4)
A device driver attempting to corrupt the system has been caught. This is
because the driver was specified in the registry as being suspect (by the
administrator) and the kernel has enabled substantial checking of this driver.
If the driver attempts to corrupt the system, bugchecks 0xC4, 0xC1 and 0xA will
be among the most commonly seen crashes.

Arguments:
Arg1: 0000000000020005, ID of the 'IrqlExApcLte1' rule that was violated.
Arg2: fffff88000e16f50, A pointer to the string describing the violated rule condition.
Arg3: 0000000000000000, An optional pointer to the rule state variable(s).
Arg4: 0000000000000000, Reserved (unused)

## Debugging Details:

...
DV_VIOLATED_CONDITION: ExAcquireFastMutex should only be called at IRQL <= APC_LEVEL.

DV_MSDN_LINK: !url http://go.microsoft.com/fwlink/p/?linkid=216022

DV_RULE_INFO: !ruleinfo 0x20005

BUGCHECK_STR: 0xc4_IrqlExApcLte1_XDV

DEFAULT_BUCKET_ID: WIN8_DRIVER_FAULT

PROCESS_NAME: TiWorker.exe

CURRENT_IRQL: 9

```

In the preceding output, you can see the name and description of the rule, **IrqlExApcLte1**, that was violated, and you can click a link to the reference page that describes the rule: <http://go.microsoft.com/fwlink/p/?linkid=216022>. You can also click a debugger command link, **!ruleinfo 0x20005**, to get information about the rule. In this case, the rule states that you cannot call **ExAcquireFastMutex** if the interrupt request level (IRQL) is greater than APC_LEVEL. The output shows that the current IRQL is 9, and in wdm.h you can see that APC_LEVEL has a value of 1. For more information about IRQLs, see [Managing Hardware Priorities](#).

The output of **!analyze -v** continues with a stack trace and information about the code that caused the error. In the following output, you can see that the **OnInterrupt** routine in MyDriver.sys called **ExAcquireFastMutex**.

OnInterrupt is an interrupt service routine that runs at an IRQL greater than APC_LEVEL, so it is a violation for this routine to call **ExAcquireFastMutex**.

```

Noninvasive Debugging (User Mode)

5/26/2017 • 2 min to read • [Edit Online](#)

If a user-mode application is already running, the debugger can debug it *noninvasively*. With noninvasive debugging, you do not have as many debugging actions. However, you can minimize the debugger's interference with the target application. Noninvasive debugging is useful if the target application has stopped responding.

In noninvasive debugging, the debugger does not actually attach to the target application. The debugger suspends all of the target's threads and has access to the target's memory, registers, and other such information. However, the debugger cannot control the target, so commands like **g (Go)** do not work.

If you try to execute commands that are not permitted during noninvasive debugging, you receive an error message that states, "The debugger is not attached, so process execution cannot be monitored."

Selecting the Process to Debug

You can specify the target application by the process ID (PID) or process name.

If you specify the application by name, you should use the complete name of the process, including the file name extension. If two processes have the same name, you must use the process ID instead.

For more information about how to determine the process ID and the process name, see [Finding the Process ID](#).

For information about starting and stopping a noninvasive debugging session, see the following topics:

- [Debugging a User-Mode Process Using Visual Studio](#)
- [Debugging a User-Mode Process Using WinDbg](#)
- [Debugging a User-Mode Process Using CDB](#)

CDB Command Line

To noninvasively debug a running process from the CDB command line, specify the **-pv** option, the **-p** option, and the process ID, in the following syntax.

cdb -pv -p ProcessID

Or, to noninvasively debug a running process by specifying the process name, use the following syntax instead.

cdb -pv -pn ProcessName

There are several other useful command-line options. For more information about the command-line syntax, see

[CDB Command-Line Options](#)

WinDbg Command Line

To noninvasively debug a running process from the WinDbg command line, specify the **-pv** option, the **-p** option, and the process ID, in the following syntax.

windbg -pv -p ProcessID

Or, to noninvasively debug a running process by specifying the process name, use the following syntax instead.

windbg -pv -pn ProcessName

There are several other useful command-line options. For more information about the command-line syntax, see

[WinDbg Command-Line Options](#)

WinDbg Menu

When WinDbg is in dormant mode, you can noninvasively debug a running process by clicking **Attach to a Process** on the **File** menu or by pressing F6.

When the **Attach to Process** dialog box appears, select the **Noninvasive** check box. Then, select the line that contains the process ID and name that you want. (You can also enter the process ID in the **Process ID** box.) Finally, click **OK**.

Debugger Command Window

If the debugger is already active, you can noninvasively debug a running process by using the [.attach -v \(Attach to Process\)](#) command in the [Debugger Command window](#).

You can use the `.attach` command if the debugger is already debugging one or more processes invasively. You can use this command in CDB if it is dormant, but not in a dormant WinDbg.

If the `.attach -v` command is successful, the debugger debugs the specified process the next time that the debugger issues an execution command. Because execution is not permitted during noninvasive debugging, the debugger cannot noninvasively debug more than one process at a time. This restriction also means that using the `.attach -v` command might make an existing invasive debugging session less useful.

Beginning the Debugging Session

For more information about how to begin a debugging session, see [Debugger Operation](#).

Debugging in Assembly Mode

5/31/2017 • 4 min to read • [Edit Online](#)

If you have C or C++ source files for your application, you can use the debugger much more powerfully if you [debug in source mode](#).

However, there are many times you cannot perform source debugging. You might not have the source files for your application. You might be debugging someone else's code. You might not have built your executable files with full .pdb symbols. And even if you can do source debugging on your application, you might have to trace Microsoft Windows routines that your application calls or that are used to load your application.

In these situations, you have to debug in assembly mode. Moreover, assembly mode has many useful features that are not present in source debugging. The debugger automatically displays the contents of memory locations and registers as they are accessed and displays the address of the program counter. This display makes assembly debugging a valuable tool that you can use together with source debugging.

Disassembly Code

The debugger primarily analyzes binary executable code. Instead of displaying this code in raw format, the debugger *disassembles* this code. That is, the debugger converts the code from machine language to assembly language.

You can display the resulting code (known as *disassembly code*) in several different ways:

- The **u (Unassemble)** command disassembles and displays a specified section of machine language.
- The **uf (Unassemble Function)** command disassembles and displays a function.
- The **up (Unassemble from Physical Memory)** command disassembles and displays a specified section of machine language that has been stored in physical memory.
- The **ur (Unassemble Real Mode BIOS)** command disassembles and displays a specified 16-bit real-mode code.
- The **ux (Unassemble x86 BIOS)** command disassembles and displays the x86-based BIOS code instruction set at a specified address.
- (WinDbg only) The [disassembly window](#) disassembles and displays a specified section of machine language. this window is automatically active if you select the **automatically open disassembly** command on the **window** menu. you can also open this window by clicking **disassembly** on the **view** menu, pressing alt+7, or pressing the **disassembly (alt+7)** button () on the WinDbg toolbar.

The disassembly display appears in four columns: address offset, binary code, assembly language mnemonic, and assembly language details. The following example shows this display.

0040116b	45	inc	ebp
0040116c	fc	cld	
0040116d	8945b0	mov	eax, [ebp-0x1c]

To the right of the line that represents the current program counter, the display shows the values of any memory locations or registers that are being accessed. If this line contains a branch instruction, the notation **[br=1]** or **[br=0]** appears. This notation indicates a branch that is or is not taken, respectively.

You can use the [.asm \(Change Disassembly Options\)](#) command to change how the disassembled instructions

are displayed.

In WinDbg's Disassembly window, the line that represents the current program counter is highlighted. Lines where breakpoints are set are also highlighted.

You can also use the following commands to manipulate assembly code:

- The **# (Search for Disassembly Pattern)** command searches a region of memory for a specific pattern. This command is equivalent to searching the four columns of the disassembly display.
- The **a (Assemble)** command can take assembly instructions and translate them into binary machine code.

Assembly Mode and Source Mode

The debugger has two different operating modes: *assembly mode* and *source mode*.

When you are single-stepping through an application, the size of a single step is one line of assembly code or one line of source code, depending on the mode.

Several commands create different data displays depending on the mode.

In WinDbg, the [Disassembly window](#) automatically moves to the foreground when you run or step through an application in assembly mode. In source mode, the [Source window](#) moves to the foreground.

To set the mode, you can do one of the following:

- Use the **I+, I- (Set Source Options)** command to control the mode. The **I-t** command activates assembly mode.
- (WinDbg only) Clear the **Source Mode** command on the **Debug** menu to cause the debugger to enter assembly mode. You can also click the **Source mode off** button (101) on the toolbar.

In WinDbg, when you are in assembly mode, **ASM** appears visible on the status bar.

The shortcut menu in WinDbg's Disassembly window includes the **Highlight instructions from the current source line** command. This command highlights all of the instructions that correspond to the current source line. Frequently, a single source line corresponds to multiple assembly instructions. If code has been optimized, these assembly instructions might not be consecutive. The **Highlight instructions from the current source line** command enables you to find all of the instructions that were assembled from the current source line.

Assembly Language Source Files

If your application was written in assembly language, the disassembly that the debugger produces might not exactly match your original code. In particular, NO-OPs and comments will not be present.

If you want to debug your code by referencing the original .asm files, you must use source mode debugging. You can load the assembly file like a C or C++ source file. For more information about this kind of debugging, see [Debugging in Source Mode](#).

[Send comments about this topic to Microsoft](#)

Debugging in Source Mode

5/31/2017 • 7 min to read • [Edit Online](#)

Debugging an application is easier if you can analyze the source of the code, instead of the disassembled binaries.

WinDbg, CDB, and KD can use source code in debugging, if the source language is C, C++, or assembly.

Compilation Requirements

To use source debugging, you must have your compiler or linker create symbol files (.pdb files) when the binaries are built. These symbol files show the debugger how the binary instructions correspond to the source lines.

Also, the debugger must be able to access the actual source files, because symbol files do not contain the actual source text.

If it is possible, the compiler and linker should not optimize your code. Source debugging and access to local variables are more difficult, and sometimes almost impossible, if the code has been optimized. If you are using the Build utility as your compiler and linker, set the MSC_OPTIMIZATION macro to **/Od /Oi** to avoid optimization.

Locating the Symbol Files and Source Files

To debug in source mode, the debugger must be able to find the source files and the symbol files. For more information, see [Source Code](#).

Beginning Source Debugging

The debugger can display source information whenever it has proper symbols and source files for the thread that is currently being debugged.

If you start a new user-mode application by using the debugger, the initial break occurs when Ntdll.dll loads the application. Because the debugger does not have access to the Ntdll.dll source files, you cannot access source information for your application at this point.

To move the program counter to the beginning of the application, add a breakpoint at the entry point to your binary. In the [Debugger Command window](#), type the following command.

```
bp main  
g
```

The application is then loaded and stops when the **main** function is entered. (Of course, you can use any entry point, not only **main**.)

If the application throws an exception, it breaks into the debugger. Source information is available at this point. However, if you issue a break by using the **CTRL+C**, **CTRL+BREAK**, or **Debug | Break** command, the debugger creates a new thread, so you cannot see your source code.

After you have reached a thread that you have source files for, you can use the Debugger Command window to execute source debugging commands. If you are using WinDbg, the [Source window](#) appears. If you have already opened a Source window by clicking **Open Source File** on the **File** menu, WinDbg typically create a new window for the source. You can close the previous window without affecting the debugging process.

Source Debugging in the WinDbg GUI

If you are using WinDbg, a Source window appears as soon as the program counter is in code that the debugger has source information for.

WinDbg displays one Source window for each source file that you or WinDbg opened. For more information about the text properties of this window, see [Source Windows](#).

You can then step through your application or execute to a breakpoint or to the cursor. For more information about stepping and tracing commands, see [Controlling the Target](#).

If you are in source mode, the appropriate Source window moves to the foreground as you step through your application. Because there are also Microsoft Windows routines that are called during the application's execution, the debugger might move a [Disassembly window](#) to the foreground when this kind of call occurs (because the debugger does not have access to the source for these functions). When the program counter returns to known source files, the appropriate Source window becomes active.

As you move through the application, WinDbg highlights your location in the Source window and the Disassembly window. Lines at which breakpoints are set are also highlighted. The source code is colored according to the parsing of the language. If the Source window has been selected, you can hover over a symbol with the mouse to evaluate it. For more information about these features and how to control them, see [Source Windows](#).

To activate source mode in WinDbg, use the **I+t** command, click **source mode** on the **debug** menu, or click the **source mode on** button () on the toolbar.

When source mode is active, the **ASM** indicator appears unavailable on the status bar.

You can view or alter the values of any local variables as you step through a function in source mode. For more information, see [Reading and Writing Memory](#).

Source Debugging in the Debugger Command Window

If you are using CDB, you do not have a separate Source window. However, you can still view your progress as you step through the source.

Before you can do source debugging in CDB, you have to load source line symbols by issuing the [.lines \(Toggle Source Line Support\)](#) command or by starting the debugger with the [-lines command-line option](#).

If you execute an **I+t** command, all program stepping is performed one source line at a time. Use **I-t** to step one assembly instruction at a time. If you are using WinDbg, this command has the same effect as selecting or clearing **Source Mode** on the **Debug** menu or using the toolbar buttons.

The **I+s** command displays the current source line and line number at the prompt. If you want to see only the line number, use **I+l** instead.

If you use **I+o** and **I+s**, only the source line is displayed while you step through the program. The program counter, disassembly code, and register information are hidden. This kind of display enables you to quickly step through the code and view nothing but the source.

You can use the [Isp \(Set Number of Source Lines\)](#) command to specify exactly how many source lines are displayed when you step through or execute the application.

The following sequence of commands is an effective way to step through a source file.

```
.lines      enable source line information
bp main    set initial breakpoint
l+t        stepping will be done by source line
l+s        source lines will be displayed at prompt
g          run program until "main" is entered
pr         execute one source line, and toggle register display off
p          execute one source line
```

Because **ENTER** repeats the last command, you can now step through the application by using the **ENTER** key. Each step causes the source line, memory offset, and assembly code to appear.

For more information about how to interpret the disassembly display, see [Debugging in Assembly Mode](#).

When the assembly code is displayed, any memory location that is being accessed is displayed at the right end of the line. You can use the **d*** ([Display Memory](#)) and **e*** ([Enter Values](#)) commands to view or change the values in these locations.

If you have to view each assembly instruction to determine offsets or memory information, use **I-t** to step by assembly instructions instead of source lines. The source line information can still be displayed. Each source line corresponds to one or more assembly instructions.

All of these commands are available in WinDbg and in CDB. You can use the commands to view source line information from WinDbg's [Debugger Command window](#) instead of from the Source window.

Source Lines and Offsets

You can also perform source debugging by using the expression evaluator to determine the offset that corresponds to a specific source line.

The following command displays a memory offset.

```
? `[[module!]filename][:linenumber]`
```

If you omit *filename*, the debugger searches for the source file that corresponds to the current program counter.

The debugger reads *linenumber* as a decimal number unless you add **0x** before it, regardless of the current default radix. If you omit *linenumber*, the expression evaluates to the initial address of the executable file that corresponds to the source file.

This syntax is understood in CDB only if the **.lines** command or the **-lines** command-line option has loaded source line symbols.

This technique is very versatile, because you can use it regardless of where the program counter is pointing. For example, this technique enables you to set breakpoints in advance, by using commands such as the following.

```
bp `source.c:31`
```

For more information, see [Source Line Syntax](#) and [Using Breakpoints](#).

Stepping and Tracing in Source Mode

When you are debugging in source mode, there can be multiple function calls on a single source line. You cannot use the **p** and **t** commands to separate these function calls.

For example, in the following command, the **t** command steps into both **GetTickCount** and **printf**, while the **p** command steps over both function calls.

```
printf( "%x\n", GetTickCount() );
```

If you want to step over certain calls while tracing into other calls, use [.step_filter \(Set Step Filter\)](#) to indicate which calls to step over.

You can use `_step_filter` to filter out framework functions (for example, Microsoft Foundation Classes (MFC) or Active Template Library (ATL) calls).

[Send comments about this topic to Microsoft](#)

Debugging Optimized Code and Inline Functions

5/31/2017 • 7 min to read • [Edit Online](#)

For Windows 8, the debugger and the Windows compiler have been enhanced so that you can debug optimized code and debug inline functions. The debugger displays parameters and local variables regardless of whether they are stored in registers or on the stack. The debugger also displays inline functions in the call stack. For inline functions, the debugger displays local variables, but not parameters.

When code gets optimized, it is transformed to run faster and use less memory. Sometimes functions are removed as a result of dead code removal, code being merged, or functions being placed inline. Local variables and parameters can also be removed. Many code optimizations remove local variables that are not needed or used; other optimizations remove induction variables in loops. Common sub-expression elimination merges local variables together.

Retail builds of Windows are optimized. So if you are running a retail build of Windows, it is especially helpful to have a debugger that is designed to work well with optimized code. To make debugging of optimized code effective, two primary features are required: 1) accurate display of local variables, and 2) display of inline functions on the call stack.

Accurate display of local variables and parameters

To facilitate the accurate display of local variables and parameters, the compiler records information about the locations of local variables and parameters in symbol (PDB) files. These location records track the variables' storage locations and the specific code ranges where these locations are valid. These records not only help track the locations (in registers or in stack slots) of the variables, but also the movement of the variables. For example, a parameter might first be in register RCX, but is moved to a stack slot to free up RCX, then moved to register R8 when it is heavily used in a loop, and then moved to different stack slot when the code is out of the loop. The Windows debugger consumes the rich location records in the PDB files and uses the current instruction pointer to select the appropriate location records for the local variables and parameters.

This screen shot of the Locals window in Visual Studio shows the parameters and local variables for a function in an optimized 64-bit application. The function is not inline, so we see both parameters and local variables.

Locals		
Name	Value	Type
p1	0n6	int
p2	0n13	int
p3	0n27	int
num1	0n8	int
num2	0n0	int
num3	0n0	int

You can use the **dv -v** command to see the locations of the parameters and local variables.

Debugger Immediate Window	
0:000>	dv -v
@ebx	p1 = 0n6
@edi	p2 = 0n13
@esi	p3 = 0n27
00000000`00fcfed8	num1 = 0n8
00000000`00fcfee0	num2 = 0n0
00000000`00fcfed0	num3 = 0n0

Notice that the Locals window displays the parameters correctly even though they are stored in registers.

In addition to tracking variables with primitive types, the location records track data members of local structures and classes. The following debugger output displays local structures.

```
0:000> dt My1
Local var Type _LocalStruct
+0x000 i1          : 0n0 (edi)
+0x004 i2          : 0n1 (rsp+0x94)
+0x008 i3          : 0n2 (rsp+0x90)
+0x00c i4          : 0n3 (rsp+0x208)
+0x010 i5          : 0n4 (r10d)
+0x014 i6          : 0n7 (rsp+0x200)

0:000> dt My2
Local var @ 0xefa60 Type _IntSum
+0x000 sum1         : 0n4760 (edx)
+0x004 sum2         : 0n30772 (ecx)
+0x008 sum3         : 0n2 (r12d)
+0x00c sum4         : 0n0
```

Here are some observations about the preceding debugger output.

- The local structure **My1** illustrates that the compiler can spread local structure data members to registers and non-contiguous stack slots.
- The output of the command **dt My2** will be different from the output of the command **dt _IntSum 0xefa60**. You cannot assume that the local structure will occupy a contiguous block of stack memory. In the case of **My2**, only **sum4** stays in the original stack block; the other three data members are moved to registers.
- Some data members can have multiple locations. For example, **My2.sum2** has two locations: one is register ECX (which the Windows debugger chooses) and the other is 0xefa60+0x4 (the original stack slot). This could happen for primitive-type local variables also, and the Windows debugger imposes precedent heuristics to determine which location to use. For example, register locations always trump stack locations.

Display of inline functions on the call stack

During code optimization, some functions are placed in line. That is, the body of the function is placed directly in the code like a macro expansion. There is no function call and no return to the caller. To facilitate the display of inline functions, the compiler stores data in the PDB files that helps decode the code chunks for the inline functions (that is, sequences of code blocks in caller functions that belong to the callee functions that are being placed inline) as well as the local variables (scoped local variables in those code blocks). This data helps the debugger include inline functions as part of the stack unwind.

Suppose you compile an application and force a function named **func1** to be inline.

```
__forceinline int func1(int p1, int p2, int p3)
{
    int num1 = 0;
    int num2 = 0;
    int num3 = 0;
    ...
}
```

You can use the **bm** command to set a breakpoint at **func1**.

```

0:000> bm MyApp!func1
1: 000007f6`8d621088 @! "MyApp!func1" (MyApp!func1 inlined in MyApp!main+0x88)
0:000> g

Breakpoint 1 hit
MyApp!main+0x88:
000007f6`8d621088 488d0d21110000  lea      rcx,[MyApp!`string' (000007f6`8d6221b0)]

```

After you take one step into `func1`, you can use the `k` command to see `func1` on the call stack. You can use the `dv` command to see the local variables for `func1`. Notice that the local variable `num3` is shown as unavailable. A local variable can be unavailable in optimized code for a number of reasons. It might be that the variable doesn't exist in the optimized code. It might be that the variable has not been initialized yet or that the variable is no longer being used.

```

0:000> p
MyApp!func1+0x7:
000007f6`8d62108f 8d3c33          lea      edi,[rbx+rsi]

0:000> knL
# Child-SP      RetAddr      Call Site
00 (Inline Function) -----`----- MyApp!func1+0x7
01 00000000`0050fc90 000007f6`8d6213f3 MyApp!main+0x8f
02 00000000`0050fcf0 000007ff`c6af0f7d MyApp!__tmainCRTStartup+0x10f
03 00000000`0050fd20 000007ff`c7063d6d KERNEL32!BaseThreadInitThunk+0xd
04 00000000`0050fd50 00000000`00000000 ntdll!RtlUserThreadStart+0x1d

0:000> dv -v
00000000`0050fcb0      num1 = 0n0
00000000`0050fcb4      num2 = 0n0
<unavailable>          num3 = <value unavailable>

```

If you look at frame 1 in the stack trace, you can see the local variables for the `main` function. Notice that two of the variables are stored in registers.

```

0:000> .frame 1
01 00000000`0050fc90 000007f6`8d6213f3 MyApp!main+0x8f

0:000> dv -v
00000000`0050fd08      c = 0n7
@ebx                     b = 0n13
@esi                     a = 0n6

```

The Windows debugger aggregates data from PDB files to find all the places where a specific function has been placed inline. You can use the `x` command to list all the caller sites of the an inline function.

```

0:000> x simple!MoreCalculate
00000000`ff6e1455 simple!MoreCalculate = (inline caller) simple!wmain+8d
00000000`ff6e1528 simple!MoreCalculate = (inline caller) simple!wmain+160

0:000> x simple!Calculate
00000000`ff6e141b simple!Calculate = (inline caller) simple!wmain+53

```

Because the Windows debugger can enumerate all the caller sites of an inline function, it can set a breakpoints inside the inline function by calculating the offsets from the caller sites. You can use the `bm` command (which is used to set breakpoints that match regular expression patterns) to set breakpoints for inline functions.

The Windows debugger groups all breakpoints that are set for a specific inline function into a breakpoint container. You can manipulate the breakpoint container as a whole by using commands like `be`, `bd`, `bc`. See the

following **bd 3** and **bc 3** command examples. You can also manipulate individual breakpoints. See the following **be 2** command example.

```
0:000> bm simple!MoreCalculate
2: 00000000`ff6e1455 @!"simple!MoreCalculate" (simple!MoreCalculate inlined in simple!wmain+0x8d)
4: 00000000`ff6e1528 @!"simple!MoreCalculate" (simple!MoreCalculate inlined in simple!wmain+0x160)

0:000> b1
0 e 00000000`ff6e13c8 [n:\win7\simple\simple.cpp @ 52] 0001 (0001) 0:**** simple!wmain
3 e <inline function> 0001 (0001) 0:**** {simple!MoreCalculate}
2 e 00000000`ff6e1455 [n:\win7\simple\simple.cpp @ 58] 0001 (0001) 0:**** simple!wmain+0x8d (inline
function simple!MoreCalculate)
4 e 00000000`ff6e1528 [n:\win7\simple\simple.cpp @ 72] 0001 (0001) 0:**** simple!wmain+0x160 (inline
function simple!MoreCalculate)

0:000> bd 3
0:000> be 2

0:000> b1
0 e 00000000`ff6e13c8 [n:\win7\simple\simple.cpp @ 52] 0001 (0001) 0:**** simple!wmain
3 d <inline function> 0001 (0001) 0:**** {simple!MoreCalculate}
2 e 00000000`ff6e1455 [n:\win7\simple\simple.cpp @ 58] 0001 (0001) 0:**** simple!wmain+0x8d (inline
function simple!MoreCalculate)
4 d 00000000`ff6e1528 [n:\win7\simple\simple.cpp @ 72] 0001 (0001) 0:**** simple!wmain+0x160 (inline
function simple!MoreCalculate)

0:000> bc 3

0:000> b1
0 e 00000000`ff6e13c8 [n:\win7\simple\simple.cpp @ 52] 0001 (0001) 0:**** simple!wmain
```

Because there are no explicit call or return instructions for inline functions, source-level stepping is especially challenging for a debugger. For example, you could unintentionally step in to an inline function (if the next instruction is part of an inline function), or you could step in and step out of the same inline function multiple times (because the code blocks for the inline function have been split and moved by the compiler). To preserve the familiar stepping experience, the Windows debugger maintains a small conceptual call stack for every code instruction address and builds an internal state machine to execute step-in, step-over, and step-out operations. This gives a reasonably accurate approximation to the stepping experience for non-inline functions.

Additional Information

Note You can use the **.inline 0** command to disable inline function debugging. The **.inline 1** command enables inline function debugging. [Standard Debugging Techniques](#)

Debugging Managed Code Using the Windows Debugger

5/31/2017 • 6 min to read • [Edit Online](#)

You can use the windows debuggers (WinDbg, CDB, and NTSD) to debug target applications that contain managed code. To debug managed code, you must load the [SOS debugging extension \(sos.dll\)](#) and a data access component (mscordacwks.dll).

The windows debuggers are separate from the Visual Studio debugger. For information about the distinction between the windows debuggers and the Visual Studio debugger, see [Windows Debugging](#).

Introduction to Managed Code

Managed code is executed together with the Microsoft .NET common language runtime (CLR). In a managed-code application, the binary code that the compiler produces is in Microsoft intermediate language (MSIL), which is platform-independent.

When managed code is run, the runtime produces native code that is platform-specific. The process of generating native code from MSIL is called *just-in-time (JIT) compiling*. After the JIT compiler has compiled the MSIL for a specific method, the method's native code remains in memory. Whenever this method is later called, the native code executes and the JIT compiler does not have to be involved.

You can build managed code by using several compilers that are manufactured by a variety of software producers. In particular, Microsoft Visual Studio can build managed code from several different languages including C#, Visual Basic, JScript, and C++ with managed extensions.

The CLR is not updated every time the .NET Framework is updated. For example, versions 2.0, 3.0, and 3.5 of the .NET Framework all use version 2.0 of the CLR. The following table shows the version and filename of the CLR used by each version of the .NET Framework.

.NET FRAMEWORK VERSION	CLR VERSION	CLR FILENAME
1.1	1.1	mscorwks.dll
2.0	2.0	mscorwks.dll
3.0	2.0	mscorwks.dll
3.5	2.0	mscorwks.dll
4.0	4.0	clr.dll
4.5	4.0	clr.dll

Debugging Managed Code

To debug managed code, the debugger must load these two components.

- Data access component (DAC) (mscordacwks.dll)
- [SOS debugging extension \(sos.dll\)](#)

Note For all versions of the .NET Framework, the filename of the DAC is mscordacwks.dll, and the filename of the SOS debugging extension is sos.dll.

Getting the SOS Debugging Extension (sos.dll)

The SOS debugging extension (sos.dll) files are not included in the current version of Debugging Tools for Windows.

For .NET Framework versions 2.0 and later, sos.dll is included in the .NET Framework installation.

For version 1.x of the .NET Framework, sos.dll is not included in the .NET Framework installation. To get sos.dll for .NET Framework 1.x, download the 32-bit version of Windows 7 Debugging Tools for Windows.

Windows 7 Debugging Tools for Windows is included in the Windows SDK for Windows 7, which is available at these two places:

- [Windows SDK for Windows 7 and .NET Framework 4.0](#)
- [Windows SDK for Windows 7 and .NET Framework 4.0 \(ISO\)](#)

If you are running an x64 version of Windows, use the [ISO](#) site, so that you can specify that you want the 32-bit version of the SDK. Sos.dll is included only in the 32-bit version of Windows 7 Debugging Tools for Windows.

Loading mscordacwks.dll and sos.dll (live debugging)

Assume that the debugger and the application being debugged are running on the same computer. Then the .NET Framework being used by the application is installed on the computer and is available to the debugger.

The debugger must load a version of the DAC that is the same as the version of the CLR that the managed-code application is using. The bitness (32-bit or 64-bit) must also match. The DAC (mscordacwks.dll) comes with the .NET Framework. To load the correct version of the DAC, attach the debugger to the managed-code application, and enter this command.

.cordll -ve -u -l

The output should be similar to this.

```
CLRDLL: Loaded DLL C:\Windows\Microsoft.NET\Framework64\v4.0.30319\mscordacwks.dll
CLR DLL status: Loaded DLL C:\Windows\Microsoft.NET\Framework64\v4.0.30319\mscordacwks.dll
```

To verify that the version of mscordacwks.dll matches the version of the CLR that the application is using, enter one of the following commands to display information about the loaded CLR module.

!mv mclr (for version 4.0 of the CLR)

!mv mscorewks (for version 1.0 or 2.0 of the CLR)

The output should be similar to this.

```
start           end           module name
000007ff`26710000 000007ff`2706e000  clr      (deferred)
  Image path: C:\Windows\Microsoft.NET\Framework64\v4.0.30319\clr.dll
...
...
```

In the preceding example, notice that the version of the CLR (clr.dll) matches the version of the DAC (mscordacwks.dll): v4.0.30319. Also notice that both components are 64-bit.

When you use **.cordll** to load the DAC, the SOS debugging extension (sos.dll) might get loaded automatically. If sos.dll doesn't get loaded automatically, you can use one of these commands to load it.

.loadby sos clr (for version 4.0 of the CLR)

.loadby sos mscorewks (for version 1.0 or 2.0 of the CLR)

As an alternative to using **.loadby**, you can use **.load**. For example, to load version 4.0 of the 64-bit CLR, you could enter a command similar to this.

.load C:\Windows\Microsoft.NET\Framework64\v4.0.30319\sos.dll

In the preceding output, notice that the version of the SOS debugging extension (sos.dll) matches the version of the CLR and the DAC: v4.0.30319. Also notice that all three components are 64-bit.

Loading mscoredacwks.dll and sos.dll (dump file)

Suppose you use the debugger to open a dump file (of a managed-code application) that was created on another computer.

The debugger must load a version of the DAC that is the same as the version of the CLR that the managed-code application was using on the other computer. The bitness (32-bit or 64-bit) must also match.

The DAC (mscoredacwks.dll) comes with the .NET Framework, but let's assume that you do not have the correct version of the .NET Framework installed on the computer that is running the debugger. You have three options.

- Load the DAC from a symbol server. For example, you could include Microsoft's public symbol server in your symbol path.
- Install the correct version of the .NET Framework on the computer that is running the debugger.
- Get the correct version of mscoredacwks.dll from the person who created the dump file (on another computer) and manually copy it to the computer that is running the debugger.

Here we illustrate using Microsoft's public symbol server.

Enter these commands.

.sympath+ srv* (Add symbol server to symbol path.)

!sym noisy

.cordll -ve -u -l

The output will be similar to this.

```
CLRDLL: Unable to get version info for 'C:\Windows\Microsoft.NET
         \Framework64\v4.0.30319\mscoredacwks.dll', Win32 error 0n87

SYMSRV:  C:\ProgramData\dbo\sym\mscoredacwks_AMD64_AMD64_4.0.30319.18010.dll
          \5038768C95e000\mscoredacwks_AMD64_AMD64_4.0.30319.18010.dll not found

SYMSRV:  mscoredacwks_AMD64_AMD64_4.0.30319.18010.dll from
          http://msdl.microsoft.com/download/symbols: 570542 bytes - copied
          ...
SYMSRV:  C:\ProgramData\dbo\sym\SOS_AMD64_AMD64_4.0.30319.18010.dll
          \5038768C95e000\SOS_AMD64_AMD64_4.0.30319.18010.dll not found

SYMSRV:  SOS_AMD64_AMD64_4.0.30319.18010.dll from
          http://msdl.microsoft.com/download/symbols: 297048 bytes - copied
          ...
Automatically loaded SOS Extension
...
```

In the preceding output, you can see that the debugger first looked for mscoredacwks.dll and sos.dll on the local computer in C:\Windows\Microsoft.NET and in the symbol cache (C:\ProgramData\dbo\sym). When the debugger did not find the correct versions of the files on the local computer, it retrieved them from the public symbol server.

To verify that the version of mscoredacwks.dll matches the version of the CLR that the application was using, enter

one of the following commands to display information about the loaded CLR module.

!lmv -mclr (for version 4.0 of the CLR)

!lmv -mscorwks (for version 1.0 or 2.0 of the CLR)

The output should be similar to this.

```
start           end           module name
000007ff`26710000 000007ff`2706e000  clr      (deferred)
  Image path: C:\Windows\Microsoft.NET\Framework64\v4.0.30319\clr.dll
  ...
  ...
```

In the preceding example, notice that the version of the CLR (clr.dll) matches the version of the DAC (mscordacwks.dll): v4.0.30319. Also notice that both components are 64-bit.

Using the SOS Debugging Extension

To verify that the SOS debugging extension loaded correctly, enter the [.chain](#) command.

```
0:000> .chain
Extension DLL search Path:
...
Extension DLL chain:
C:\ProgramData\dbg\sym\SOS_AMD64_AMD64_4.0.30319.18010.dll\...
...
dbghelp: image 6.13.0014.1665, API 6.2.6, built Wed Dec 12 03:02:43 2012
...
```

To test the SOS debugging extension, enter **!sos.help**. Then try one of the command provided by the SOS debugging extension. For example, you could try **!sos.DumpDomain** or the **!sos.Threads** command.

Notes

Sometimes a managed-code application loads more than one version of the CLR. In that case, you must specify which version of the DAC to load. For more information, see [.cordll](#).

Debugging Windows Apps Using the Windows Debugger

5/26/2017 • 1 min to read • [Edit Online](#)

You can use the Windows debuggers (WinDbg, CDB, and NTSD) to debug Windows apps. Use the **PLMDebug** tool to take control of suspending, resuming, and terminating a Windows app while you are debugging.

To debug a managed-code Windows app, load the [SOS debugging extension \(sos.dll\)](#) and a data access component (mscordacwks.dll). For more information, see [Debugging Managed Code Using the Windows Debugger](#).

The windows debuggers are separate from the Visual Studio debugger. For information about the distinction between the windows debuggers and the Visual Studio debugger, see [Windows Debugging](#).

[Send comments about this topic to Microsoft](#)

Changing Contexts

5/26/2017 • 6 min to read • [Edit Online](#)

In kernel-mode debugging, there are many processes, threads, and sometimes user sessions that are executing at the same time. Therefore, phrases such as "virtual address 0x80002000" or "the **eax** register" are ambiguous. You must specify the *context* in which such phrases can be understood.

The debugger has five different contexts that you can set while you are debugging:

1. The session context indicates the default user session. (This context applies to only Microsoft Windows XP and later versions of Windows. These operating systems allow multiple logon sessions to coexist.)
2. The process context determines how the debugger interprets virtual addresses.
3. The *user-mode address context* is almost never set directly. This context is automatically set when you change the process context.
4. The register context determines how the debugger interprets registers and also controls the results of a stack trace. This context is also known as the *thread context*, although that term is not completely accurate. An *explicit context* is also a type of register context. If you specify an explicit context, that context is used instead of the current register context.
5. The local context determines how the debugger interprets local variables. This context is also known as the *scope*.

Session Context

In Windows XP and later versions of Windows, multiple logon sessions can run at the same time. Each logon session has its own processes.

The **!session** extension displays all logon sessions or changes the current session context.

The session context is used by the **!sprocess** and **!spoolused** extensions when the session number is entered as "-2".

When the session context is changed, the process context is automatically changed to the active process for that session.

Process Context

Each process has its own page directory that records how virtual addresses are mapped to physical addresses. When any thread within a process is executing, the Windows operating system uses this page directory to interpret virtual addresses.

During user-mode debugging, the current process determines the process context. Virtual addresses that are used in debugger commands, extensions, and debugging information windows are interpreted by using the page directory of the current process.

During kernel-mode debugging, you can set the process context by using the **.process (Set Process Context)** command. Use this command to select which process's page directory is used to interpret virtual addresses. After you set the process context, you can use this context in any command that takes addresses. You can even set breakpoints at this address. By including a **/i** option in the **.process** command to specify invasive debugging, you can also use the kernel debugger to set breakpoints in user space.

You can also set user-mode breakpoints from the kernel debugger by using a process-specific breakpoint on a kernel-space function. Set strategic breakpoints and wait for the appropriate context to come up.

The *user-mode address context* is part of the process context. Typically, you do not have to set the user-mode address context directly. If you set the process context, the user-mode address context automatically changes to the directory base of the relevant page table for the process. However, on an Itanium-based processor, a single process might have more than one page directory. In this situation, you can use the [.context \(Set User-Mode Address Context\)](#) command to change the user-mode address context.

When you set the process context during kernel-mode debugging, that process context is retained until another [.process](#) command changes the context. The user-mode address context is also retained until a [.process](#) or [.context](#) command changes it. These contexts are not changed when the target computer executes, and they are not affected by changes to the register context or the local context.

Register Context

Each thread has its own register values. These values are stored in the CPU registers when the thread is executing and are stored in memory when another thread is executing.

During user-mode debugging, the current thread typically determines the register context. Any reference to registers in debugger commands, extensions, and debugging information windows is interpreted according to the current thread's registers.

You can change the register context to a value other than the current thread while you are performing user-mode debugging by using one of the following commands:

[.cxr \(Display Context Record\)](#)

[.ecxr \(Display Exception Context Record\)](#)

During kernel-mode debugging, you can control the register context by using a variety of debugger commands, including the following commands:

[.thread \(Set Register Context\)](#)

[.cxr \(Display Context Record\)](#)

[.trap \(Display Trap Frame\)](#)

These commands do not change the values of the CPU registers. Instead, the debugger retrieves the specified register context from its location in memory. Actually, the debugger can retrieve only the *saved* register values. (Other values are set dynamically and are not saved. The saved values are sufficient to re-create a stack trace.)

After the register context is set, the new register context is used for any commands that use register values, such as [k \(Display Stack Backtrace\)](#) and [r \(Registers\)](#).

However, when you are debugging multiprocessor computers, some commands enable you to specify a processor. (For more information about such commands, see [Multiprocessor Syntax](#).) If you specify a processor for a command, the command uses the register context of the active thread on the specified processor instead of the current register context, even if the specified processor is the currently-active processor.

Also, if the register context does not match the current processor mode setting, these commands produce incorrect or meaningless output. To avoid the output errors, commands that depend on the register state fail until you change the processor mode to match the register context. To change the processor mode, use the [.effmach \(Effective Machine\)](#) command.

Changing the register context can also change the local context. In this manner, the register context can affect the display of local variables.

If any application execution, stepping, or tracing occurs, the register context is immediately reset to match the program counter's position. In user mode, the register context is also reset if the current process or thread is

changed.

The register context affects stack traces, because the stack trace begins at the location that the stack pointer register (**esp** on an x86-based processor or **sp** on an Itanium-based processor) points to. If the register context is set to an invalid or inaccessible value, stack traces cannot be obtained.

You can apply a processor breakpoint (data breakpoint) to a specific register context by using the [.apply_dbp \(Apply Data Breakpoint to Context\)](#) command.

Local Context

When a program is executing, the meaning of local variables depends on the location of the program counter, because the scope of such variables extends only to the function that they are defined in.

When you are performing user-mode or kernel-mode debugging, the debugger uses the scope of the current function (the current frame on the stack) as the local context. To change this context, use the [.frame \(Set Local Context\)](#) command, or double-click the desired frame in the [Calls window](#).

In user-mode debugging, the local context is always a frame within the stack trace of the current thread. In kernel-mode debugging, the local context is always a frame within the stack trace of the current register context's thread.

You can use only one stack frame at a time for the local context. Local variables in other frames cannot be accessed.

The local context is reset if any of the following events occur:

- Any program execution, stepping or tracing
- Any use of the thread delimiter (~) in any command
- Any change to the register context

The **!for_each_frame** extension enables you to execute a single command repeatedly, once for each frame in the stack. This command changes the local context for each frame, executes the specified command, and then returns the local context to its original value.

[Send comments about this topic to Microsoft](#)

Controlling Processes and Threads

5/31/2017 • 3 min to read • [Edit Online](#)

When you are performing user-mode debugging, you activate, display, freeze, unfreeze, suspend, and unsuspend processes and threads.

The *current* or *active* process is the process that is currently being debugged. Similarly, the *current* or *active* thread is the thread that the debugger is currently controlling. The actions of many debugger commands are determined by the identity of the current process and thread. The current process also determines the virtual address mappings that the debugger uses.

When debugging begins, the current process is the one that the debugger is attached to or that caused the exception that broke into the debugger. Similarly, the current thread is the one that was active when the debugger attached to the process or that caused the exception. However, you can use the debugger to change the current process and thread and to freeze or unfreeze individual threads.

In kernel-mode debugging, processes and threads are not controlled by the methods that are described in this section. For more information about how processes and threads are manipulated in kernel mode, see [Changing Contexts](#).

Displaying Processes and Threads

To display process and thread information, you can use the following methods:

- The **| (Process Status)** command
- The **~ (Thread Status)** command
- (WinDbg only) The [Processes and Threads window](#)

Setting the Current Process and Thread

To change the current process or thread, you can use the following methods:

- The **|s (Set Current Process)** command
- The **~s (Set Current Thread)** command
- (WinDbg only) The [Processes and Threads window](#)

Freezing and Suspending Threads

The debugger can change the execution of a thread by *suspending* the thread or by *freezing* the thread. These two actions have somewhat different effects.

Each thread has a *suspend count* that is associated with it. If this count is one or larger, the system does not run the thread. If the count is zero or lower, the system runs the thread when appropriate.

Typically, each thread has a suspend count of zero. When the debugger attaches to a process, it increments the suspend counts of all threads in that process by one. If the debugger detaches from the process, it decrements all suspend counts by one. When the debugger executes the process, it temporarily decrements all suspend counts by one.

You can control the suspend count of any thread from the debugger by using the following methods:

- The **~n (Suspend Thread)** command increments the specified thread's suspend count by one.
- The **~m (Resume Thread)** command decrements the specified thread's suspend count by one.

The most common use for these commands is to raise a specific thread's suspend count from one to two. When the debugger executes or detaches from the process, the thread then has a suspend count of one and remains suspended, even if other threads in the process are executing.

You can suspend threads even when you are performing [noninvasive debugging](#).

The debugger can also *freeze* a thread. This action is similar to suspending the thread in some ways. However, "frozen" is only a debugger setting. Nothing in the Windows operating system recognizes that anything is different about this thread.

By default, all threads are unfrozen. When the debugger causes a process to execute, threads that are frozen do not execute. However, if the debugger detaches from the process, all threads unfreeze.

To freeze and unfreeze individual threads, you can use the following methods:

- The [~f \(Freeze Thread\)](#) command freezes the specified thread.
- The [~u \(Unfreeze Thread\)](#) command unfreezes the specified thread.

In any event, threads that belong to the target process never execute when the debugger has broken into the target. The suspend count of a thread affects the thread's behavior only when the debugger executes the process or detaches. The frozen status affects the thread's behavior only when the debugger executes the process.

Threads and Processes in Other Commands

You can add thread specifiers or process specifiers before many other commands. For more information, see the individual command topics.

You can add the [~e \(Thread-Specific Command\)](#) qualifier before many commands and extension commands. This qualifier causes the command to be executed with respect to the specified thread. This qualifier is especially useful if you want to apply a command to more than one thread. For example, the following command repeats the [!gle](#) extension command for every thread that is being debugged.

```
~*e !gle
```

Multiple Systems

The debugger can attach to multiple targets at the same time. When these processes include dump files or include live targets on more than one computer, the debugger references a system, process, and thread for each action. For more information about this kind of debugging, see [Debugging Multiple Targets](#).

[Send comments about this topic to Microsoft](#)

Using Debugger Markup Language

5/26/2017 • 4 min to read • [Edit Online](#)

Debugger commands can provide output in plain text or in an enhanced format that uses Debugger Markup Language (DML). Output that is enhanced with DML includes links that you can click to execute related commands.

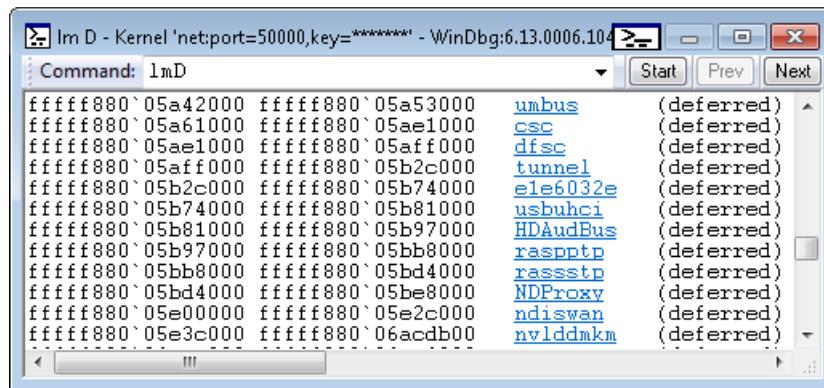

DML is available in Windows 10 and later.

DML Capable Commands

The following commands are capable of generating DML output:

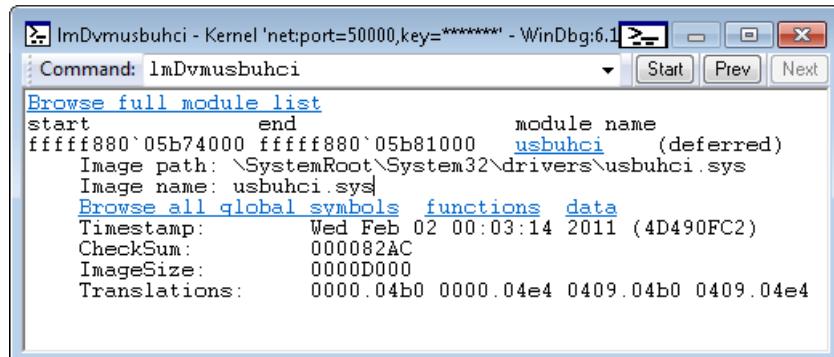

- [.dml_start](#)
- [.dml_flow](#)
- [!dml_proc](#)
- [!mD](#)
- [kM](#)
- [.chain /D](#)
- [.help /D](#)
- [.printf /D](#)

The [!mD](#) command is an example of a command that is capable of providing DML output. The [!mD](#) command displays a list of loaded modules. As the following image shows, each module name is a link that you can click to get more detailed information about the module.

```
!m D - Kernel 'net:port=50000,key=*****' - WinDbg:6.13.0006.104
Command: !mD
fffff880`05a42000 fffff880`05a53000 umbus (deferred)
fffff880`05a61000 fffff880`05ae1000 csc (deferred)
fffff880`05ae1000 fffff880`05aff000 dfsc (deferred)
fffff880`05aff000 fffff880`05b2c000 tunnel (deferred)

Turning DML On and Off

The **.prefer_dml** command turns DML on or off. When DML is turned on (.prefer_dml 1), commands that are capable of generating DML output will generate DML output by default.

Console Enhancements

All of the Windows debuggers now have command output areas which support DML parsing. In windbg the command window supports all DML behavior and will show colors, font styles and links. The console debuggers, ntsd, cdb and kd, only support the color attributes of DML, and the only when running in a true console with color mode enabled. Debuggers with redirected I/O, ntsd -d or remote.exe sessions will not display any colors.

Console Debugger Color Mode

The console debuggers, ntsd, cdb and kd now have the ability to display colored output when running in a true console. This is not the default, it requires color mode to be explicitly enabled via tools.ini. The new col_mode <true|false> token in tools.ini controls the color mode setting. For more information about working with the tools.ini file, see [Configuring tools.ini](#)

When color mode is enabled the debugger can produce colored output. By default most colors are not set and instead default to the current console colors.

Windbg Command Browser Window

In Windows 10 and later Windbg the command browser window parses and displays DML. All tags such as <link>, <exec> and appearance modifications, are fully supported.

To start a command browser session using the menu in WinDbg, select **View, Command Browser**. The .browse <command> in the command window will open a new command browser window and execute the given command. For more information see [Using the Command Browser Window in WinDbg](#). A new command browser window can also be opened with Ctrl+N.

The command browser window deliberately mimics the behavior of a web browser, with a drop-down history and previous/next buttons. The history drop-down only displays the last twenty commands but full history is kept so by going back in the commands you can get the drop-down to display older history.

You can have as many command windows open at once as you like. Command windows persist in workspaces but only save the current command; the history is not kept.

The WinDbg **View** menu has a **Set Browser Start Command** option which allows a user to set a preferred command for new browser windows to start with, such as .dml_start. This command is saved in workspaces.

A **Recent Commands** sub-window is available on the **View** menu to hold commands of interest. Selecting a recent command opens a new browser with the given command. There is a menu item on the browser window's context menu that adds the window's current command to the list of recent commands. The list of recent commands is persisted in workspaces.

The command browser window executes the command synchronously and so does not display output until the command has completed. Long-running commands will not show anything until they have finished.

Links have a right-click context menu similar to the right-click context menu in a web browser. Links can be opened in a new browser window. A link's command can be copied to the clipboard for use.

Clicking the icon near the upper-right corner of the title bar to set the command browser windows to either auto-refresh or manual-refresh. Auto-refresh browsers will automatically re-run their command on debugger state changes. This keeps the output live but at the cost of executing the command on all changes. Auto-refresh is on by default. If the browser does not need to be live the window's context menu can be used to disable auto-refresh.

Because commands are executed by the engine, not by the user interface, user-interface specific commands, such as [.cls \(Clear Screen\)](#), will return a syntax error in when used in command browser windows. It also

means that when the user interface is a remote client, the command will be executed by the server, not by the client, and the command output will show server state.

Command browser windows can run any debugger command, it does not have to be a command that produces DML. You can use browser windows to have an arbitrary set of commands active for use.

Customizing DML

DML defines a small set of tags that can be included in command output. One example is the `<link>` tag. You can experiment with the `<link>` tag (and other DML tags) by using the `.dml_start` and `.browse` commands. The command `.browse .dml_start filepath` executes the commands stored in a DML file. The output is displayed in the [Command Browser window](#) instead of the regular command window.

Suppose the file `c:\DmlExperiment.txt` contains the following lines.

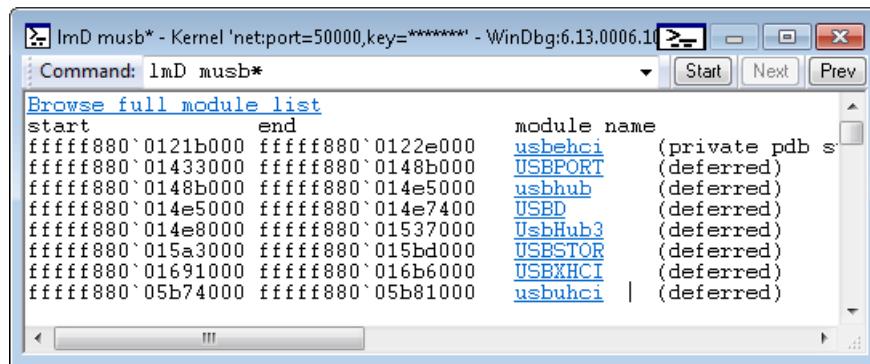

```
My DML Experiment
<link cmd="!mD musb*">List modules that begin with usb.</link>
```

The following command displays the text and link in the Command Browser window.

```
.browse .dml_start c:\DmlExperiment.txt
```

If you click the **List modules that begin with usb** link, you see output similar to the following image.

For a thorough discussion of DML customization and a complete list of DML tags, see [Customizing Debugger Output Using DML](#).

[Send comments about this topic to Microsoft](#)

Controlling Exceptions and Events

5/26/2017 • 12 min to read • [Edit Online](#)

You can catch and handle exceptions in user-mode and kernel-mode applications by a variety of methods. An active debugger, a postmortem debugger, or an internal error handling routine are all common ways to handle exceptions.

For more information about the precedence order of these various exception handlers, see [Enabling Postmortem Debugging](#).

When the Microsoft Windows operating system allows a debugger to handle an exception, the application that generated the exception *breaks into* the debugger. That is, the application stops and the debugger becomes active. The debugger can then handle the exception in some way or analyze the situation. The debugger can then end the process or let it resume running.

If the debugger ignores the exception and lets the application continue running, the operating system looks for other exception handlers as if no debugger was present. If the exception is handled, the application continues running. However, if the exception remains unhandled, the debugger is then given a second opportunity to deal with the situation.

Using the Debugger to Analyze an Exception

When an exception or event breaks into the debugger, you can use the debugger to examine the code that is being executed and the memory that the application is using. By altering certain quantities or jumping to a different point in the application, you might be able to remove the cause of the exception.

You can resume execution by issuing a **gh (Go with Exception Handled)** or **gn (Go with Exception Not Handled)** command.

If you issue the **gn** command in the debugger's second opportunity to handle the exception, the application ends.

Kernel-Mode Exceptions

Exceptions that occur in kernel-mode code are more serious than user-mode exceptions. If kernel-mode exceptions are not handled, a **bug check** is issued and the system stops.

As with user-mode exceptions, if a kernel-mode debugger is attached to the system, the debugger is notified before the *bug check screen* (also known as a *blue screen*) appears. If no debugger is attached, the bug check screen appears. In this case, the operating system might create a [crash dump file](#).

Controlling Exceptions and Events from the Debugger

You can configure the debugger to react to specified exceptions and events in a specific way.

The debugger can set the break status for each exception or event:

- The event can cause a break into the debugger as soon as it occurs (the "first chance").
- The event can break in after other error handlers have been given an opportunity to respond (the "second chance").
- The event can also send the debugger a message but continue executing.
- The debugger can ignore the event.

The debugger can also set the handling status for each exception and event. The debugger can treat the event

like a handled exception or an unhandled exception. (Of course, events that are not actually errors do not require any handling.)

You can control the break status and handling status by doing one of the following:

- Use the **SXE**, **SXD**, **SXN**, or **SXI** command in the [Debugger Command window](#).
- (CDB only) Use the **-x**, **-xe**, **-xd**, **-xn**, or **-xi** option on the CDB [command line](#).
- (CDB only) Use the **sxe** or **sxd** keyword in the [Tools.ini](#) file.
- (WinDbg only) Click [Event Filters](#) on the **Debug** menu to open the **Event Filters** dialog box, and then choose the options that you want.

The **SX*** command, the **-X*** command-line option, and the **sx*** Tools.ini keyword typically set the break status of the specified event. You can add the **-h** option to cause the handling status to be set instead.

There are four special event codes (**cc**, **hc**, **bpec**, and **ssec**) that always specify handling status instead of break status.

You can display the most recent exception or event by using the [.lastevent \(Display Last Event\)](#) command.

Controlling Break Status

When you set the break status of an exception or event, you can use the following options.

COMMAND	STATUS NAME	DESCRIPTION
SXE or -xe	Break (Enabled)	When this exception occurs, the target immediately breaks into the debugger. This break occurs before any other error handlers are activated. This method is called <i>first-chance handling</i> .
SXD or -xd	Second chance break (Disabled)	The debugger does not break in for this kind of first-chance exception (although a message is displayed). If other error handlers cannot address this exception, execution stops and the target breaks into the debugger. This method is called <i>second-chance handling</i> .
SXN or -xn	Output (Notify)	When this exception occurs, the target application does not break into the debugger at all. However, a message is displayed that informs the user of this exception.
SXI or -xi	Ignore	When this exception occurs, the target application does not break into the debugger, and no message is displayed.

If an exception is not anticipated by an **SX*** setting, the target application breaks into the debugger on the second chance. The default status for events is listed in the following "Event Definitions and Defaults" section

of this topic.

To set break status by using the WinDbg graphical interface, [Event Filters](#) on the **Debug** menu, click the event that you want from the list in the **Event Filters** dialog box, and then select **Enabled**, **Disabled**, **Output**, or **Ignore**.

Controlling Handling Status

All events are considered unhandled, unless you use the [gh \(Go with Exception Handled\)](#) command.

All exceptions are considered unhandled, unless you use the [sx*](#) command together with the **-h** option.

Additionally, **SX*** options can configure the handling status for invalid handles, STATUS_BREAKPOINT break instructions, and single-step exceptions. (This configuration is separate from their break configuration.) When you configure their break status, these events are named **ch**, **bpe**, and **sse**, respectively. When you configure their handling status, these events are named **hc**, **bpec**, and **ssec**, respectively. (For the full listing of events, see the following "Event Definitions and Defaults" section.)

You can configure the handling status for the CTRL+C event (**cc**), but not its break status. If an application receives a CTRL+C event, the application always breaks into the debugger.

When you use the **SX*** command on **cc**, **hc**, **bpec**, and **ssec** events, or when you use the **SX*** command together with the **-h** option on an exception, the following actions occur.

COMMAND	STATUS NAME	DESCRIPTION
SXE	Handled	The event is considered handled when execution resumes.
SXD,SXN,SXI	Not Handled	The event is considered not handled when execution resumes.

To set handling status by using the WinDbg graphical interface, click [Event Filters](#) on the **Debug** menu, click the event that you want from the list in the **Event Filters** dialog box, and then select **Handled** or **Not Handled**.

Automatic Commands

The debugger also enables you to set commands that are automatically executed if the event or exception causes a break into the debugger. You can set a command string for the first-chance break and a command string for the second-chance break. You can set these strings with the [SX*](#) command or the [Debug | Event Filters](#) command. Each command string can contain multiple commands that are separated with semicolons.

These commands are executed regardless of the break status. That is, if the break status is "Ignore," the command is still executed. If the break status is "Second-chance break," the first-chance command is executed when the exception first occurs, before any other exception handlers are involved. The command string can end with an execution command such as [g \(Go\)](#), [gh \(Go with Exception Handled\)](#), or [gn \(Go with Exception Not Handled\)](#).

Event Definitions and Defaults

You can change the break status or handling status of the following exceptions. Their default break status is indicated.

The following exceptions' default handling status is always "Not Handled". Be careful about changing this status. If you change this status to "Handled", all first-chance and second-chance exceptions of this type are considered handled, and this configuration bypasses all of the exception-handling routines.

EVENT CODE	MEANING	DEFAULT BREAK STATUS
asrt	Assertion failure	Break
av	Access violation	Break
dm	Data misaligned	Break
dz	Integer division by zero	Break
c000008e	Floating point division by zero	Break
eh	C++ EH exception	Second-chance break
gp	Guard page violation	Break
ii	Illegal instruction	Second-chance break
iov	Integer overflow	Break
ip	In-page I/O error	Break
isc	Invalid system call	Break
lsq	Invalid lock sequence	Break
sbo	Stack buffer overflow	Break
sov	Stack overflow	Break
wkd	Wake debugger	Break
aph	Application hang This exception is triggered if the Windows operating system concludes that a process has stopped responding (that is, <i>is hung</i>).	Break
3c	Child application termination	Second-chance break

EVENT CODE	MEANING	DEFAULT BREAK STATUS
chhc	Invalid handle	Break
<i>Number</i>	Any numbered exception	Second-chance break

Note You can override the **asrt** break status for a specific address by using the **ah (Assertion Handling)** command. The **ch** and **hc** event codes refer to the same exception. When you are controlling its break status, use **sx* ch**. When you are controlling its handling status, use **sx* hc**.

You can change the break status or handling status of the following exceptions. Their default break status is indicated.

The following exceptions' default handling status is always "Handled". Because these exceptions are used to communicate with the debugger, you should not typically change their status to "Not Handled". This status causes other exception handlers to catch the exceptions if the debugger ignores them.

An application can use **DBG_COMMAND_EXCEPTION (dbce)** to communicate with the debugger. This exception is similar to a breakpoint, but you can use the **SX*** command to react in a specific way when this exception occurs.

EVENT CODE	MEANING	DEFAULT BREAK STATUS
dbce	Special debugger command exception	Ignore
vcpp	Special Visual C++ exception	Ignore
wos	WOW64 single-step exception	Break
wob	WOW64 breakpoint exception-	Break
ssessec	Single-step exception	Break
bpebpec	Breakpoint exception	Break
ccecc	CTRL+C or CTRL+BREAK This exception is triggered if the target is a console application and CTRL+C or CTRL+BREAK is passed to it.	Break

Note The final three exceptions in the preceding table have two different event codes. When you are controlling their break status, use **sse**, **bpe**, and **cce**. When you are controlling their handling status, use **ssec**, **bpec**, and **cc**.

The following exceptions are useful when you are debugging managed code.

EVENT CODE	MEANING	DEFAULT STATUS
clr	Common Language Runtime exception	Second-chance break Not handled
clrn	Common Language Runtime notification exception	Second-chance break Handled

You can change the break status of the following events. Because these events are not exceptions, their handling status is irrelevant.

EVENT CODE	MEANING	DEFAULT BREAK STATUS
ser	System error	Ignore
cpr[:Process]	<p>Process creation</p> <p>Setting the break status of this event applies only to user-mode debugging. This event does not occur in kernel mode.</p> <p>You can control this event only if you have activated debugging of child processes in CDB or WinDbg, either through the -ocommand-line option or through the .childdbg (Debug Child Processes) command.</p> <p>The process name can include an optional file name extension and an asterisk (*) or question mark (?) as wildcard characters. The debugger remembers only the most recent cpr setting. Separate settings for separate processes are not supported. Include a colon or a space between cpr and Process.</p> <p>If Process is omitted, the setting applies to any child process creation.</p>	Ignore

EVENT CODE	MEANING	DEFAULT BREAK STATUS
epr[:Process]	<p>Process exit</p> <p>Setting the break status of this event applies only to user-mode debugging. This event does not occur in kernel mode.</p> <p>You can control this event only if you have activated debugging of child processes in CDB or WinDbg, either through the -ocommand-line option or through the .childdb (Debug Child Processes) command.</p> <p>The process name can include an optional file name extension and an asterisk () or question mark (?) as wildcard characters. The debugger remembers only the most recent epr setting. Separate settings for separate processes are not supported. Include a colon or a space between epr and <i>Process</i>.</p> <p>If <i>Process</i> is omitted, the setting applies to any child process exit.</p>	Ignore
ct	Thread creation	Ignore
et	Thread exit	Ignore
ld[:Module]	<p>Load module</p> <p>If you specify <i>Module</i>, the break occurs when the module with this name is loaded. <i>Module</i> can specify the name or the address of the module. If the name is used, <i>Module</i> might contain a variety of wildcard characters and specifiers. (For more information about the syntax, see String Wildcard Syntax.)</p> <p>The debugger remembers only the most recent ld setting. Separate settings for separate modules are not supported. Include a colon or a space between ld and <i>Module</i>.</p> <p>If <i>Module</i> is omitted, the event is triggered when any module is loaded.</p>	Output

EVENT CODE	MEANING	DEFAULT BREAK STATUS
ud [: <i>Module</i>]	<p>Unload module</p> <p>If you specify <i>Module</i>, the break occurs when the module with this name, or at this base address, is unloaded. <i>Module</i> can specify the name or the address of the module. If the name is used, <i>Module</i> can be an exact name or include wildcard characters. If <i>Module</i> is an exact name, it is immediately resolved to a base address by using the current debugger module list and it is stored as an address. If <i>Module</i> contains wildcard characters, the pattern string is kept for later matching when unload events occur.</p> <p>Rarely, the debugger does not have name information for unload events and matches only by the base address. Therefore, if <i>Module</i> contains wildcard characters, the debugger cannot perform a name match in this particular unload case and breaks when any module is unloaded.</p> <p>The debugger remembers only the most recent ud setting. Separate settings for separate modules are not supported. Include a colon or a space between Id and <i>Module</i>.</p> <p>If <i>Module</i> is omitted, the event is triggered when any module is loaded.</p>	Output
out [: <i>Output</i>]	<p>Target application output</p> <p>If you specify <i>Output</i>, the break occurs only when output that matches the specified pattern is received. <i>Output</i> can contain a variety of wildcard characters and specifiers. (For more information about the syntax, see String Wildcard Syntax.) However, <i>Output</i> cannot contain a colon or spaces. The match is not case sensitive. Include a colon or space between out and <i>Output</i>.</p>	Ignore

EVENT CODE	MEANING	DEFAULT BREAK STATUS
ibp	Initial break point (This event occurs at the beginning of the debug session and after you restart the target computer.)	In user mode: Break. You can change this status to "Ignore" by using the -g command-line option . In kernel mode: Ignore. You can change this status to "Enabled" by a variety of methods. For more information about how to change this status, see Crashing and Rebooting the Target Computer .
iml	Initial module load (Kernel mode only)	Ignore. You can change this status to "Break" by a variety of methods. For more information about how to change this status, see Crashing and Rebooting the Target Computer .

Finding the Process ID

5/26/2017 • 1 min to read • [Edit Online](#)

Each process running in Microsoft Windows is assigned a unique decimal number called the *process ID*, or *PID*. This number is used to specify the process when attaching a debugger to it.

There are several ways to determine the PID for a given application: using the Task Manager, using the **tasklist** command, using the TList utility, or using the debugger.

Task Manager

The *Task Manager* may be activated in a number of ways, but the simplest is to press CTRL+ALT+DELETE and then click **Task Manager**.

If you select the **Processes** tab, each process and its PID will be listed, along with other useful information.

Some kernel errors may cause delays in Task Manager's graphical interface.

The Tasklist Command

In Windows XP and later versions of Windows, you can use the **tasklist** command from a Command Prompt window. This displays all processes, their PIDs, and a variety of other details.

TList

TList (Task List Viewer, tlist.exe) is a command-line utility that displays a list of tasks, or user-mode processes, currently running on the local computer. TList is included in the Debugging Tools for Windows package.

When you run TList from the command prompt, it will display a list of all the user-mode processes in memory with a unique process identification (PID) number. For each process, it shows the PID, process name, and, if the process has a window, the title of that window.

For more information, see [TList](#).

The .tlist Debugger Command

If there is already a user-mode debugger running on the system in question, the [.tlist \(List Process IDs\)](#) command will display a list of all PIDs on that system.

CSRSS and User-Mode Drivers

To debug a user-mode driver running on another computer, debug the Client Server Run-Time Subsystem (CSRSS) process. For more information, see [Debugging CSRSS](#).

[Send comments about this topic to Microsoft](#)

Debugging a Stack Overflow

5/31/2017 • 6 min to read • [Edit Online](#)

A stack overflow is an error that user-mode threads can encounter. There are three possible causes for this error:

- A thread uses the entire stack reserved for it. This is often caused by infinite recursion.
- A thread cannot extend the stack because the page file is maxed out, and therefore no additional pages can be committed to extend the stack.
- A thread cannot extend the stack because the system is within the brief period used to extend the page file.

When a function running on a thread allocates local variables, the variables are put on the thread's call stack. The amount of stack space required by the function could be as large as the sum of the sizes of all the local variables. However, the compiler usually performs optimizations that reduce the stack space required by a function. For example, if two variables are in different scopes, the compiler can use the same stack memory for both of those variables. The compiler might also be able to eliminate some local variables entirely by optimizing calculations.

The amount of optimization is influenced by compiler settings applied at build time. For example, a Debug build and a Release build have different levels of optimization. The amount of stack space required by a function in a Debug build might be larger than the amount of stack space required by that same function in a Release build.

Here is an example of how to debug a stack overflow. In this example, NTSD is running on the same computer as the target application and is redirecting its output to KD on the host computer. See [Controlling the User-Mode Debugger from the Kernel Debugger](#) for details.

The first step is see what event caused the debugger to break in:

```
0:002> .lastevent
Last event: Exception C00000FD, second chance
```

You can look up exception code 0xC00000FD in ntstatus.h, which can be found in the Microsoft Windows SDK and the Windows Driver Kit (WDK). This exception code is STATUS_STACK_OVERFLOW.

To double-check that the stack overflowed, you can use the **k (Display Stack Backtrace)** command:

```
0:002> k
ChildEBP RetAddr
009fdd0c 71a32520 COMCTL32!_chkstk+0x25
009fde78 77cf8290 COMCTL32!ListView_WndProc+0x4c4
009fde98 77cf8290 COMCTL32!ListView_WndProc+0x4c4
009fdf00 77cd55e9 USER32!UserCallWinProcCheckWow+0x17f
009fdf3c 77cd63b2 USER32!SendMessageWorker+0x4a3
009fdf5c 71a45b30 USER32!SendMessageW+0x44
009fdfec 71a45bb0 COMCTL32!CCSendNotify+0xc0e

00000000 00000000 0x9fe4a8
```

The target thread has broken into COMCTL32!_chkstk, which indicates a stack problem. Now you should investigate the stack usage of the target process. The process has multiple threads, but the important one is the one that caused the overflow, so identify this thread first:

```
0:002> ~*k

0  id: 570.574  Suspend: 1 Teb 7ffde000 Unfrozen
.....

1  id: 570.590  Suspend: 1 Teb 7ffdd000 Unfrozen
.....

. 2  id: 570.598  Suspend: 1 Teb 7ffdc000 Unfrozen
ChildEBP RetAddr
009fdd0c 71a32520 COMCTL32!_chkstk+0x25
.....

3  id: 570.760  Suspend: 1 Teb 7ffdb000 Unfrozen
```

Now you need to investigate thread 2. The period at the left of this line indicates that this is the current thread.

The stack information is contained in the TEB (Thread Environment Block) at 0x7FFDC000. The easiest way to list it is using **!teb**. However, this requires you to have the proper symbols. For maximum versatility, assume you have no symbols:

```
0:002> dd 7ffdc000 L4
7ffdc000 009fdef0 00a00000 009fc000 00000000
```

To interpret this, you need to look up the definition of the TEB data structure. If you had complete symbols, you could use **dt TEB** to do this. But in this case, you will need to look at the ntpsapi.h file in the Microsoft Windows SDK. For Windows XP and later versions of Windows, this file contains the following information:

```

typedef struct _TEB {
    NT_TIB NtTib;
    PVOID EnvironmentPointer;
    CLIENT_ID ClientId;
    PVOID ActiveRpcHandle;
    PVOID ThreadLocalStoragePointer;
    PPEB ProcessEnvironmentBlock;
    ULONG LastErrorValue;
    .....
    PVOID DeallocationStack;
    .....
} TEB;

typedef struct _NT_TIB {
    struct _EXCEPTION_REGISTRATION_RECORD *ExceptionList;
    PVOID StackBase;
    PVOID StackLimit;
    .....
} NT_TIB;

```

This indicates that the second and third DWORDs in the TEB structure point to the bottom and top of the stack, respectively. In this case, these addresses are 0x00A00000 and 0x009FC000. (The stack grows downward in memory.) You can calculate the stack size using the [?](#) ([Evaluate Expression](#)) command:

```

0:002> ? a00000-9fc000
Evaluate expression: 16384 = 00004000

```

This shows that the stack size is 16 K. The maximum stack size is stored in the field **DeallocationStack**. After some calculation, you can determine that this field's offset is 0xE0C.

```

0:002> dd 7fffdc000+e0c L1
7ffdce0c  009c0000

0:002> ? a00000-9c0000
Evaluate expression: 262144 = 00040000

```

This shows that the maximum stack size is 256 K, which means more than adequate stack space is left.

Furthermore, this process looks clean -- it is not in an infinite recursion or exceeding its stack space by using excessively large stack-based data structures.

Now break into KD and look at the overall system memory usage with the **!vm** extension command:

```

0:002> .breakin
Break instruction exception - code 80000003 (first chance)
ntoskrnl!_DbgBreakPointWithStatus+4:
80148f9c cc          int     3

kd> !vm

*** Virtual Memory Usage ***

Committed pages: 45882 ( 183528 Kb)
Commit limit: 50570 ( 202280 Kb)

Total Private: 33309 ( 133236 Kb)
.....

```

First, look at nonpaged and paged pool usage. Both are well within limits, so these are not the cause of the problem.

Next, look at the number of committed pages: 183528 out of 202280. This is very close to the limit. Although this display does not show this number to be completely at the limit, you should keep in mind that while you are performing user-mode debugging, other processes are running on the system. Each time an NTSD command is executed, these other processes are also allocating and freeing memory. That means you do not know exactly what the memory state was like at the time the stack overflow occurred. Given how close the committed page number is to the limit, it is reasonable to conclude that the page file was used up at some point and this caused the stack overflow.

This is not an uncommon occurrence, and the target application cannot really be faulted for this. If it happens frequently, you may want to consider raising the initial stack commitment for the failing application.

Analyzing a Single Function Call

It can also be useful to find out exactly how much stack space a certain function call is allocating.

To do this, disassemble the first few instructions and look for the instruction `sub esp number`. This moves the stack pointer, effectively reserving *number* bytes for local data.

Here is an example:

```
0:002> k
ChildEBP RetAddr
009ffd0c 71a32520 COMCTL32!_chkstk+0x25
009fde78 77cf8290 COMCTL32!ListView_WndProc+0x4c4
009fde98 77cf634 USER32!_InternalCallWinProc+0x18
009fdf00 77cd55e9 USER32!UserCallWinProcCheckWow+0x17f
009fdf3c 77cd63b2 USER32!SendMessageWorker+0x4a3
009fdf5c 71a45b30 USER32!SendMessageW+0x44
009fdfec 71a45bb0 COMCTL32!CCSendNotify+0xc0e
009fdffc 71a1d688 COMCTL32!CICustomDrawNotify+0x2a
009fe074 71a1db30 COMCTL32!Header_Draw+0x63
009fe0d0 71a1f196 COMCTL32!Header_OnPaint+0x3f
009fe128 77cf8290 COMCTL32!Header_WndProc+0x4e2
009fe148 77cf634 USER32!_InternalCallWinProc+0x18

0:002> u COMCTL32!Header_Draw
COMCTL32!Header_Draw :
71a1d625 55          push    ebp
71a1d626 8bec         mov     ebp,esp
71a1d628 83ec58       sub     esp,0x58
71a1d62b 53          push    ebx
71a1d62c 8b5d08       mov     ebx,[ebp+0x8]
71a1d62f 56          push    esi
71a1d630 57          push    edi
71a1d631 33f6         xor     esi,esi
```

This shows that **Header_Draw** allocated 0x58 bytes of stack space.

Manually Walking a Stack

5/31/2017 • 6 min to read • [Edit Online](#)

In some cases, the stack trace function will fail in the debugger. This can be caused by a call to an invalid address that caused the debugger to lose the location of the return address; or you may have come across a stack pointer for which you cannot directly get a stack trace; or there could be some other debugger problem. In any case, being able to manually walk a stack is often valuable.

The basic concept is fairly simple: dump out the stack pointer, find out where the modules are loaded, find possible function addresses, and verify by checking to see if each possible stack entry makes a call to the next.

Before going through an example, it is important to note that the **kb (Display Stack Backtrace)** command has an additional feature on Intel systems. By doing a kb=[ebp] [eip] [esp], the debugger will display the stack trace for the frame with the given values for base pointer, instruction pointer, and stack pointer, respectively.

For the example, a failure that actually gives a stack trace is used so the results can be checked at the end.

The first step is to find out what modules are loaded where. This is accomplished with the **x (Examine Symbols)** command (some symbols are edited out for reasons of length):

```
kd> x *!
start    end      module name
77f70000 77fb8000  ntdll    (C:\debug\ntdll.dll,  \\ntstress\symbols\dll\ntdll.DBG)
80010000 80012320  Aha154x  (load from Aha154x.sys deferred)
80013000 8001aa60  SCSIPORT (load from SCSIPORT.SYS deferred)
8001b000 8001fba0  Scsidisk (load from Scsidisk.sys deferred)

80100000 801b7b40  NT       (ntoskrnl.exe,  \\ntstress\symbols\exe\ntoskrnl.DBG)
802f0000 8033c000  Ntfs    (load from Ntfs.sys deferred)
80400000 8040c000  hal     (load from hal.dll deferred)
fe4c0000 fe4c38c0  vga     (load from vga.sys deferred)
fe4d0000 fe4d3e60  VIDEOOPRT (load from VIDEOOPRT.SYS deferred)
fe4e0000 fe4f0e40  ati     (load from ati.SYS deferred)
fe500000 fe5057a0  Msfs    (load from Msfs.SYS deferred)
fe510000 fe519560  Npfs    (load from Npfs.SYS deferred)

fe520000 fe521f60  ndistapi (load from ndistapi.sys deferred)
fe530000 fe54ed20  Fastfat  (load from Fastfat.SYS deferred)
fe5603e0 fe575360  NDIS     (NDIS.SYS,  \\ntstress\symbols\SYS\NDIS.DBG)
fe580000 fe585920  elnkii   (elnkii.sys,  \\ntstress\symbols\sys\elnkii.DBG)
fe590000 fe59b8a0  ndiswan  (load from ndiswan.sys deferred)
fe5a0000 fe5b7c40  nbf     (load from nbf.sys deferred)
fe5c0000 fe5c1b40  TDI     (load from TDI.SYS deferred)
fe5d0000 fe5dd580  nwlnkipx (load from nwlnkipx.sys deferred)

fe5e0000 fe5ee220  nwlnknb (load from nwlnknb.sys deferred)
fe5f0000 fe5fb320  afd     (load from afd.sys deferred)
fe610000 fe62bf00  tcpip   (load from tcpip.sys deferred)
fe630000 fe648600  netbt   (load from netbt.sys deferred)
fe650000 fe6572a0  netbios  (load from netbios.sys deferred)
fe660000 fe660000  Parport  (load from Parport.SYS deferred)
fe670000 fe670000  Parallel (load from Parallel.SYS deferred)
fe680000 fe6bcf20  rdr     (rdr.sys,  \\ntstress\symbols\sys\rdr.DBG)

fe6c0000 fe6f0920  srv     (load from srv.sys deferred)
```

The second step is dumping out the stack pointer to look for addresses in the modules given by the **x *!** command:

```

kd> dd esp
fe4cc97c 80136039 00000270 00000000 00000000
fe4cc98c fe682ae4 801036fe 00000000 fe68f57a
fe4cc99c fe682a78 ffb5b030 00000000 00000000
fe4cc9ac ff680e08 801036fe 00000000 00000000
fe4cc9bc fe6a1198 00000001 fe4cca78 ffae9d98

fe4cc9cc 02000901 fe4cca68 ffb50030 ff680e08
fe4cc9dc ffa449a8 8011c901 fe4cca78 00000000
fe4cc9ec 80127797 80110008 00000246 fe6a1430

kd> dd
fe4cc9fc 00000270 fe6a10ae 00000270 ffa44abc
fe4cca0c ffa449a8 ff680e08 fe6b2c04 ff680e08
fe4cca1c ffa449a8 e12820c8 e1235308 ffa449a8
fe4cca2c fe685968 ff680e08 e1235308 ffa449a8
fe4cca3c ffb0ad48 ffb0ad38 00100000 ffb0ad38
fe4cca4c 00000000 ffa44a84 e1235308 0000000a
fe4cca5c c00000d6 00000000 004ccb28 fe4ccbc4

fe4cca6c fe680ba4 fe682050 00000000 fe4ccbd4

```

To determine which values are likely function addresses and which are parameters or saved registers, the first thing to consider is what the different types of information look like on the stack. Most integers are going to be smaller value, which means they will be mostly zeros when displayed as DWORDs (like 0x00000270). Most pointers to local addresses will be near the stack pointer (like fe4cca78). Status codes usually begin with a c (c00000d6). Unicode and ASCII strings can be identified by the fact that each character will be in the range of 20-7f. (In KD, the [dc \(Display Memory\)](#) command will show the characters on the right.) Most importantly, the function addresses will be in the range listed by **x *!**.

Notice that all modules listed are in the ranges of 77f70000 to 8040c000 and fe4c0000 to fe6f0920. Based on these ranges, the possible function addresses in the preceding list are: 80136039, 801036fe (listed twice, so more likely a parameter), fe682ae4, fe68f57a, fe682a78, fe6a1198, 8011c901, 80127797, 80110008, fe6a1430, fe6a10ae, fe6b2c04, fe685968, fe680ba4, and fe682050. Investigate these locations by using an [In \(List Nearest Symbols\)](#) command for each address:

```

kd> ln 80136039
(80136039)  NT!_KiServiceExit+0x1e  |  (80136039)  NT!_KiServiceExit2-0x177
kd> ln fe682ae4

kd> ln fe685968
(fe685968)  rdr!_RdrReconnectConnection+0xb6
(fe685968)  rdr!_RdrInvalidateServerConnections-0x32
kd> ln fe682050
(fe682050)  rdr!__strnicmp+0xaa  |  (fe682050)  rdr!_BackPackSpinLock-0xa10

```

As noted before, 801036fe is not likely to be part of the stack trace as it is listed twice. If the return addresses have an offset of zero, they can be ignored (you cannot return to the beginning of a function). Based on this information, the stack trace is revealed to be:

```

NT!_KiServiceExit+0x1e
rdr!_RdrSectionInfo+0x2c
rdr!_RdrDereferenceDiscardableCode+0xb4
rdr!_SubmitTdiRequest+0xae
NT!_KeSuspendThread+0x13
NT!_ZwCloseObjectAuditAlarm+0x7
NT!_KeWaitForMultipleObjects+0x27c
rdr!_RdrTdiCloseConnection+0xa
rdr!_RdrTdiDisconnect+0x56
rdr!_CleanupTransportConnection+0x64
rdr!_RdrReconnectConnection+0xb6
rdr!__strnicmp+0xaa

```

To verify each symbol, unassemble immediately before the return address specified to see if it does a call to the function above it. To reduce length, the following is edited (the offsets used were found by trial and error):

```

kd> u 80136039-2 11      // looks ok, its a call
NT!_KiServiceExit+0x1c:
80136037 ffd3      call    ebx
kd> u fe682ae4-2 11      // paged out (all zeroes) unknown
rdr!_RdrSectionInfo+0x2a:
fe682ae2 0000      add    [eax],al
kd> u fe68f57a-6 11      // looks ok, its a call, but not anything above
rdr!_RdrDereferenceDiscardableCode+0xae:

NT!_KeSuspendThread+0x11:
8011c8ff 7424      jz     NT!_KeSuspendThread+0x37 (8011c925)
kd> u 80127797-2 11      // looks good, an int 2e -> KiServiceExit

NT!_ZwCloseObjectAuditAlarm+0x5:
80127795 cd2e      int    2e
kd> u 80110008-2 11      // not good, its a test instruction not a call
NT!_KeWaitForMultipleObjects+0x27a:
80110006 85c9      test    ecx,ecx
kd> u 80110008-5 11      // paged out (all zeroes) unknown
NT!_KeWaitForMultipleObjects+0x277:
80110003 0000      add    [eax],al
kd> u fe6a1430-6 11      // looks good its a call to ZwClose...
rdr!_RdrTdiCloseConnection+0x4:
fe6a142a ff15f83468fe    call    dword ptr [rdr!__imp__ZwClose (fe6834f8)]

kd> u fe6a10ae-2 11      // paged out (all zeroes) unknown
rdr!_RdrTdiDisconnect+0x54:
fe6a10ac 0000      add    [eax],al
kd> u fe6b2c04-5 11      // looks good, call to something above
rdr!_CleanupTransportConnection+0x5f:
fe6b2bff e854e4feff    call    rdr!_RdrTdiDisconnect (fe6a1058)
kd> u fe685968-5 11      // looks good, call to immediately above
rdr!_RdrReconnectConnection+0x1b1:
fe685963 e838d20200    call    rdr!_CleanupTransportConnection (fe6b2ba0)

kd> u fe682050-2 11      // paged out (all zeroes) unknown
rdr!_strnicmp+0xa8:
fe68204e 0000      add    [eax],al

```

Based on this, it appears that **RdrReconnectConnection** called **RdrCleanupTransportConnection**, to **RdrTdiDisconnect**, to **ZwCloseObjectAuditAlarm**, to **KiSystemServiceExit**. The other functions on the stack are probably leftover portions of previously active stacks.

In this case, the stack trace worked properly. Following is the actual stack trace to check the answer:

```
kd> k

fe4ccde4 8014d3ad NT!_ObOpenObjectByName+0xa2
fe4cce90 8016660d NT!_IoCreateFile+0x433
fe4cced0 80136039 NT!_NtCreateFile+0x2d
```

The first entry was the current location based on the stack trace, but otherwise, the stack was correct up to the point where **RdrReconnectConnection** was called. The same process could have been used to trace the entire stack. For a more exact method of manual stack walking, you would need to unassemble each potential function and follow each **push** and **pop** to identify each DWORD on the stack.

Debugging a Stack Trace that has JScript Frames

5/26/2017 • 1 min to read • [Edit Online](#)

The JScript Stack Dump Creation and Consumption feature works by collecting JScript frames and stitching them against debugger physical frames. Sometimes on x86 platforms, the debugger constructs the stack trace incorrectly.

If your stack includes JScript frames that you think might be incorrect, enter the following command in the debugger.

.stkwalk_force_frame_pointer 1

[Send comments about this topic to Microsoft](#)

Debugging an Application Failure

5/26/2017 • 1 min to read • [Edit Online](#)

There are a variety of errors possible in user-mode applications.

The most common kinds of failures include access violations, alignment faults, exceptions, critical section time-outs (deadlocks), and in-page I/O errors.

Access violations and data type misalignments are among the most common. They usually occur when an invalid pointer is dereferenced. The blame could lie with the function that caused the fault, or with an earlier function that passed an invalid parameter to the faulting function.

User-mode exceptions have many possible causes. If an unknown exception occurs, locate it in ntstatus.h or winerror.h if possible.

Critical section timeouts (or possible deadlocks) occur when one thread is waiting for a critical section for a long time. These are difficult to debug and require an in-depth analysis of the stack trace.

In-page I/O errors are almost always hardware failures. You can double-check the status code in ntstatus.h to verify.

[Send comments about this topic to Microsoft](#)

Reattaching to the Target Application

5/26/2017 • 1 min to read • [Edit Online](#)

If the debugger freezes or otherwise stops responding (that is, *crashes*) while you perform user-mode debugging, you can attach a new debugger to the existing process.

Note This method is supported only on Microsoft Windows XP and later versions of Windows. This method does not depend on whether the debugger originally created the process or attached to an existing process. This method does not depend on whether you used the **-pd** option.

To reattach a debugger to an existing target application, do the following:

1. [Determine the process ID](#) of the target application.
2. Start a new instance of CDB or WinDbg. Use the **-pe** command-line option.

```
Debugger -pe -p PID
```

You can also use other [command-line options](#).

You can also connect from a dormant debugger by using the [.attach \(Attach to Process\)](#) command together with the **-e** option.

3. After the attach is complete, end the original debugger process.
4. If the process does not respond properly, it might have a suspend count that is too high. You can use the [~m \(Resume Thread\)](#) command to reduce the suspend count. For more information about suspend counts, see [Controlling Processes and Threads](#).

If the original debugger is still operating properly, this method might not work. The two debuggers are competing for debugging events, and the Windows operating system does not necessarily assign all of the debugging events to the new debugger.

If the original debugger is ended before you attach the new debugger, the target application is also closed. (However, if the debugger attached with the **-pd** option and then exits normally, the target application continues running. In this situation, a second debugger can attach to the target application without using the **-pe** option.)

If you are already debugging a process and want to detach from the process but leave it frozen in a debugging state, you can use the [.abandon \(Abandon Process\)](#) command. After this command, any Windows debugger can reattach to the process by using the procedure that is described in this topic.

[Send comments about this topic to Microsoft](#)

Crashing and Rebooting the Target Computer

5/31/2017 • 2 min to read • [Edit Online](#)

When you perform kernel debugging, you can cause the target computer to stop responding (that is, *crash* or *bug check*) by issuing the **.crash (Force System Crash)** command. This command immediately causes the target computer to stop responding. The debugger writes a kernel-mode dump file if you have enabled crash dumps. (For more information about these files, see [Creating a Kernel-Mode Dump File](#).)

To restart the target computer, use the **.reboot (Reboot Target Computer)** command.

If you want the target computer to create a crash dump file and then restart, you should issue the **.crash** command, followed by the **.reboot** command. If you want only to restart, the **.crash** command is not required.

In the early stages of the boot process, the connection between the host computer and the target computer is lost. No information about the target computer is available to the debugger.

After the connection is broken, the debugger closes all symbol files and unloads all debugger extensions. At this point, all breakpoints are lost if you are running KD or CDB. In WinDbg, you can save the current workspace. This action saves all breakpoints.

If you want to end the debugging session at this point, use the **CTRL+B** command (in KD) or click **Exit** on the **File** menu (in WinDbg).

If you do not exit the debugger, the connection is reestablished after enough of the boot process has completed. Symbols and extensions are reloaded at this point. If you are running WinDbg, the kernel-mode workspace is reloaded.

You can tell the debugger to automatically break into the target computer during the restart process at two possible times:

- When the first kernel module is loaded into memory
- When the kernel initializes

To set an automatic breakpoint when the first kernel module loads, use the **-d** [command-line option](#).

You can also change the break state after the debugger is running:

- Control the initial module load and kernel initialization breakpoints like all exceptions and events. You can break into the debugger when these events occur, or ignore them. You can also have a specified command automatically execute when these breakpoints are hit. For more information, see [Controlling Exceptions and Events](#).
- Use the **CTRL+K** shortcut keys in KD, the **CTRL+ALT+K** shortcut keys in WinDbg, and the **Debug | Kernel Connection | Cycle Initial Break** command in WinDbg to change the break state. Every time that you use these commands, the debugger switches between three states: no automatic break, break upon kernel initialization, and break on first kernel module load. This method cannot activate both automatic breakpoints at the same time.

[Send comments about this topic to Microsoft](#)

Synchronizing with the Target Computer

5/26/2017 • 1 min to read • [Edit Online](#)

Sometimes during kernel-mode debugging, the target computer stops responding to the debugger.

In KD, you can press **CTRL+R (Re-synchronize)** and then press ENTER to synchronize with the target computer. In WinDbg, use **CTRL+ALT+R** or Debug | Kernel Connection | Resynchronize.

These commands frequently restore communication between the host and the target. However, resynchronization might not always be successful, especially if you are using a 1394 kernel connection.

The **.restart (Restart Kernel Connection)** command provides a more powerful method of resynchronization. This command is equivalent to exiting the debugger and then attaching a new debugger to the existing session. This command is available only in KD, not in WinDbg.

The **.restart** command is most useful when you are performing [remote debugging through remote.exe](#). (In this kind of debugging, it might be difficult to end and restart the debugger.) However, you cannot use **.restart** from a debugging client if you are performing remote debugging through the debugger.

[Send comments about this topic to Microsoft](#)

Finding a Memory Leak

5/26/2017 • 1 min to read • [Edit Online](#)

A memory leak occurs when a process allocates memory from the paged or nonpaged pools, but does not free the memory. As a result, these limited pools of memory are depleted over time, causing Windows to slow down. If memory is completely depleted, failures may result.

This section includes the following:

- [Determining Whether a Leak Exists](#) describes a technique you can use if you are not sure whether there is a memory leak on your system.
- [Finding a Kernel-Mode Memory Leak](#) describes how to find a leak that is caused by a kernel-mode driver or component.
- [Finding a User-Mode Memory Leak](#) describes how to find a leak that is caused by a user-mode driver or application.

[Send comments about this topic to Microsoft](#)

Determining Whether a Leak Exists

5/26/2017 • 1 min to read • [Edit Online](#)

If Windows performance is degrading over time and you suspect that a memory leak may be involved, the technique described in this section can indicate whether there is a memory leak. It will not tell you what the source of the leak is, nor whether it is user mode or kernel mode.

Begin by launching Performance Monitor. Add the following counters:

- **Memory-->Pool Nonpaged Bytes**
- **Memory-->Pool Paged Bytes**
- **Paging File-->% Usage**

Change the update time to 600 seconds to capture a graph of the leak over time. You might also want to log the data to a file for later examination.

Start the application or test that you believe is causing the leak. Allow the application or test to run undisturbed for some time; do not use the target computer during this time. Leaks are usually slow and may take hours to detect. Wait for a few hours before deciding whether a leak has occurred.

Monitor the Performance Monitor counters. After the test has started, the counter values will change rapidly, and it may take some time for the memory pools values to reach a steady state.

User-mode memory leaks are always located in pageable pool and cause both the **Pool Paged Bytes** counter and the page file **Usage** counter to increase steadily over time. Kernel-mode memory leaks usually deplete nonpaged pool, causing the **Pool Nonpaged Bytes** counter to increase, although pageable memory can be affected as well. Occasionally these counters may show false positives because an application is caching data.

[Send comments about this topic to Microsoft](#)

Finding a Kernel-Mode Memory Leak

5/26/2017 • 1 min to read • [Edit Online](#)

Use the following techniques to determine the cause of a kernel-mode memory leak:

[Using PoolMon to Find a Kernel-Mode Memory Leak](#)

[Using the Kernel Debugger to Find a Kernel-Mode Memory Leak](#)

[Using Driver Verifier to Find a Kernel-Mode Memory Leak](#)

If you do not know which kernel-mode driver or component is responsible for the leak, you should use the PoolMon technique first. This technique reveals the pool tag associated with the memory leak; the driver or component that uses this pool tag is responsible for the leak.

If you have already identified the responsible driver or component, use the second and third techniques in the preceding list to determine the cause of the leak more specifically.

[Send comments about this topic to Microsoft](#)

Using PoolMon to Find a Kernel-Mode Memory Leak

5/31/2017 • 2 min to read • [Edit Online](#)

If you suspect there is a kernel-mode memory leak, the easiest way to determine which pool tag is associated with the leak is to use the PoolMon tool.

PoolMon (Poolmon.exe) monitors pool memory usage by pool tag name. This tool is included in the Windows Driver Kit (WDK). For a full description, see [PoolMon](#) in the WDK documentation.

Enable Pool Tagging (Windows 2000 and Windows XP)

On Windows 2000 and Windows XP you must first use GFlags to enable pool tagging. GFlags is included in Debugging Tools for Windows. Start GFlags, choose the **System Registry** tab, check the **Enable Pool Tagging** box, and then click **Apply**. You must restart Windows for this setting to take effect. For more details, see [GFlags](#).

On Windows Server 2003 and later versions of Windows, pool tagging is always enabled.

Using PoolMon

The PoolMon header displays the total paged and non-paged pool bytes. The columns show pool use for each pool tag. The display is updated automatically every few seconds. For example:

```
Memory: 16224K Avail: 4564K PageFlts: 31 InRam Krnl: 684K P: 680K
Commit: 24140K Limit: 24952K Peak: 24932K Pool N: 744K P: 2180K
```

##	Tag	Type	Allocs	Frees	Diff	Bytes	Per Alloc		
CM	Paged	1283	(0)	1002	(0)	281	1377312	(0)	4901
Strg	Paged	10385	(10)	6658	(4)	3727	317952	(512)	85
Fat	Paged	6662	(8)	4971	(6)	1691	174560	(128)	103
MmSt	Paged	614	(0)	441	(0)	173	83456	(0)	482

PoolMon has command keys that sort the output according to various criteria. Press the letter associated with each command in order to re-sort the data. It takes a few seconds for each command to work.

The sort commands include:

COMMAND KEY	OPERATION
P	Limits the tags shown to nonpaged pool, paged pool, or both. Repeatedly pressing P cycles through each of these options, in that order.
B	Sorts tags by maximum byte usage.
M	Sorts tags by maximum byte allocations.
T	Sorts tags alphabetically by tag name.

COMMAND KEY	OPERATION
E	Causes the display to include the paged and non-paged totals across the bottom.
A	Sorts tags by allocation size.
F	Sorts tags by free operations.
S	Sorts tags by the difference between allocations and frees.
Q	Quits PoolMon.

Using the PoolMon Utility to Find a Memory Leak

To find a memory leak with the PoolMon utility, follow this procedure:

1. Start PoolMon.
2. If you have determined that the leak is occurring in non-paged pool, press **P** once; if you have determined that it is occurring in paged pool, press **P** twice. If you do not know, do not press **P** and both kinds of pool are included.
3. Press **B** to sort the display by maximum byte use.
4. Start your test. Take a screen shot and copy it to Notepad.
5. Take a new screen shot every half hour. By comparing screen shots, determine which tag's bytes are increasing.
6. Stop your test and wait a few hours. How much of the tag was freed up in this time?

Typically, after an application reaches a stable running state, it allocates memory and free memory at roughly the same rate. If it tends to allocate memory faster than it frees it, its memory use will grow over time. This often indicates a memory leak.

Addressing the Leak

After you have determined which pool tag is associated with the leak, this might reveal all you need to know about the leak. If you need to determine which specific instance of the allocation routine is causing the leak, see [Using the Kernel Debugger to Find Kernel-Mode Memory Leaks](#).

[Send comments about this topic to Microsoft](#)

Using the Kernel Debugger to Find a Kernel-Mode Memory Leak

5/31/2017 • 3 min to read • [Edit Online](#)

The kernel debugger determines the precise location of a kernel-mode memory leak.

Enable Pool Tagging (Windows 2000 and Windows XP)

On Windows 2000 and Windows XP, you must first use [GFlags](#) to enable pool tagging. GFlags is included in Debugging Tools for Windows. Start GFlags, choose the **System Registry** tab, check the **Enable Pool Tagging** box, and then click **Apply**. You must restart Windows for this setting to take effect.

On Windows Server 2003 and later versions of Windows, pool tagging is always enabled.

Determining the Pool Tag of the Leak

To determine which pool tag is associated with the leak, it is usually easiest to use the PoolMon tool for this step. For details, see [Using PoolMon to Find Kernel-Mode Memory Leaks](#).

Alternatively, you can use the kernel debugger to look for tags associated with large pool allocations. To do so, follow this procedure:

1. Reload all modules by using the [.reload \(Reload Module\)](#) command.
2. Use the [!poolused](#) extension. Include the flag "4" to sort the output by paged memory use:

```
kd> !poolused 4
Sorting by Paged Pool Consumed

Pool Used:
      NonPaged          Paged
      Tag    Allocs    Used    Allocs    Used
          Abc        0      0    36405  33930272
          Tron       0      0      552  7863232
          IoN7       0      0    10939  998432
          Gla5       1    128    2222  924352
          Ggb        0      0      22   828384
```

3. Determine which pool tag is associated with the greatest usage of memory. In this example, the driver using the tag "Abc" is using the most memory--almost 34 MB. Therefore, the memory leak is most likely to be in this driver.

Finding the Leak

After you have determined the pool tag associated with the leak, follow this procedure to locate the leak itself:

1. Use the [ed \(Enter Values\)](#) command to modify the value of the global system variable **PoolHitTag**. This global variable causes the debugger to break whenever a pool tag matching its value is used.
2. Set **PoolHitTag** equal to the tag that you suspect to be the source of the memory leak. The module name "nt" should be specified for faster symbol resolution. The tag value must be entered in little-endian format (that is, backward). Because pool tags are always four characters, this tag is actually A-b-c-space, not merely A-b-c. So use the following command:

```
kd> ed nt!poolhittag ' cbA'
```

3. To verify the current value of **PoolHitTag**, use the **db (Display Memory)** command:

```
kd> db nt!poolhittag L4
820f2ba4 41 62 63 20          Abc
```

4. The debugger will break every time that pool is allocated or freed with the tag **Abc**. Each time the debugger breaks on one of these allocations or free operations, use the **kb (Display Stack Backtrace)** debugger command to view the stack trace.

Using this procedure, you can determine which code resident in memory is overallocating pool with the tag **Abc**.

To clear the breakpoint, set **PoolHitTag** to zero:

```
kd> ed nt!poolhittag 0
```

If there are several different places where memory with this tag is being allocated and these are in an application or driver that you have written, you can alter your source code to use unique tags for each of these allocations.

If you cannot recompile the program but you want to determine which one of several possible locations in the code is causing the leak, you can unassemble the code at each location and use the debugger to edit this code resident in memory so that each instance uses a distinct (and previously unused) pool tag. Then allow the system to run for several minutes or more. After some time has passed, break in again with the debugger and use the **!poolfind** extension to find all pool allocations associated with each of the new tags.

[Send comments about this topic to Microsoft](#)

Using Driver Verifier to Find a Kernel-Mode Memory Leak

5/26/2017 • 1 min to read • [Edit Online](#)

Driver Verifier determines whether a kernel-mode driver is leaking memory.

The Pool Tracking feature of Driver Verifier monitors the memory allocations made by a specified driver. At the time that the driver is unloaded, Driver Verifier verifies that all allocations made by the driver have been freed. If some of the driver's allocations have not been freed, a bug check is issued, and the parameters of the bug check indicate the nature of the problem.

While this feature is active, use the Driver Verifier Manager graphical interface to monitor pool allocation statistics. If a kernel debugger is attached to the driver, use the **`!Verifier 0x3`** extension to display allocation statistics.

If the driver uses Direct Memory Access (DMA), the DMA Verification feature of Driver Verifier is also helpful in finding memory leaks. DMA Verification tests for a number of common misuses of DMA routines, including failure to free common buffers and other errors that can lead to memory leaks. If a kernel debugger is attached while this option is active, use the **`!dma`** extension to show allocation statistics.

For information about Driver Verifier, see [Driver Verifier](#) in the Windows Driver Kit (WDK) documentation.

Finding a User-Mode Memory Leak

5/26/2017 • 1 min to read • [Edit Online](#)

Use the following techniques to determine the cause of a user-mode memory leak:

[Using Performance Monitor to Find a User-Mode Memory Leak](#)

[Using UMDH to Find a User-Mode Memory Leak](#)

The first technique determines which process is leaking memory. After you know which process is involved, the second technique can determine the specific routine that is at fault.

[Send comments about this topic to Microsoft](#)

Using Performance Monitor to Find a User-Mode Memory Leak

5/26/2017 • 1 min to read • [Edit Online](#)

If you suspect there is a user-mode memory leak but are not sure which process is causing it, you can use Performance Monitor to measure the memory usage of individual processes.

Launch Performance Monitor. Add the following counters:

- **Process-->Private Bytes** (for each process you want to examine)
- **Process-->Virtual Bytes** (for each process you wish to examine)

Change the update time to 600 seconds to capture a graph of the leak over time. You might also want to log the data to a file for later examination.

The **Private Bytes** counter indicates the total amount of memory that a process has allocated, not including memory shared with other processes. The **Virtual Bytes** counter indicates the current size of the virtual address space that the process is using.

Some memory leaks appear in the data file as an increase in private bytes allocated. Other memory leaks show up as an increase in the virtual address space.

After you have determined which process is leaking memory, use the UMDH tool to determine the specific routine that is at fault. For details, see [Using UMDH to Find User-Mode Memory Leaks](#).

[Send comments about this topic to Microsoft](#)

Using UMDH to Find a User-Mode Memory Leak

5/31/2017 • 5 min to read • [Edit Online](#)

The user-mode dump heap (UMDH) utility works with the operating system to analyze Windows heap allocations for a specific process. UMDH locates which routine in a specific process is leaking memory.

UMDH is included in Debugging Tools for Windows. For full details, see [UMDH](#).

Preparing to Use UMDH

If you have not already determined which process is leaking memory, do that first. For details, see [Using Performance Monitor to Find User-Mode Memory Leaks](#).

The most important data in the UMDH logs are the stack traces of the heap allocations. To determine whether a process is leaking heap memory, analyze these stack traces.

Before using UMDH to display the stack trace data, you must use [GFlags](#) to configure your system properly. GFlags is included in Debugging Tools for Windows.

The following GFlags settings enable UMDH stack traces:

- In the GFlags graphical interface, choose the Image File tab, type the process name (including the file name extension), press the TAB key, select **Create user mode stack trace database**, and then click **Apply**.

Or, equivalently, use the following GFlags command line, where *ImageName* is the process name (including the file name extension):

```
gflags /i ImageName +ust
```

- By default, the amount of stack trace data that Windows gathers is limited to 32 MB on an x86 processor, and 64 MB on an x64 processor. If you must increase the size of this database, choose the **Image File** tab in the GFlags graphical interface, type the process name, press the TAB key, check the **Stack Backtrace (Megs)** check box, type a value (in MB) in the associated text box, and then click **Apply**. Increase this database only when necessary, because it may deplete limited Windows resources. When you no longer need the larger size, return this setting to its original value.
- If you changed any flags on the **System Registry** tab, you must restart Windows to make these changes effective. If you changed any flags on the **Image File** tab, you must restart the process to make the changes effective. Changes to the **Kernel Flags** tab are effective immediately, but they are lost the next time Windows restarts.

Before using UMDH, you must have access to the proper symbols for your application. UMDH uses the symbol path specified by the environment variable `_NT_SYMBOL_PATH`. Set this variable equal to a path containing the symbols for your application. If you also include a path to Windows symbols, the analysis may be more complete. The syntax for this symbol path is the same as that used by the debugger; for details, see [Symbol Path](#).

For example, if the symbols for your application are located at `C:\MySymbols`, and you want to use the public Microsoft symbol store for your Windows symbols, using `C:\MyCache` as your downstream store, you would use the following command to set your symbol path:

```
set _NT_SYMBOL_PATH=c:\mysymbols;srv*c:\mycache*https://msdl.microsoft.com/download/symbols
```

In addition, to assure accurate results, you must disable BSTR caching. To do this, set the `OANOCACHE`

environment variable equal to one (1). Make this setting before you launch the application whose allocations are to be traced.

If you need to trace the allocations made by a service, you must set OANOCACHE as a system environment variable and then restart Windows for this setting to take effect.

On Windows 2000, in addition to setting OANOCACHE equal to 1, you must also install the hotfix available with [Microsoft Support Article 139071](#). This hotfix is not needed on Windows XP and later versions of Windows.

Detecting Increases in Heap Allocations with UMDH

After making these preparations, you can use UMDH to capture information about the heap allocations of a process. To do so, follow this procedure:

1. Determine the [process ID \(PID\)](#) for the process you want to investigate.
2. Use UMDH to analyze the heap memory allocations for this process, and save it to a log file. Use the -p switch with the PID, and the -f switch with the name of the log file. For example, if the PID is 124, and you want to name the log file Log1.txt, use the following command:

```
umdh -p:124 -f:log1.txt
```

3. Use Notepad or another program to open the log file. This file contains the call stack for each heap allocation, the number of allocations made through that call stack, and the number of bytes consumed through that call stack.
4. Because you are looking for a memory leak, the contents of a single log file are not sufficient. You must compare log files recorded at different times to determine which allocations are growing.

UMDH can compare two different log files and display the change in their respective allocation sizes. You can use the greater-than symbol (>) to redirect the results into a third text file. You may also want to include the -d option, which converts the byte and allocation counts from hexadecimal to decimal. For example, to compare Log1.txt and Log2.txt, saving the results of the comparison to the file LogCompare.txt, use the following command:

```
umdh log1.txt log2.txt > logcompare.txt
```

5. Open the LogCompare.txt file. Its contents resemble the following:

```
+ 5320 ( f110 - 9df0) 3a allocs BackTrace00B53
Total increase == 5320
```

For each call stack (labeled "BackTrace") in the UMDH log files, there is a comparison made between the two log files. In this example, the first log file (Log1.txt) recorded 0x9DF0 bytes allocated for BackTrace00B53, while the second log file recorded 0xF110 bytes, which means that there were 0x5320 additional bytes allocated between the time the two logs were captured. The bytes came from the call stack identified by BackTrace00B53.

6. To determine what is in that backtrace, open one of the original log files (for example, Log2.txt) and search for "BackTrace00B53." The results are similar to this data:

```
00005320 bytes in 0x14 allocations (@ 0x00000428) by: BackTrace00B53
ntdll!RtlDebugAllocateHeap+0x000000FD
ntdll!RtlAllocateHeapSlowly+0x0000005A
ntdll!RtlAllocateHeap+0x00000808
MyApp!_heap_alloc_base+0x00000069
MyApp!_heap_alloc_dbg+0x000001A2
MyApp!_nh_malloc_dbg+0x00000023
MyApp!_nh_malloc+0x00000016
MyApp!operator new+0x0000000E
MyApp!DisplayMyGraphics+0x0000001E
MyApp!main+0x0000002C
MyApp!mainCRTStartup+0x000000FC
KERNEL32!BaseProcessStart+0x0000003D
```

This UMDH output shows that there were 0x5320 (decimal 21280) total bytes allocated from the call stack. These bytes were allocated from 0x14 (decimal 20) separate allocations of 0x428 (decimal 1064) bytes each.

The call stack is given an identifier of "BackTrace00B53," and the calls in this stack are displayed. In reviewing the call stack, you see that the **DisplayMyGraphics** routine is allocating memory through the **new** operator, which calls the routine *malloc*, which uses the Visual C++ run-time library to obtain memory from the heap.

Determine which of these calls is the last one to explicitly appear in your source code. In this case, it is probably the **new** operator because the call to *malloc* occurred as part of the implementation of **new** rather than as a separate allocation. So this instance of the **new** operator in the **DisplayMyGraphics** routine is repeatedly allocating memory that is not being freed.

[Send comments about this topic to Microsoft](#)

Debugging a Time Out

5/26/2017 • 1 min to read • [Edit Online](#)

There are two main time outs that occur on Windows systems:

[Resource Time Outs](#) (kernel mode)

[CriticalSection Time Outs](#) (user mode)

In many cases, these problems are simply a matter of a thread taking too long to release a resource or exit a section of code.

On a retail system, the time-out value is set high enough that you would not see the break (a true deadlock would simply hang). The time-out values are set in the registry under

HKEY_LOCAL_MACHINE\System\CurrentControlSet\Control\SessionManager. The integer values specify the number of seconds in each time out.

[Send comments about this topic to Microsoft](#)

Resource Time Outs

5/31/2017 • 2 min to read • [Edit Online](#)

During a resource time out, the thread waiting for the resource will break into the kernel debugger with a message similar to the following:

```
Resource @ 800e99c0
ActiveCount = 0001  Flags = IsOwnedExclusive sharedWaiter
NumberOfExclusiveWaiters = 0000

Thread = 809ebc50, Count = 01
Thread = 00000000, Count = 00
Thread = 00000000, Count = 00
Thread = 00000000, Count = 00
NT!DbgBreakPoint+0x4:
800cee04: 000000ad callkd
```

The thread that holds the lock is the first thread listed (or multiple threads if it is a shared lock). To examine that thread, use a **!thread** extension on the thread ID (809cd2f0, in the previous example). This will give a stack for the thread owning the resource. If it is also waiting for a resource to become available, either the **ExpWaitForResourceExclusive** function or the **ExpWaitForResourceShared** function will be on the stack for that thread.

The first parameter to **ExpWaitForResource**Xxx**** is the lock that is being waited on. To find out about that resource, use a **!locks <resource id>** extension, which will give you another thread to check.

If you get to a thread that is not waiting for another resource, that thread is probably the source of the problem. For a list of all held locks, use a **!locks** extension with no parameter at the **kd>** prompt.

Example

```

Resource @ fc664ee0          // Here's the resource lock address

ActiveCount = 0001  Flags = IsOwnedExclusive ExclusiveWaiter
NumberOfExclusiveWaiters = 0001
Thread = ffaf5410, Count = 01          // Here's the owning thread

Critical Section Time Outs

5/31/2017 • 3 min to read • [Edit Online](#)

Critical section time outs can be identified by the stack trace that shows the routine **RtlpWaitForCriticalSection** near the top of the stack. Another variety of critical section time out is a possible deadlock application error. To debug critical section time outs properly, CDB or WinDbg is necessary.

As with resource time outs, the **!ntsdexts.locks** extension will give a list of locks currently held and the threads that own them. Unlike resource time outs, the thread IDs given are not immediately useful. These are system IDs that do not map directly to the thread numbers used by CDB.

Just as with **ExpWaitForResource*XXX**, the lock identifier is the first parameter to ****RtlpWaitForCriticalSection***. Continue tracing the chain of waits until either a loop is found or the final thread is not waiting for a critical section time out.

Example of Debugging a Critical Time Out

Start by displaying the stack:

```
0:024> kb

ChildEBP RetAddr  Args to Child
0569fca4 77f79c78 77f71000 002a6b88 7fffffff ntdll!_DbgBreakPoint
0569fd04 77f71048 5ffa9f9c 5fef0b4b 5ffa9f9c ntdll!_RtlpWaitForCriticalSection+0x89
0569fd0c 5fef0b4b 5ffa9f9c 002a6b88 002a0019 ntdll!_RtlEnterCriticalSection+0x48
0569fd70 5fedf83f 002a6b88 0569fdc0 0000003e winsrv!_StreamScrollRegion+0x1f0
0569fd8c 5fedfa5b 002a6b88 00190000 00000000 winsrv!_AdjustCursorPosition+0x8e
0569fdc0 5fedf678 0569ff18 0031c200 0335ee88 winsrv!_DoWriteConsole+0x104

0569fefc 5fe6311b 0569ff18 0569ffd0 00000005 winsrv!_SrvWriteConsole+0x96
0569fff4 00000000 00000000 00000024 00000024 csrssrv!_CsrApiRequestThread+0x4ff
```

Now use the **!ntsdexts.locks** extension to find the critical section:

```
0:024> !locks
CritSec winsrv!_ScrollBufferLock at 5ffa9f9c      5ffa9f9c is the first one
LockCount      5
RecursionCount 1
OwningThread   88      // here's the owning thread ID
EntryCount     11c
ContentionCount 135
*** Locked

CritSec winsrv!_gcsUserSrv+0 at 5ffa91b4      //second critical section found below

LockCount      8
RecursionCount 1
OwningThread   6d      // second owning thread
EntryCount     1d6c
ContentionCount 1d47
*** Locked
```

Now search for the thread that has the ID number 0x6D:

```

0:024> ~
0  id: 16.15  Teb 7fffd000 Unfrozen
1  id: 16.13  Teb 7ffdb000 Unfrozen
2  id: 16.30  Teb 7ffd0000 Unfrozen
3  id: 16.2f  Teb 7ffd9000 Unfrozen
4  id: 16.2e  Teb 7ffd8000 Unfrozen
5  id: 16.6c  Teb 7ff6c000 Unfrozen
6  id: 16.6d  Teb 7ff68000 Unfrozen // this thread owns the second critical section
7  id: 16.2d  Teb 7ffd7000 Unfrozen
8  id: 16.33  Teb 7ffd6000 Unfrozen
9  id: 16.42  Teb 7ff6f000 Unfrozen
10 id: 16.6f  Teb 7ff6e000 Unfrozen
11 id: 16.6e  Teb 7ffd5000 Unfrozen
12 id: 16.52  Teb 7ff6b000 Unfrozen
13 id: 16.61  Teb 7ff6a000 Unfrozen
14 id: 16.7e  Teb 7ff69000 Unfrozen
15 id: 16.43  Teb 7ff67000 Unfrozen
16 id: 16.89  Teb 7ff50000 Unfrozen
17 id: 16.95  Teb 7ff65000 Unfrozen
18 id: 16.90  Teb 7ff64000 Unfrozen
19 id: 16.71  Teb 7ff63000 Unfrozen
20 id: 16.bb  Teb 7ff62000 Unfrozen
21 id: 16.88  Teb 7ff61000 Unfrozen // this thread owns the first critical section
22 id: 16.cd  Teb 7ff5e000 Unfrozen
23 id: 16.c1  Teb 7ff5f000 Unfrozen
24 id: 16.bd  Teb 7ff5d000 Unfrozen

```

Thread 21 owns the first critical section. Make that the active thread and get a stack trace:

```

0:024> ~21s
ntdll!_ZwWaitForSingleObject+0xb:
77f71bfb c20c00          ret     0xc

0:021> kb

ChildEBP RetAddr  Args to Child

0556fc00 77f71048 5ffa91b4 5feb4f7e 5ffa91b4 ntdll!_RtlpWaitForCriticalSection+0x31
0556fc08 5feb4f7e 5ffa91b4 0556fd70 77f71000 ntdll!_RtlEnterCriticalSection+0x48
0556fcf4 5fef0b76 01302005 00000000 ffffff4 winsrv!__ScrollDC+0x14
0556fd70 5fedf83f 002bd880 0556fdc0 00000025 winsrv!_StreamScrollRegion+0x21b
0556fd8c 5fedfa5b 002bd880 00190000 00000000 winsrv!_AdjustCursorPosition+0x8e

0556fdc0 5fedf678 0556ff18 002bd70 002a4d58 winsrv!_DoWriteConsole+0x104
0556fefc 5fe6311b 0556ff18 0556ffd0 00000005 winsrv!_SrvWriteConsole+0x96
0556fff4 00000000 00000000 00000024 00000024 csrsrv!_CsrApiRequestThread+0x4ff

```

Thread 6 owns the second critical section. Examine its stack as well:

```

0:021> ~6s
winsrv!_PtiFromThreadId+0xd:
5fe8429a 394858          cmp     [eax+0x58],ecx    ds:0023:7f504da8=000000f8

0:006> kb

ChildEBP RetAddr  Args to Child
01ecfeb4 5fec0d07 00000086 00000000 7f5738e0 winsrv!_PtiFromThreadId+0xd
01ecfed0 5feccf62 00000086 01ecfff4 00000113 winsrv!__GetThreadDesktop+0x12
01ecfefc 5fe6311b 01ecff18 01ecffd0 00000005 winsrv!__GetThreadDesktop+0x8b
01ecfff4 00000000 00000000 00000024 00000024 csrsrv!_CsrApiRequestThread+0x4ff

```

Thread 21 has **RtlpWaitForCriticalSection** near the top of its stack. Thread 6 does not. So thread 21 is the culprit.

Debugging a Stalled System

5/26/2017 • 1 min to read • [Edit Online](#)

There are times when the computer can stop responding without actually initiating a bug check. This "freeze" can appear in a variety of forms:

- The mouse pointer can be moved, but does not affect any windows on the screen.
- The entire screen is still and the mouse pointer does not move, but paging continues between the memory and the disk.
- The screen is still and the disk is silent.

If the mouse pointer moves or there is paging to the disk, this is usually due to a problem within the Client Server Run-Time Subsystem (CSRSS).

If NTSD is running on CSRSS, press F12 and dump out each thread to see if there is anything out of the ordinary. (See [Debugging CSRSS](#) for more details.)

If an examination of CSRSS reveals nothing, then the problem may be with the kernel after all.

If there is no mouse movement or paging, then it is almost certainly a kernel problem.

Analyzing a kernel crash of this sort is generally a difficult task. To begin, break into KD (with **CTRL+C**) or WinDbg (with **CTRL+BREAK**). You can now use the debugger commands to examine the situation.

Some useful techniques in this case include:

[Finding the Failed Process](#)

[Debugging an Interrupt Storm](#)

[Send comments about this topic to Microsoft](#)

Finding the Failed Process

5/31/2017 • 2 min to read • [Edit Online](#)

Before finding the failed process, make sure that you are in the context of the accepting processor. To determine the accepting processor, use the **!pcr** extension on each processor and looking for the processor for which an exception handler has been loaded. The exception handler of the accepting processor has an address other than 0xFFFFFFFF.

For example, because the address of **NtTib.ExceptionList** on this processor, is 0xFFFFFFFF, this is not the processor with the failed process:

```
0: kd> !pcr
PCR Processor 0 @ffdff000
  NtTib.ExceptionList: ffffffff
    NtTib.StackBase: 80470650
    NtTib.StackLimit: 8046d860
    NtTib.SubSystemTib: 00000000
    NtTib.Version: 00000000
    NtTib.UserPointer: 00000000
    NtTib.SelfTib: 00000000

    SelfPcr: ffdff000
    Prcb: ffdff120
    Irql: 00000000
    IRR: 00000000
    IDR: ffffffff
  InterruptMode: 00000000
    IDT: 80036400
    GDT: 80036000
    TSS: 80257000

  CurrentThread: 8046c610
  NextThread: 00000000
  IdleThread: 8046c610

  DpcQueue:
```

However, the results for Processor 1 are quite different. In this case, the value of **NtTib.ExceptionList** is **f0823cc0**, not 0xFFFFFFFF, indicating that this is the processor on which the exception occurred.

```

0: kd> ~1
1: kd> !pcr
PCR Processor 1 @81497000
NtTib.ExceptionList: f0823cc0
    NtTib.StackBase: f0823df0
    NtTib.StackLimit: f0821000
    NtTib.SubSystemTib: 00000000
    NtTib.Version: 00000000
    NtTib.UserPointer: 00000000
    NtTib.SelfTib: 00000000

        SelfPcr: 81497000
        Prcb: 81497120
        Irql: 00000000
IRR: 00000000
        IDR: ffffffff
        InterruptMode: 00000000
        IDT: 8149b0e8
GDT: 8149b908
        TSS: 81498000

        CurrentThread: 81496d28
        NextThread: 00000000
        IdleThread: 81496d28

        DpcQueue:

```

When you are in the correct processor context, the **!process** extension displays the currently running process.

The most interesting parts of the process dump are:

- The times (a high value indicates that process might be the culprit).
- The handle count (this is the number in parentheses after **ObjectTable** in the first entry).
- The thread status (many processes have multiple threads). If the current process is *Idle*, it is likely that either the machine is truly idle or it hung due to some unusual problem.

Although using the **!process 0 7** extension is the best way to find the problem on a hung system, it is sometimes too much information to filter. Instead, use a **!process 0 0** and then a **!process** on the process handle for CSRSS and any other suspicious processes.

When using a **!process 0 7**, many of the threads might be marked "kernel stack not resident" because those stacks are paged out. If those pages are still in the cache that is in transition, you can get more information by using a **.cache decodeptes** before **!process 0 7**:

```

kd> .cache decodeptes
kd> !process 0 7

```

If you can identify the failing process, use **!process <process> 7** to show the kernel stacks for each thread in the process. This output can identify the problem in kernel mode and reveal what the suspect process is calling.

In addition to **!process**, the following extensions can help to determine the cause of an unresponsive computer:

EXTENSION	EFFECT
!ready	Identifies the threads that are ready to run, in order of priority.

EXTENSION	EFFECT
!kdext*.locks	Identifies any held resource locks, in case there is a deadlock with retail time outs.
!vm	Checks the virtual memory usage.
!poolused	Determines whether one type of pool allocation is disproportionately large (pool tagging required).
!memusage	Checks the physical memory status.
!heap	Checks the validity of the heap.
!irpfind	Searches nonpaged pool for active IRPs.

If the information provided does not indicate an unusual condition, try setting a breakpoint at **ntoskrnl!KiSwapThread** to determine whether the processor is stuck in one process or if it is still scheduling other processes. If it is not stuck, set breakpoints in common functions, such as **NtReadFile**, to determine whether the computer is stuck in a specific code path.

[Send comments about this topic to Microsoft](#)

Debugging an Interrupt Storm

5/31/2017 • 7 min to read • [Edit Online](#)

One of the most common examples of a stalled system is an interrupt storm. An *interrupt storm* is a level-triggered interrupt signal that remains in the asserted state.

The following events can cause an interrupt storm:

- A hardware device does not release its interrupt signal after being directed to do so by the device driver.
- A device driver does not instruct its hardware to release the interrupt signal, because it does not detect that the interrupt was initiated from its hardware.
- A device driver claims the interrupt even though the interrupt was not initiated from its hardware. This situation can only occur when multiple devices are sharing the same IRQ.
- The edge level control register (ELCR) is not set correctly.
- Edge and level interrupt-triggered devices share an IRQ (for example, a COM port and a PCI SCSI controller).

This example demonstrates one method for detecting and debugging an interrupt storm.

When the machine hangs, use a kernel debugger to break in. Use the **!irpfind** extension command to look for pending IRPs. Then, use the **!irp** extension to obtain details about any pending IRPs. For example:

```
kd> !irp 81183468
Irp is active with 2 stacks 2 is current (= 0x811834fc)
No Mdl Thread 00000000:  Irp stack trace.
  cmd  flg cl Device   File   Completion-Context
  [ 0, 0]  0  0 8145f470 00000000 00000000-00000000
          \Driver\E100B
          Args: 00000000 00000000 00000000 00000000
>[ 16, 2]  0 e1 8145f470 00000000 8047f744-814187a8 Success Error Cancel pending
          \Driver\E100B  ntoskrnl!PopCompleteSystemPowerIrp
          Args: 00000000 00000000 00000002 00000002
```

This example shows that \driver\ e100b has not returned the IRP for **ntoskrnl!PopCompleteSystemPowerIrp**. It appears to be stuck and might be experiencing an interrupt storm.

To investigate, use the **kb** command to request a stack trace. For example:

```
kd> kb
ChildEBP RetAddr  Args to Child
f714ee68 8046355a 00000001 80068c10 00000030 ntoskrnl!RtlpBreakWithStatusInstruction
f714ee68 80067a4f 00000001 80068c10 00000030 ntoskrnl!KeUpdateSystemTime+0x13e
f714eec 8046380b 01001010 0000003b f714ef00 halacpi!HalBeginSystemInterrupt+0x83
f714eec 80463c50 01001010 0000003b f714ef00 ntoskrnl!KiChainedDispatch+0x1b
f714ef78 80067cc2 00000000 00000240 8000017c ntoskrnl!KiDispatchInterrupt
f714ef78 80501cb5 00000000 00000240 8000017c halacpi!HalpDispatchInterrupt2ndEnt
```

Notice that the section in bold is an interrupt dispatch. If you use the **g** command and break in again, you will very likely see a different stack trace, but you will still see an interrupt dispatch. To determine which interrupt is responsible for the system stall, look at the second parameter passed into **HalBeginSystemInterrupt** (in this case, 0x3B). The standard rule is that the interrupt vector displayed (0x3B) is the IRQ line plus 0x30, so the interrupt is number 0xB. Running another stack trace may provide more information about which device issued the interrupt.

service request (ISR). In this case, a second stack trace has the following result:

```
kd> kb

```

The system is currently running the ISR for the video card. The system will run the ISR for each of the devices sharing IRQ 0xB. If no process claims the interrupt, the operating system will wait infinitely, requesting the driver ISRs to handle the interrupt. It is also possible that a process might handle the interrupt and stop it, but if the hardware is broken the interrupt may simply be re-asserted.

Use the **!arbiter 4** extension to determine which devices are on IRQ 0xB. If there is only one device on IRQ 0xB, you have found the cause of the problem.. If there is more than one device sharing the interrupt (99% of the cases), you will need to isolate the device either by manually programming LNK nodes (which is destructive to the system state), or by removing or disabling hardware.

```
kd> !arbiter 4

```

In this case, the audio, Universal Serial Bus (USB), network interface card (NIC), and video are all using the same IRQ.

To find out which ISR claims ownership of the interrupt, examine the return value from the ISR. Simply disassemble the ISR using the **U** command with address given in the **!arbiter** display, and set a breakpoint on the last instruction of the ISR (which will be a 'ret' instruction). Note that using the command **g <address>** is the equivalent of setting a breakpoint on that address:

```

kd> g bfe33e7b
ds1wdm!AdapterIsr+ad:
bfe33e7b c20800      ret      0x8

```

Use the **r** command to examine the registers. In particular, look at the EAX register. If the portion of the register contents in bold (in the following code example) is anything other then zero, this ISR claimed the interrupt.

Otherwise, the interrupt was not claimed, and the operating system will call the next ISR. This example shows that the video card is not claiming the interrupt:

```
kd> r
eax=00000000 ebx=813f4ff0 ecx=00000010 edx=ffdff848 esi=8145d168 edi=813f4fc8
eip=bfe33e7b esp=f714eec4 ebp=f714eee0 iopl=0 nv up ei pl zr na po nc
cs=0008 ss=0010 ds=0023 es=0023 fs=0030 gs=0000
ds1wdm!AdapterIsr+ad:
bfe33e7b c20800 ret 0x8
```

In fact, in this case, the interrupt is not claimed by any of the devices on IRQ 0xb. When you encounter this problem, you should also check to see if each piece of hardware associated with the interrupt is actually enabled. For PCI, this is easy -- look at the CMD register displayed by the **!pci** extension output:

```
kd> !pci 0 0
PCI Bus 0
00:0 8086:7190.03 Cmd[0006:.mb...] Sts[2210:c....] Device Host bridge
01:0 8086:7191.03 Cmd[0107:imb..s] Sts[0220:.6...] PciBridge 0->1-1 PCI-PCI bridge
03:0 1073:000c.03 Cmd[0000:.....] Sts[0210:c....] Device SubID:1073:000c Audio device
04:0 8086:1229.05 Cmd[0007:imb...] Sts[0290:c....] Device SubID:8086:0008 Ethernet
07:0 8086:7110.02 Cmd[000f:imb...] Sts[0280:.....] Device ISA bridge
07:1 8086:7111.01 Cmd[0005:i.b...] Sts[0280:.....] Device IDE controller
07:2 8086:7112.01 Cmd[0005:i.b...] Sts[0280:.....] Device USB host controller
07:3 8086:7113.02 Cmd[0003:im....] Sts[0280:.....] Device Class:6:80:0
```

Note that the audio chip's CMD register is zero. This means the audio chip is effectively disabled at this time. This also means that the audio chip will not be capable of responding to accesses by the driver.

In this case, the audio chip needs to be manually re-enabled.

Debugging Multiple Targets

6/10/2017 • 2 min to read • [Edit Online](#)

You can debug multiple dump files or live user-mode applications at the same time. Each target contains one or more processes, and each process contains one or more threads.

These targets are also grouped into *systems*. Systems are sets of targets that are grouped together for easy identification and manipulation. Systems are defined as follows:

- Each kernel-mode or user-mode dump file is a separate system.
- When you are debugging live user-mode applications on different computers (by using a [process server](#), such as Dbgsrv), each application is a separate system.
- When you are debugging live user-mode applications on the local computer, the applications are combined into a single system.

The *current* or *active* system is the system that you are currently debugging.

Acquiring Multiple Targets

The first target is acquired in the usual manner.

You can debug additional live user-mode applications by using the [.attach \(Attach to Process\)](#) or [.create \(Create Process\)](#) command, followed by the [g \(Go\)](#) command.

You can debug additional dump files by using the [.opendump \(Open Dump File\)](#) command, followed by the [g \(Go\)](#) command. You can also open multiple dump files when the debugger is started. To open multiple dump files, include multiple **-z** switches in the command, each followed by a different file name.

You can use the preceding commands even if the processes are on different systems. You must start a process server on each system and then use the **-premove** parameter with [.attach](#) or [.create](#) to identify the proper process server. If you use the [.attach](#) or [.create](#) command again without specifying the **-premove** parameter, the debugger attaches to, or creates, a process on the current system.

Manipulating Systems and Targets

When debugging begins, the current system is the one that the debugger most recently attached to. If an exception occurs, the current system switches to the system that this exception occurred on.

To close one target and continue to debug the other targets, use the [.kill \(Kill Process\)](#) command. You can use the [.detach \(Detach from Process\)](#) command or WinDbg's [Debug | Detach Debuggee](#) menu command instead. These commands detach the debugger from the target but leave the target running.

To control the debugging of multiple systems, you can use the following methods:

- The [|| \(System Status\)](#) command displays information about one or more systems
- The [||s \(Set Current System\)](#) command enables you to select the current system
- (WinDbg only) The [Processes and Threads window](#) enables you display or select systems, processes, and threads

By using these commands to select the current system, and by using the standard commands to [select the current process and thread](#), you can determine the context of commands that display memory and registers.

However, you cannot separate execution of these processes. The [g \(Go\)](#) command always causes all targets to

execute together.

Note We recommend that you do not debug live targets and dump targets together, because commands behave differently for each type of debugging. For example, if you use the **g (Go)** command when the current system is a dump file, the debugger begins executing, but you cannot break back into the debugger, because the break command is not recognized as valid for dump file debugging.

Tracking Down a Processor Hog

5/26/2017 • 3 min to read • [Edit Online](#)

If one application is consuming ("hogging") all the processor's attention, other processes will end up "starving" and unable to run.

Use the following procedure to correct a bug of this sort.

Debugging an application that is using all the CPU cycles

1. **Identify which application is causing this problem:** Use **Task Manager** or **Perfmon** to find which process is using 99% or 100% of the processor's cycles. This may tell you the offending thread as well.
2. Attach WinDbg, KD, or CDB to this process.
3. **Identify which thread is causing the problem:** Break into the offending application. Use the **!runaway 3** extension to take a "snapshot" of where all the CPU time is going. Use **g (Go)** and wait a few seconds. Then break in and use **!runaway 3** again.

```
0:002> !runaway 3
User Mode Time
Thread      Time
4e0        0:12:16.0312
268        0:00:00.0000
22c        0:00:00.0000

Kernel Mode Time
Thread      Time
4e0        0:00:05.0312
268        0:00:00.0000
22c        0:00:00.0000

0:002> g

0:001> !runaway 3
User Mode Time
Thread      Time
4e0        0:12:37.0609
3d4        0:00:00.0000
22c        0:00:00.0000

Kernel Mode Time
Thread      Time
4e0        0:00:07.0421
3d4        0:00:00.0000
22c        0:00:00.0000
```

Compare the two sets of numbers and look for the thread whose user-mode time or kernel-mode time has increased the most. Because **!runaway** sorts by descending CPU time, the offending thread is usually the one at the top of the list. In this case, thread 0x4E0 is causing the problem.

4. Use the **~ (Thread Status)** and **~s (Set Current Thread)** commands to make this the current thread:

```
0:001> ~
  0  Id: 3f4.3d4 Suspend: 1 Teb: 7ffd000 Unfrozen
  . 1  Id: 3f4.22c Suspend: 1 Teb: 7ffdd000 Unfrozen
  2  Id: 3f4.4e0 Suspend: 1 Teb: 7ffdc000 Unfrozen

0:001> ~2s
```

5. Use **kb** (Display Stack Backtrace) to obtain a stack trace of this thread:

```
0:002> kb
FramePtr  RetAddr  Param1  Param2  Param3  Function Name

```

6. Set a breakpoint on the return address of the currently-running function. In this case, the return address is shown on the first line as 0x77F6C600. The return address is equivalent to the function offset shown on the second line (**BuggyProgram!OpenDestFileStream+0xB3**). If no symbols are available for the application, the function name may not appear. Use the **g (Go)** command to execute until this return address is reached, using either the symbolic or hexadecimal address:

```
0:002> g BuggyProgram!OpenDestFileStream+0xb3
```

7. If this breakpoint is hit, repeat the process. For example, suppose this breakpoint is hit. The following steps should be taken:

```
0:002> kb

0b4fff90  77e1ac1c  77e15eaf  00149210  0b4ffffec  RPCRT4!?ReceiveLotsaCalls@OSF_ADDRESS@@QAEXXZ+0x76

0:002> g BuggyProgram!DispatchToConn+0xa4

```

- Finally you will find a breakpoint that is not hit. In this case, you should assume that the last **g** command set the target running and it did not break. This means that the **SaveMsgToDestFolder()** function will never return.
- Break into the thread again and set a breakpoint on **BuggyProgram!SaveMsgToDestFolder+0xB3** with the **bp (Set Breakpoint)** command. Then use the **g** command repeatedly. If this breakpoint hits immediately, regardless of how many times you have executed the target, it is very likely that you have identified the offending function:

```

0:002> bp BuggyProgram!SaveMsgToDestFolder+0xb3
0:002> g
0:002> g

```

- Use the **p (Step)** command to proceed through the function until you identify the place where the looping sequence of instructions are. You can then analyze the application's source code to identify the cause of the spinning thread. The cause will usually turn out to be a problem in the logic of a **while**, **do-while**, **goto**, or **for** loop.

Determining the ACL of an Object

5/31/2017 • 1 min to read • [Edit Online](#)

You can use the debugger to examine the access control list (ACL) of an object.

The following method can be used if you are performing kernel debugging. To use it while you are performing user-mode debugging, you need to redirect control to a kernel debugger. See [Controlling the User-Mode Debugger from the Kernel Debugger](#) for details.

First, use the **!object** debugger extension with the name of the object in question:

```
kd> !object \BaseNamedObjects\AgentToWkssvcEvent
Object: ffbb8a98  Type: (80e30e70) Event
  ObjectHeader: ffbb8a80
  HandleCount: 2  PointerCount: 3
  Directory Object: e14824a0  Name: AgentToWkssvcEvent
```

This shows that the object header has address 0xFFBB8A80. Use the **dt (Display Type)** command with this address and the **nt!_OBJECT_HEADER** structure name:

```
kd> dt nt!_OBJECT_HEADER ffbb8a80
+0x000 PointerCount      : 3
+0x004 HandleCount       : 2
+0x004 NextToFree        : 0x00000002
+0x008 Type              : 0x80e30e70
+0x00c NameInfoOffset    : 0x10 '
+0x00d HandleInfoOffset : 0 '
+0x00e QuotaInfoOffset   : 0 '
+0x00f Flags              : 0x20 ''
+0x010 ObjectCreateInfo  : 0x8016b460
+0x010 QuotaBlockCharged : 0x8016b460
+0x014 SecurityDescriptor : 0xe11f08b6
+0x018 Body               : _QUAD
```

The security descriptor pointer value is shown as 0xE11F08B6. The lowest 3 bits of this value represent an offset past the beginning of this structure, so you should ignore them. In other words, the **SECURITY_DESCRIPTOR** structure actually begins at 0xE11F08B6 & ~0x7. Use the **!sd** extension on this address:

```
kd> !sd e11f08b0
->Revision: 0x1
->Sbz1 : 0x0
->Control : 0x8004
    SE_DACL_PRESENT
SE_SELF_RELATIVE
->Owner : S-1-5-32-544
->Group : S-1-5-18
->Dacl :
->Dacl : ->AclRevision: 0x2
->Dacl : ->Sbz1 : 0x0
->Dacl : ->AclSize : 0x44
->Dacl : ->AceCount : 0x2
->Dacl : ->Sbz2 : 0x0
->Dacl : ->Ace[0]: ->AceType: ACCESS_ALLOWED_ACE_TYPE
->Dacl : ->Ace[0]: ->AceFlags: 0x0
->Dacl : ->Ace[0]: ->AceSize: 0x14
->Dacl : ->Ace[0]: ->Mask : 0x001f0003
->Dacl : ->Ace[0]: ->SID: S-1-5-18

->Dacl : ->Ace[1]: ->AceType: ACCESS_ALLOWED_ACE_TYPE
->Dacl : ->Ace[1]: ->AceFlags: 0x0
->Dacl : ->Ace[1]: ->AceSize: 0x18
->Dacl : ->Ace[1]: ->Mask : 0x00120001
->Dacl : ->Ace[1]: ->SID: S-1-5-32-544

->Sacl : is NULL
```

This displays the security information for this object.

Displaying a Critical Section

5/31/2017 • 5 min to read • [Edit Online](#)

Critical sections can be displayed in user mode by a variety of different methods. The exact meaning of each field depends on the version of Microsoft Windows version you are using.

Displaying Critical Sections

Critical sections can be displayed by the **!ntsdexts.locks** extension, the **!critsec** extension, the **!cs** extension, and the **dt (Display Type)** command.

The **!ntsdexts.locks** extension displays a list of critical sections associated with the current process. If the **-v** option is used, all critical sections are displayed. Here is an example:

```
0:000> !locks

CritSec ntdll!FastPebLock+0 at 77FC49E0
LockCount      0
RecursionCount 1
OwningThread   c78
EntryCount     0
ContentionCount 0
*** Locked

.....
Scanned 37 critical sections
```

If you know the address of the critical section you wish to display, you can use the **!critsec** extension. This displays the same collection of information as **!ntsdexts.locks**. For example:

```
0:000> !critsec 77fc49e0

CritSec ntdll!FastPebLock+0 at 77FC49E0
LockCount      0
RecursionCount 1
OwningThread   c78
EntryCount     0
ContentionCount 0
*** Locked
```

The **!cs** extension is only available in Microsoft Windows XP and later versions of Windows. It can display a critical section based on its address, search an address range for critical sections, and even display the stack trace associated with each critical section. Some of these features require full Windows symbols to work properly. If Application Verifier is active, **!cs -t** can be used to display the critical section tree. See the **!cs** reference page for details and examples.

The information displayed by **!cs** is slightly different than that shown by **!ntsdexts.locks** and **!critsec**. For example:

```
## 0:000> !cs 77fc49e0

CriticalSection = 0x77fc49e0 (ntdll!FastPebLock+0x0)
DebugInfo      = 0x77fc3e00
LOCKED
LockCount      = 0x0
OwningThread   = 0x000000c78
RecursionCount = 0x1
LockSemaphore  = 0x0
SpinCount       = 0x00000000
```

The **dt (Display Type)** command can be used to display the literal contents of the RTL_CRITICAL_SECTION structure. For example:

```
0:000> dt RTL_CRITICAL_SECTION 77fc49e0
+0x000 DebugInfo      : 0x77fc3e00
+0x004 LockCount      : 0
+0x008 RecursionCount : 1
+0x00c OwningThread   : 0x000000c78
+0x010 LockSemaphore  : (null)
+0x014 SpinCount       : 0
```

Interpreting Critical Section Fields in Windows XP and Windows 2000

The most important fields of the critical section structure are as follows:

- In Microsoft Windows 2000, and Windows XP, the **LockCount** field indicates the number of times that any thread has called the **EnterCriticalSection** routine for this critical section, minus one. This field starts at -1 for an unlocked critical section. Each call of **EnterCriticalSection** increments this value; each call of **LeaveCriticalSection** decrements it. For example, if **LockCount** is 5, this critical section is locked, one thread has acquired it, and five additional threads are waiting for this lock.
- The **RecursionCount** field indicates the number of times that the owning thread has called **EnterCriticalSection** for this critical section.
- The **EntryCount** field indicates the number of times that a thread other than the owning thread has called **EnterCriticalSection** for this critical section.

A newly initialized critical section looks like this:

```
0:000> !critsec 433e60
CritSec mymodule!cs+0 at 00433E60
LockCount      NOT LOCKED
RecursionCount 0
OwningThread   0
EntryCount     0
ContentionCount 0
```

The debugger displays "NOT LOCKED" as the value for **LockCount**. The actual value of this field for an unlocked critical section is -1. You can verify this with the **dt (Display Type)** command:

```
0:000> dt RTL_CRITICAL_SECTION 433e60
+0x000 DebugInfo      : 0x77fcec80
+0x004 LockCount      : -1
+0x008 RecursionCount : 0
+0x00c OwningThread   : (null)
+0x010 LockSemaphore  : (null)
+0x014 SpinCount       : 0
```

When the first thread calls the **EnterCriticalSection** routine, the critical section's **LockCount**, **RecursionCount**, **EntryCount** and **ContentionCount** fields are all incremented by one, and **OwningThread** becomes the thread ID of the caller. **EntryCount** and **ContentionCount** are never decremented. For example:

```
0:000> !critsec 433e60
CritSec mymodule!cs+0 at 00433E60
LockCount      0
RecursionCount 1
OwningThread   4d0
EntryCount     0
ContentionCount 0
```

At this point, four different things can happen.

1. The owning thread calls **EnterCriticalSection** again. This will increment **LockCount** and **RecursionCount**. **EntryCount** is not incremented.

```
0:000> !critsec 433e60
CritSec mymodule!cs+0 at 00433E60
LockCount      1
RecursionCount 2
OwningThread   4d0
EntryCount     0
ContentionCount 0
```

2. A different thread calls **EnterCriticalSection**. This will increment **LockCount** and **EntryCount**. **RecursionCount** is not incremented.

```
0:000> !critsec 433e60
CritSec mymodule!cs+0 at 00433E60
LockCount      1
RecursionCount 1
OwningThread   4d0
EntryCount     1
ContentionCount 1
```

3. The owning thread calls **LeaveCriticalSection**. This will decrement **LockCount** (to -1) and **RecursionCount** (to 0), and will reset **OwningThread** to 0.

```
0:000> !critsec 433e60
CritSec mymodule!cs+0 at 00433E60
LockCount      NOT LOCKED
RecursionCount 0
OwningThread   0
EntryCount     0
ContentionCount 0
```

4. Another thread calls **LeaveCriticalSection**. This produces the same results as the owning thread calling **LeaveCriticalSection** -- it will decrement **LockCount** (to -1) and **RecursionCount** (to 0), and will reset **OwningThread** to 0.

When any thread calls **LeaveCriticalSection**, Windows decrements **LockCount** and **RecursionCount**. This feature has both good and bad aspects. It allows a device driver to enter a critical section on one thread and leave the critical section on another thread. However, it also makes it possible to accidentally call **LeaveCriticalSection** on the wrong thread, or to call **LeaveCriticalSection** too many times and cause **LockCount** to reach values lower than -1. This corrupts the critical section and causes all threads to wait indefinitely on the critical section.

Interpreting Critical Section Fields in Windows Server 2003 SP1 and Later

In Microsoft Windows Server 2003 Service Pack 1 and later versions of Windows, the **LockCount** field is parsed as follows:

- The lowest bit shows the lock status. If this bit is 0, the critical section is locked; if it is 1, the critical section is not locked.
- The next bit shows whether a thread has been woken for this lock. If this bit is 0, then a thread has been woken for this lock; if it is 1, no thread has been woken.
- The remaining bits are the ones-complement of the number of threads waiting for the lock.

As an example, suppose the **LockCount** is -22. The lowest bit can be determined in this way:

```
0:009> ? 0x1 & (-0n22)
Evaluate expression: 0 = 00000000
```

The next-lowest bit can be determined in this way:

```
0:009> ? (0x2 & (-0n22)) >> 1
Evaluate expression: 1 = 00000001
```

The ones-complement of the remaining bits can be determined in this way:

```
0:009> ? ((-1) - (-0n22)) >> 2
Evaluate expression: 5 = 00000005
```

In this example, the first bit is 0 and therefore the critical section is locked. The second bit is 1, and so no thread has been woken for this lock. The complement of the remaining bits is 5, and so there are five threads waiting for this lock.

Additional Information

For information about how to debug critical section time outs, see [CriticalSection Time Outs](#). For general information about critical sections, see the Microsoft Windows SDK, the Windows Driver Kit (WDK), or *Microsoft Windows Internals* by Mark Russinovich and David Solomon. (These resources may not be available in some languages and countries.)

Debugging a Deadlock

5/31/2017 • 6 min to read • [Edit Online](#)

When a thread needs exclusive access to code or some other resource, it requests a *lock*. If it can, Windows responds by giving this lock to the thread. At this point, nothing else in the system can access the locked code. This happens all the time and is a normal part of any well-written multithreaded application. Although a particular code segment can only have one lock on it at a time, multiple code segments can each have their own lock.

A *deadlock* arises when two or more threads have requested locks on two or more resources, in an incompatible sequence. For instance, suppose that Thread One has acquired a lock on Resource A and then requests access to Resource B. Meanwhile, Thread Two has acquired a lock on Resource B and then requests access to Resource A. Neither thread can proceed until the other thread's lock is relinquished, and, therefore, neither thread can proceed.

User-mode deadlocks arise when multiple threads of one application have blocked each others' access to the same resources. Kernel-mode deadlocks arise when multiple threads (from the same process or from distinct processes) have blocked each others' access to the same kernel resource. The procedure used to debug a deadlock depends on whether the deadlock occurs in user mode or in kernel mode.

Debugging a User-Mode Deadlock

When a deadlock occurs in user mode, use the following procedure to debug it:

1. Issue the **!ntdexts.locks** extension. In user mode, you can just type **!locks** at the debugger prompt; the **ntdexts** prefix is assumed.
2. This extension displays all the critical sections associated with the current process, along with the ID for the owning thread and the lock count for each critical section. If a critical section has a lock count of zero, it is not locked. Use the **~ (Thread Status)** command to see information about the threads that own the other critical sections.
3. Use the **kb (Display Stack Backtrace)** command for each of these threads to determine whether they are waiting on other critical sections.
4. Using the output of these **kb** commands, you can find the deadlock: two threads that are each waiting on a lock held by the other thread. In rare cases, a deadlock could be caused by more than two threads holding locks in a circular pattern, but most deadlocks involve only two threads.

Here is an illustration of this procedure. You begin with the **!ntdexts.locks** extension:

```

0:006> !locks
CritSec ftpsvc2!g_csServiceEntryLock+0 at 6833dd68
LockCount      0
RecursionCount 1
OwningThread   a7
EntryCount     0
ContentionCount 0
*** Locked

CritSec isatq!AtqActiveContextList+a8 at 68629100
LockCount      2
RecursionCount 1
OwningThread   a3
EntryCount     2
ContentionCount 2
*** Locked

CritSec +24e750 at 24e750
LockCount      6
RecursionCount 1
OwningThread   a9
EntryCount     6
ContentionCount 6
*** Locked

```

The first critical section displayed has no locks and, therefore, can be ignored.

The second critical section displayed has a lock count of 2 and is, therefore, a possible cause of a deadlock. The owning thread has a thread ID of 0xA3.

You can find this thread by listing all threads with the [~ \(Thread Status\)](#) command, and looking for the thread with this ID:

```

0:006> ~
 0  Id: 1364.1330 Suspend: 1 Teb: 7ffd000 Unfrozen
 1  Id: 1364.17e0 Suspend: 1 Teb: 7ffde000 Unfrozen
 2  Id: 1364.135c Suspend: 1 Teb: 7ffdd000 Unfrozen
 3  Id: 1364.1790 Suspend: 1 Teb: 7ffdc000 Unfrozen
 4  Id: 1364.a3 Suspend: 1 Teb: 7ffdb000 Unfrozen
 5  Id: 1364.1278 Suspend: 1 Teb: 7ffda000 Unfrozen
 6  Id: 1364.a9 Suspend: 1 Teb: 7ffd9000 Unfrozen
 7  Id: 1364.111c Suspend: 1 Teb: 7ffd8000 Unfrozen
 8  Id: 1364.1588 Suspend: 1 Teb: 7ffd7000 Unfrozen

```

In this display, the first item is the debugger's internal thread number. The second item (the `Id` field) contains two hexadecimal numbers separated by a decimal point. The number before the decimal point is the process ID; the number after the decimal point is the thread ID. In this example, you see that thread ID 0xA3 corresponds to thread number 4.

You then use the [kb \(Display Stack Backtrace\)](#) command to display the stack that corresponds to thread number 4:

```

0:006> ~4 kb
 4 id: 97.a3 Suspend: 0 Teb 7ffd9000 Unfrozen
ChildEBP RetAddr  Args to Child
014cfe64 77f6cc7b 00000460 00000000 00000000 ntdll!NtWaitForSingleObject+0xb

00000001 000003e6 00000000 00000001 000c000a kernel32!BaseThreadStart+0x51

```

Notice that this thread has a call to the **WaitForCriticalSection** function, which means that not only does it have a lock, it is waiting for code that is locked by something else. We can find out which critical section we are waiting on by looking at the first parameter of the call to **WaitForCriticalSection**. This is the first address under **Args to Child**: "24e750". So this thread is waiting on the critical section at address 0x24E750. This was the third critical section listed by the **!locks** extension that you used earlier.

In other words, thread 4, which owns the second critical section, is waiting on the third critical section. Now turn your attention to the third critical section, which is also locked. The owning thread has thread ID 0xA9. Returning to the output of the `~` command that you saw previously, note that the thread with this ID is thread number 6. Display the stack backtrace for this thread:

```

0155ffec 00000000 68622644 abcdef01 00000000 kernel32!BaseThreadStart+0x51

```

This thread, too, is waiting for a critical section to be freed. In this case, it is waiting on the critical section at 0x68629100. This was the second critical section in the list generated earlier by the **!locks** extension.

This is the deadlock. Thread 4, which owns the second critical section, is waiting on the third critical section. Thread 6, which owns the third critical section, is waiting on the second critical section.

Having confirmed the nature of this deadlock, you can use the usual debugging techniques to analyze threads 4 and 6.

Debugging a Kernel-Mode Deadlock

There are several debugger extensions that are useful for debugging deadlocks in kernel mode:

- The **!kdexts.locks** extension displays information about all locks held on kernel resources and the threads holding these locks. (In kernel mode, you can just type **!locks** at the debugger prompt; the **kdexts** prefix is assumed.)

- The **!qlocks** extension displays the state of all queued spin locks.
- The **!wdfkd.wdfspinlock** extension displays information about a Kernel-Mode Driver Framework (KMDF) spin-lock object.
- The **!deadlock** extension is used in conjunction with Driver Verifier to detect inconsistent use of locks in your code that have the potential to cause deadlocks.

When a deadlock occurs in kernel mode, use the **!kdexts.locks** extension to list all the locks currently acquired by threads.

You can usually pinpoint the deadlock by finding one non-executing thread that holds an exclusive lock on a resource that is required by an executing thread. Most of the locks are shared.

Debugging a Failed Driver Unload

5/31/2017 • 1 min to read • [Edit Online](#)

A driver will not unload if there is a leaked reference to **DeviceObject** or **DriverObject**. This is a common cause of failed driver unloads.

Apart from **IoCreateDevice**, there are several functions that take reference to **DriverObject** and **DeviceObject**. If you do not follow the guidelines for using the functions, you will end up leaking the reference.

Here is an example of how to debug this problem. Although **DeviceObject** is used in this example, this technique works for all objects.

Fixing a driver that fails to unload

1. Put a breakpoint right after the driver calls **IoCreateDevice**. Get the **DeviceObject** address.
2. Find the object header by using the **!object** extension on this object address:

```
kd> !object 81a578c0
Object: 81a578c0  Type: (81bd0e70) Device
  ObjectHeader: 81a578a8
  HandleCount: 0  PointerCount: 3
  Directory Object: e1001208  Name: Serial0
```

The first variable in the **ObjectHeader** is the *pointer count* or *reference count*.

3. Put a write breakpoint on the pointer count, using the **ObjectHeader**'s address:

```
kd> ba w4 81a578a8 "k;g"
```

4. Use **g (Go)**. The debugger will produce a log.
5. Look for the mismatched reference/dereference pair -- specifically, a missing dereference. (Note that **ObReferenceObject** is implemented as a macro inside the kernel.)

Reading Bug Check Callback Data

5/31/2017 • 4 min to read • [Edit Online](#)

Many drivers supply *bug check callback routines*. When Windows issues a bug check, it calls these routines before shutting down the system. These routines can specify and write to areas of memory known as *callback data* and *secondary callback data*.

[BugCheckCallback](#)

Data written by this routine becomes part of callback data. The data is not included in the crash dump file. (See [Earlier Versions of Windows](#) for an exception.)

[BugCheckSecondaryDumpDataCallback](#)

Data written by this routine becomes part of secondary callback data. The data is included in the crash dump file.

[BugCheckAddPagesCallback](#)

Pages specified by this routine become part of callback data. The data in those pages is included in the crash dump file.

The amount of callback and secondary callback data that is available to the debugger depends on several factors:

- If you are performing live debugging of a crashed system, callback data that has already been written by [BugCheckCallback](#) or specified by [BugCheckAddPagesCallback](#) will be available. Secondary callback data will not be available, because it is not stored in any fixed memory location.
- If you are debugging a Complete Memory Dump or Kernel Memory Dump, callback data specified by [BugCheckAddPagesCallback](#) and secondary callback data written by [BugCheckSecondaryDumpDataCallback](#) will be available. Callback data written by [BugCheckCallback](#) will not be available. (See [Earlier Versions of Windows](#) for an exception.)
- If you are debugging a Small Memory Dump, callback data will not be available. Secondary callback data will be available.

See [Varieties of Kernel-Mode Dump Files](#) for more details on these different dump file sizes.

Earlier Versions of Windows

In versions of Windows earlier than Windows XP SP1, callback data written by [BugCheckCallback](#) is included in the crash dump file.

Displaying Callback Data

To display bug check callback data, you can use the **!bugdump** extension.

Without any parameters, **!bugdump** will display data for all callbacks.

To view data for one specific callback routine, use **!bugdump Component**, where *Component* is the same parameter that was passed to **KeRegisterBugCheckCallback** when that routine was registered.

Displaying Secondary Callback Data

There are two methods for displaying secondary callback data in Windows XP SP1, Windows Server 2003, and later versions of Windows. You can use the **.enumtag** command or you can write your own debugger extension.

Each block of secondary callback data is identified by a GUID tag. This tag is specified by the **Guid** field of the **(KBUGCHECK_SECONDARY_DUMP_DATA)ReasonSpecificData** parameter passed to

BugCheckSecondaryDumpDataCallback.

The **.enumtag (Enumerate Secondary Callback Data)** command is not a very precise instrument. It displays every secondary data block, showing the tag and then showing the data in hexadecimal and ASCII format. It is generally useful only to determine what tags are actually being used for secondary data blocks.

To use this data in a more practical way, it is recommended that you write your own debugger extension. This extension must call methods in the dbgeng.h header file. For details, see [Writing New Debugger Extensions](#).

If you know the GUID tag of the secondary data block, your extension should use the method

IDebugDataSpaces3::ReadTagged to access the data. Its prototype is as follows:

```
STDMETHOD(ReadTagged)(  
    THIS_  
    IN LPGUID Tag,  
    IN ULONG Offset,  
    OUT OPTIONAL PVOID Buffer,  
    IN ULONG BufferSize,  
    OUT OPTIONAL PULONG TotalSize  
) PURE;
```

Here is an example of how to use this method:

```
UCHAR RawData[MY_DATA_SIZE];  
GUID MyGuid = .... ;  
  
Success = DataSpaces->ReadTagged( &MyGuid, 0, RawData,  
                                    sizeof(RawData), NULL);
```

If you supply a *BufferSize* that is too small, **ReadTagged** will succeed but will write only the requested number of bytes to *Buffer*. If you specify a *BufferSize* that is too large, **ReadTagged** will succeed but will write only the actual block size to *Buffer*. If you supply a pointer for *TotalSize*, **ReadTagged** will use it to return the size of the actual block. If the block cannot be accessed, **ReadTagged** will return a failure status code.

If two blocks have identical GUID tags, the first matching block will be returned, and the second block will be inaccessible.

If you are not sure of the GUID tag of your block, you can use the **IDebugDataSpaces3::StartEnumTagged**, **IDebugDataSpaces3::GetNextTagged**, and **IDebugDataSpaces3::EndEnumTagged** methods to enumerate the tagged blocks. Their prototypes are as follows:

```
STDMETHOD(StartEnumTagged)(  
    THIS_  
    OUT PULONG64 Handle  
) PURE;  
  
STDMETHOD(GetNextTagged)(  
    THIS_  
    IN ULONG64 Handle,  
    OUT LPGUID Tag,  
    OUT PULONG Size  
) PURE;  
  
STDMETHOD(EndEnumTagged)(  
    THIS_  
    IN ULONG64 Handle  
) PURE;
```

Debugging Callback Routines

It is also possible to debug the callback routine itself. Breakpoints within callback routines work just like any other breakpoint.

If the callback routine causes a second bug check, this new bug check will be processed first. However, Windows will not repeat certain parts of the Stop process—for example, it will not write a second crash dump file. The Stop code displayed on the blue screen will be the second bug check code. If a kernel debugger is attached, messages about both bug checks will usually appear.

Debugging a User-Mode Failure with KD

5/26/2017 • 1 min to read • [Edit Online](#)

To properly debug user-mode failures, you need CDB or WinDbg. However, sometimes a user-mode exception will break into KD because no user-mode debugger is present. There are also times when it is helpful to monitor what specific user-mode processes are doing while debugging a kernel-mode problem.

By default, the kernel debugger attempts to load the first user-mode symbol that matches the address specified (for a **k**, **u**, or **ln** command).

Unfortunately, user-mode symbols are often not specified in the symbol path or the first symbol is not the correct one. If the symbols are not there, either copy them into the symbol path or use a [.sympath \(Set Symbol Path\)](#) command to point to the full symbol tree, and then use the [.reload \(Reload Module\)](#) command. If the wrong symbol is loaded, you can explicitly load a symbol by doing a [.reload <binary.ext>](#).

Most of the Windows DLLs are rebased so they load at different addresses, but there are exceptions. Video adapters are the most common exceptions. There are dozens of video adapters that all load at the same base address, so KD will almost always find ati.dll (the first video symbol, alphabetically). For video, there is also a .sys file loaded that can be identified by using a [!drivers](#) extension. With that information, you can issue a [.reload](#) to get the correct video DLLs. There are also times when the debugger gets confused and reloading specific symbols will help give the correct stack. Unassemble the functions to see if the symbols look correct.

Similar to the video DLLs, almost all executables load at the same address, so KD will report access. If you see a stack trace in access, do a [!process](#) and then a [.reload](#) of the executable name given. If the executable does not have symbols in the symbol path, copy them there and do the [.reload](#) again.

Sometimes KD or WinDbg has trouble loading the correct user-mode symbols even when the full symbol tree is in the symbol path. In this case, ntdll.dll and kernel32.dll are two of the most common symbols that would be required. In the case of debugging CSRSS from KD, winsrv.dll and csrssrv.dll are also common DLLs to load.

Crashing and Rebooting the Target Computer

5/31/2017 • 2 min to read • [Edit Online](#)

When you perform kernel debugging, you can cause the target computer to stop responding (that is, *crash* or *bug check*) by issuing the **.crash (Force System Crash)** command. This command immediately causes the target computer to stop responding. The debugger writes a kernel-mode dump file if you have enabled crash dumps. (For more information about these files, see [Creating a Kernel-Mode Dump File](#).)

To restart the target computer, use the **.reboot (Reboot Target Computer)** command.

If you want the target computer to create a crash dump file and then restart, you should issue the **.crash** command, followed by the **.reboot** command. If you want only to restart, the **.crash** command is not required.

In the early stages of the boot process, the connection between the host computer and the target computer is lost. No information about the target computer is available to the debugger.

After the connection is broken, the debugger closes all symbol files and unloads all debugger extensions. At this point, all breakpoints are lost if you are running KD or CDB. In WinDbg, you can save the current workspace. This action saves all breakpoints.

If you want to end the debugging session at this point, use the **CTRL+B** command (in KD) or click **Exit** on the **File** menu (in WinDbg).

If you do not exit the debugger, the connection is reestablished after enough of the boot process has completed. Symbols and extensions are reloaded at this point. If you are running WinDbg, the kernel-mode workspace is reloaded.

You can tell the debugger to automatically break into the target computer during the restart process at two possible times:

- When the first kernel module is loaded into memory
- When the kernel initializes

To set an automatic breakpoint when the first kernel module loads, use the **-d** [command-line option](#).

You can also change the break state after the debugger is running:

- Control the initial module load and kernel initialization breakpoints like all exceptions and events. You can break into the debugger when these events occur, or ignore them. You can also have a specified command automatically execute when these breakpoints are hit. For more information, see [Controlling Exceptions and Events](#).
- Use the **CTRL+K** shortcut keys in KD, the **CTRL+ALT+K** shortcut keys in WinDbg, and the **Debug | Kernel Connection | Cycle Initial Break** command in WinDbg to change the break state. Every time that you use these commands, the debugger switches between three states: no automatic break, break upon kernel initialization, and break on first kernel module load. This method cannot activate both automatic breakpoints at the same time.

Mapping Driver Files

5/31/2017 • 6 min to read • [Edit Online](#)

Replacing driver files can be difficult. Frequently, you have to boot to the Microsoft Windows *safe build*, replace the driver binary, and then boot again.

However, Windows XP and later versions of Windows support a simpler method of replacing driver files. You can use this method to replace any kernel-mode driver (including display drivers), any Windows subsystem driver, or any other kernel-mode module. For simplicity, these files are called *drivers* in this topic, even though you can use this method for any kernel-mode module.

You can use this method whenever WinDbg or KD is attached as a kernel debugger. You can also use this method on a boot driver, but it is more difficult. For more information about how to use this method with boot drivers, see [Replacing Boot Drivers](#).

To use a driver replacement map to replace driver files, do the following:

1. Create a *driver replacement map file*. This file is a text file that lists the drivers on the target computer and their replacement drivers on the host computer. You can replace any number of drivers. For example, you might create a file that is named Mymap.ini in the d:\Map_Files directory of your host computer that contains the following information.

```
map
\Systemroot\system32\drivers\videoprt.sys
\\myserver\myshare\new_drivers\videoprt.sys
```

For more information about the syntax of this file, see [Driver Replacement Map File Format](#).

2. Set up a kernel debugging connection to the target computer, and start the kernel debugger (KD or WinDbg) on your host computer. (You do not have to actually break in to the target computer.)
3. Load the driver replacement map file by doing one of the following:

- Set the _NT_KD_FILES [environment variable](#) before you start the kernel debugger.

```
D:\Debugging Tools for Windows> set _NT_KD_FILES=d:\Map_Files\mymap.ini
D:\Debugging Tools for Windows> kd
```

- Use the [.kdfiles \(Set Driver Replacement Map\)](#) command after you start the kernel debugger.

```
D:\Debugging Tools for Windows> kd
kd> .kdfiles d:\Map_Files\mymap.ini
KD file associations loaded from 'd:\Map_Files\mymap.ini'
```

You can also use the [.kdfiles](#) command to display the current driver replacement map file or to delete the driver replacement map. If you do not use this command, the map persists until you exit the debugger.

After you complete this procedure, the driver replacement map takes effect.

Whenever the target computer is about to load a driver, it queries the kernel debugger to determine whether this driver has been mapped. If the driver has been mapped, the replacement file is sent over the kernel connection

and copied over the old driver file. The new driver is then loaded.

Driver Replacement Map File Format

Each driver file replacement is indicated by three lines in the driver replacement map file.

- The first line consists of the word "map".
- The second line specifies the path and file name of the old driver on the target computer.
- The third line specifies the full path of the new driver. This driver can be located on the host computer or on some other server.

You can repeat this pattern of information any number of times.

Paths and file names are case insensitive, and the actual driver file names can be different. The file that you specify on the third line is copied over the file that you specify on the second line when the target computer is about to load that driver.

Kdfiles will attempt to match the file name that is stored in the Service Control Manager (SCM) database. The name in the SCM database is identical to the name that was passed to MmLoadSystemImage.

In Windows 10 and later versions of the debugging tools, driver mapping works to match the driver name dynamically and determine the proper path. The full path does not need to be specified and the file extension is optional. You can use any of these entries to match the NT file system driver.

- ntfs
- NTFS
- ntfs.sys
- windows\system32\drivers\ntfs.sys

You can use any of these entries to match the NT kernel driver.

- ntoskrnl
- NTOSKRNL
- ntoskrnl.sys
- windows\system32\drivers\ntoskrnl.sys

The map file can include blank lines and can include comment lines that begin with a number sign (#). However, after "map" appears in the file, the next two lines must be the old driver and the new driver. The blank lines and comment lines cannot break up the three-line map blocks.

The following example shows a driver replacement map file.

```
map
\Systemroot\system32\drivers\videoprt.sys
e:\MyNewDriver\binaries\videoprt.sys
map
\Systemroot\system32\mydriver.sys
\\myserver\myshare\new_drivers\mydriver0031.sys

# Here is a comment
map
\??\c:\windows\system32\beep.sys
\\myserver\myshare\new_drivers\new_beep.sys
```

The driver replacement map file must be a text file, but you can use any file name and file name extension (.ini, .txt, .map, and so on).

Additional Notes

When driver substitution occurs, a message appears in the kernel debugger.

If you use **CTRL+D** (in KD) or CTRL+ALT+D (in WinDbg), you see verbose information about the replacement request. This information can be useful if you are not sure whether the name that you have listed matches the one in the SCM database.

You can enable the bcdedit bootdebug option to view early boot information that is useful for replacing the kernel, the hal, or boot drivers.

```
bcddedit -bootdebug on
```

For more information, see [BCDEdit Options Reference](#).

If the kernel debugger exits, no more driver replacement occurs. However, any drivers that have already been replaced do not revert to their old binaries, because the driver files are actually overwritten.

This driver replacement feature automatically bypasses Windows File Protection (WFP).

You do not have to restart the target computer. Driver replacement occurs any time that the target computer loads a driver, regardless of whether it has been restarted. Of course, most drivers are loaded during the boot process, so in practice you should restart the target computer after the map file has been loaded.

If the `_NT_KD_FILES` variable is defined, the specified driver replacement map file is read when the kernel debugger is started. If you issue the `.kdfiles` command, the specified file is read immediately. At this point, the debugger verifies that the file has the basic map/line/line format. But the actual paths and file names are not verified until substitution occurs.

After the map file has been read, the debugger stores its contents. If you change this file after this point, the changes have no effect (unless you reissue the `.kdfiles` command).

Replacing Boot Drivers

If you want to replace a boot driver file by using this driver replacement method, you must connect the kernel debugger to the Windows boot loader (Ntldr), not to the Windows kernel. Before you can make this connection, you must install a special debugger-enabled version of Ntldr. You can find this version of Ntldr in the Windows Driver Kit (WDK), in the `%DDKROOT%\debug` directory.

Because the target computer bypasses its Boot.ini file, you cannot set the kernel connection protocol in the typical manner. You must make the connection through the COM1 port on the target computer. The baud rate is 115200. Therefore, the kernel debugger on the host computer should be configured to use a COM connection at the 115200 speed.

This special method applies only to boot drivers (that is, Acpi.sys, Classpnp.sys, Disk.sys, and anything else that `lm tn` displays at the initial Windows breakpoint). If you have to replace a standard driver that **MmLoadSystemImage** loads after the boot has been completed, you should use the standard method described earlier.

You cannot replace boot drivers on a computer that uses EFI firmware instead of the Boot.ini file.

Messages from the Target

5/26/2017 • 1 min to read • [Edit Online](#)

A target application or target computer can send messages to the debugger or break into the debugger, either conditionally or unconditionally, by using a variety of routines. A kernel-mode target can also test whether a debugger is currently attached.

This section includes:

- [Breaking Into the Debugger](#)
- [Sending Output to the Debugger](#)
- [Reading and Filtering Debugging Messages](#)
- [Determining if a Debugger is Attached](#)

[Send comments about this topic to Microsoft](#)

Breaking Into the Debugger

5/26/2017 • 2 min to read • [Edit Online](#)

User-mode and kernel-mode code use different routines to break into the debugger.

User-Mode Break Routines

A break routine causes an exception to occur in the current process, so that the calling thread can signal the debugger associated with the calling process.

To break into a debugger from a user-mode program, use the **DebugBreak** routine. For complete documentation of this routine, see the Microsoft Windows SDK.

When a user-mode program calls **DebugBreak**, the following possible actions will occur:

1. If a user-mode debugger is attached, the program will break into the debugger. This means that the program will pause and the debugger will become active.
2. If no user-mode debugger is attached, but kernel-mode debugging was enabled at boot time, the entire computer will break into the kernel debugger. If no kernel debugger is attached, the computer will freeze and await a kernel debugger.
3. If no user-mode debugger is attached, and kernel-mode debugging is not enabled, the program will terminate with an unhandled exception, and the post-mortem (just-in-time) debugger will be activated. For more information, see [Enabling Postmortem Debugging](#).

Kernel-Mode Break Routines

When a kernel-mode program breaks into the debugger, the entire operating system freezes until the kernel debugger allows execution to resume. If no kernel debugger is present, this is treated as a bug check.

The **DbgBreakPoint** routine works in kernel-mode code, but is otherwise similar to the **DebugBreak** user-mode routine.

DbgBreakPointWithStatus also causes a break, but it additionally sends a 32-bit status code to the debugger.

KdBreakPoint and **KdBreakPointWithStatus** are identical to **DbgBreakPoint** and **DbgBreakPointWithStatus**, respectively, when compiled in the checked build environment. When compiled in the free build environment, they have no effect.

For complete documentation of these routines, as well as the build environment, see the Windows Driver Kit.

Kernel-Mode Conditional Break Routines

Two conditional break routines are available for kernel-mode code. These routines test a logical expression. If the expression is false, execution halts and the debugger becomes active.

The **ASSERT** macro causes the debugger to display the failed expression and its location in the program. The **ASSERTMSG** macro is similar, but allows an additional message to be sent to the debugger.

ASSERT and **ASSERTMSG** are only active when compiled in the checked build environment. When compiled in the free build environment, they have no effect.

For complete documentation of these routines, as well as the build environment, see the Windows Driver Kit.

[Send comments about this topic to Microsoft](#)

Sending Output to the Debugger

5/26/2017 • 1 min to read • [Edit Online](#)

User-mode and kernel-mode code use different routines to send output to the debugger.

User-Mode Output Routines

OutputDebugString sends a null-terminated string to the debugger of the calling process. In a user-mode driver, **OutputDebugString** displays the string in the Debugger Command window. If a debugger is not running, this routine has no effect. **OutputDebugString** does not support the variable arguments of a **printf** formatted string.

For complete documentation of this routine, see the Microsoft Windows SDK.

Kernel-Mode Output Routines

DbgPrint displays output in the debugger window. This routine supports the basic **printf** format parameters. Only kernel-mode code can call **DbgPrint**.

DbgPrintEx is similar to **DbgPrint**, but it allows you to "tag" your messages. When running the debugger, you can permit only those messages with certain tags to be sent. This allows you to view only those messages that you are interested in. For details, see [Reading and Filtering Debugging Messages](#).

Note In Windows Vista and later versions of Windows, **DbgPrint** produces tagged messages as well. This is a change from previous versions of Windows.

KdPrint and **KdPrintEx** are identical to **DbgPrint** and **DbgPrintEx**, respectively, when compiled in the checked build environment. When compiled in the free build environment, they have no effect.

For complete documentation of these routines, as well as the build environment, see the Windows Driver Kit.

[Send comments about this topic to Microsoft](#)

Reading and Filtering Debugging Messages

5/31/2017 • 10 min to read • [Edit Online](#)

Kernel-mode code can use the **DbgPrintEx** and **KdPrintEx** routines to send messages to the kernel debugger that are only transmitted under certain conditions. This allows you to filter out messages that you are not interested in.

Note In Windows Server 2003 and earlier versions of Windows, **DbgPrint** and **KdPrint** send messages to the kernel debugger unconditionally. In Windows Vista and later versions of Windows, these routines send messages conditionally, like **DbgPrintEx** and **KdPrintEx**. Whichever version of Windows you are using, it is recommended that you use **DbgPrintEx** and **KdPrintEx**, since these allow you to control the conditions under which the message will be sent.

For complete documentation of these routines, see the Windows Driver Kit.

The basic procedure is as follows:

To filter debugging messages

1. For each message you wish to send to the debugger, use the function **DbgPrintEx** or **KdPrintEx** in your driver's code. Pass the appropriate component name to the *ComponentId* parameter, and pass a value to the *Level* parameter that reflects the severity or nature of this message. The message itself is passed to the *Format* and *arguments* parameters as with **printf**.
2. Set the value of the appropriate *component filter mask*. Each component has a different mask; the mask value indicates which of that component's messages will be displayed. The component filter mask may be set in the registry using a registry editor, or in memory using a kernel debugger.
3. Attach a kernel debugger to the computer. Each time your driver passes a message to **DbgPrintEx** or **KdPrintEx**, the values passed to *ComponentId* and *Level* will be compared with the value of the corresponding component filter mask. If these values satisfy certain criteria, the message will be sent to the kernel debugger and displayed. Otherwise, no message will be sent.

Full details follow. All references on this page to **DbgPrintEx** apply equally to **KdPrintEx**.

Identifying the Component Name

Each component has a separate filter mask. This allows the debugger to configure the filter for each component separately.

Each component is referred to in different ways, depending on the context. In the *ComponentId* parameter of **DbgPrintEx**, the component name is prefixed with "DPFLTR_" and suffixed with "_ID". In the registry, the component filter mask has the same name as the component itself. In the debugger, the component filter mask is prefixed with "Kd_" and suffixed with "_Mask".

There is a complete list of all component names (in DPFLTR_XXXX_ID format) in the Microsoft Windows Driver Kit (WDK) header ntddk.h and the Windows SDK header ntrtl.h. Most of these component names are reserved for Windows and for drivers written by Microsoft.

There are six component names reserved for independent hardware vendors. To avoid mixing your driver's output with the output of Windows components, you should use one of the following component names:

COMPONENT NAME	DRIVER TYPE
IHVVIDEO	Video driver
IHVAUDIO	Audio driver
IHVNETWORK	Network driver
IHVSTREAMING	Kernel streaming driver
IHVBUS	Bus driver
IHVDRIVER	Any other type of driver

For example, if you are writing a video driver, you would use DPFLTR_IHVVIDEO_ID as the *ComponentId* parameter of **DbgPrintEx**, use the value name **IHVVIDEO** in the registry, and refer to **Kd_IHVVIDEO_Mask** in the debugger.

In Windows Vista and later versions of Windows, all messages sent by **DbgPrint** and **KdPrint** are associated with the **DEFAULT** component.

Choosing the Correct Level

The *Level* parameter of the **DbgPrintEx** routine is of type **DWORD**. It is used to determine the *importance bit field*. The connection between the *Level* parameter and this bit field depends on the size of *Level*:

- If *Level* is equal to a number between 0 and 31, inclusive, it is interpreted as a bit shift. The importance bit field is set to the value $1 << Level$. Thus choosing a value between 0 and 31 for *Level* results in a bit field with exactly one bit set. If *Level* is 0, the bit field is equivalent to 0x00000001; if *Level* is 31, the bit field is equivalent to 0x80000000.
- If *Level* is a number between 32 and 0xFFFFFFFF inclusive, the importance bit field is set to the value of *Level* itself.

Thus, if you wish to set the bit field to 0x00004000, you can specify *Level* as 0x00004000 or simply as 14. Note that certain bit field values are not possible by this system -- including a bit field which is entirely zero.

The following constants can be useful for setting the value of *Level*. They are defined in the Microsoft Windows Driver Kit (WDK) header ntddk.h and the Windows SDK header ntrtl.h:

```
#define DPFLTR_ERROR_LEVEL 0
#define DPFLTR_WARNING_LEVEL 1
#define DPFLTR_TRACE_LEVEL 2
#define DPFLTR_INFO_LEVEL 3
#define DPFLTR_MASK 0x80000000
```

One easy way to use the *Level* parameter is to always use values between 0 and 31 -- using the bits 0, 1, 2, 3 with the meaning given by DPFLTR_XXXX_LEVEL, and using the other bits to mean whatever you choose.

Another easy way to use the *Level* parameter is to always use explicit bit fields. If you choose this method, you may wish to OR the value DPFLTR_MASK with your bit field; this assures that you will not accidentally use a value less than 32.

To make your driver compatible with the way Windows uses message levels, you should only set the lowest bit (0x1) of the importance bit field if a serious error occurs. If you are using *Level* values less than 32, this corresponds to DPFLTR_ERROR_LEVEL. If this bit is set, your message is going to be viewed any time someone attaches a kernel debugger to a computer on which your driver is running.

The warning, trace, and information levels should be used in the appropriate situations. Other bits can be freely used for any purposes that you find useful. This allows you to have a wide variety of message types that can be selectively seen or hidden.

In Windows Vista and later versions of Windows, all messages sent by **DbgPrint** and **KdPrint** behave like **DbgPrintEx** and **KdPrintEx** messages with *Level* equal to DPFLTR_INFO_LEVEL. In other words, these messages have the third bit of their importance bit field set.

Setting the Component Filter Mask

There are two ways to set a component filter mask:

- The component filter mask can be accessed in the registry key **HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager\Debug Print Filter**. Using a registry editor, create or open this key. Under this key, create a value with the name of the desired component, in uppercase. Set it equal to the DWORD value that you wish to use as the component filter mask.
- If a kernel debugger is active, it can access the component filter mask value by dereferencing the address stored in the symbol **Kd_XXXX_Mask**, where XXXX is the desired component name. You can display the value of this mask in WinDbg or KD with the **dd (Display DWORD)** command, or enter a new component filter mask with the **ed (Enter DWORD)** command. If there is a danger of symbol ambiguity, you may wish to specify this symbol as **nt!Kd_XXXX_Mask**.

Filter masks stored in the registry take effect during boot. Filter masks created by the debugger take effect immediately, and persist until Windows is rebooted. A value set in the registry can be overridden by the debugger, but the component filter mask will return to the value specified in the registry if the system is rebooted.

There is also a system-wide mask called **WIN2000**. This is equal to 0x1 by default, though it can be changed through the registry or the debugger like all other components. When filtering is performed, each component filter mask is first ORed with the **WIN2000** mask. In particular, this means that components whose masks have never been specified default to 0x1.

Criteria for Displaying the Message

When **DbgPrintEx** is called in kernel-mode code, Windows compares the message importance bit field specified by *Level* with the filter mask of the component specified by *ComponentId*.

Note Recall that when the *Level* parameter is between 0 and 31, the importance bit field is equal to $1 << Level$, but when the *Level* parameter is 32 or higher, the importance bit field is simply equal to *Level*.

Windows performs an AND operation on the importance bit field and the component filter mask. If the result is nonzero, the message is sent to the debugger.

Example

Here is an example.

Suppose that before the last boot, you created the following values in the **Debug Print Filter** key:

- **IHVVIDEO**, with a value equal to DWORD 0x2
- **IHVBUS**, equal to DWORD 0x7FF

Now you issue the following commands in the kernel debugger:

```
kd> ed Kd_IHVVVIDEO_Mask 0x8
kd> ed Kd_IHVAUDIO_Mask 0x7
```

At this point, the **IHVVIDEO** component has a filter mask of 0x8, the **IHVAUDIO** component has a filter mask of 0x7, and the **IHVBUS** component has a filter mask of 0x7FF.

However, because these masks are automatically ORed with the **WIN2000** system-wide mask (which is usually equal to 0x1), the **IHVVIDEO** mask is effectively equal to 0x9. Indeed, components whose filter masks have not been set at all (for instance, **IHVSTREAMING** or **DEFAULT**) will have a filter mask of 0x1.

Now suppose that the following function calls occur in various drivers:

```
DbgPrintEx( DPFLTR_IHVVIDEO_ID, DPFLTR_INFO_LEVEL, "First message.\n");
DbgPrintEx( DPFLTR_IHVAUDIO_ID, 7, "Second message.\n");
DbgPrintEx( DPFLTR_IHVBUS_ID, DPFLTR_MASK | 0x10, "Third message.\n");
DbgPrint( "Fourth message.\n");
```

The first message has its *Level* parameter equal to DPFLTR_INFO_LEVEL, which is 3. Since this is less than 32, it is treated as a bit shift, resulting in an importance bit field of 0x8. This value is then ANDed with the effective **IHVVIDEO** component filter mask of 0x9, giving a nonzero result. So the first message is transmitted to the debugger.

The second message has its *Level* parameter equal to 7. Again, this is treated as a bit shift, resulting in an importance bit field of 0x80. This is then ANDed with the **IHVAUDIO** component filter mask of 0x7, giving a result of zero. So the second message is not transmitted.

The third message has its *Level* parameter equal to DPFLTR_MASK | 0x10. This is greater than 31, and therefore the importance bit field is set equal to the value of *Level* -- in other words, to 0x80000010. This is then ANDed with the **IHVBUS** component filter mask of 0x7FF, giving a nonzero result. So the third message is transmitted to the debugger.

The fourth message was passed to **DbgPrint** instead of **DbgPrintEx**. In Windows Server 2003 and earlier versions of Windows, messages passed to this routine are always transmitted. In Windows Vista and later versions of Windows, messages passed to this routine are always given a default filter. The importance bit field is equal to 1 << DPFLTR_INFO_LEVEL, which is 0x00000008. The component for this routine is **DEFAULT**. Since you have not set the **DEFAULT** component filter mask, it has a value of 0x1. When this is ANDed with the importance bit field, the result is zero. So the fourth message is not transmitted.

The DbgPrint Buffer

When **DbgPrint**, **DbgPrintEx**, **KdPrint**, or **KdPrintEx** transmits a message to the debugger, the formatted string is sent to the *DbgPrint buffer*. In most cases, the contents of this buffer are displayed immediately in the Debugger Command window. This display can be disabled by using the **Buffer DbgPrint Output** option of the Global Flags Utility (gflags.exe). This display does not automatically appear during local kernel debugging.

During local kernel debugging, and any other time this display has been disabled, the contents of the DbgPrint buffer can only be viewed by using the **!dbgprint** extension command.

Any single call to **DbgPrint**, **DbgPrintEx**, **KdPrint**, or **KdPrintEx** will only transmit 512 bytes of information. Any output longer than this will be lost. The DbgPrint buffer itself can hold up to 4 KB of data on a free build of Windows, and up to 32 KB of data on a checked build of Windows. On Windows Server 2003 and later versions of Windows, you can use the KDbgCtrl tool to alter the size of the DbgPrint buffer. See [Using KDbgCtrl](#) for details.

If a message is filtered out because of its *ComponentId* and *Level* values, it is not transmitted across the debugging connection. Therefore there is no way to display this message in the debugger.

Determining if a Debugger is Attached

5/26/2017 • 1 min to read • [Edit Online](#)

Kernel-mode code can determine the status of kernel debugging by using the following variables and routines:

- (Windows XP and later) The `KD_DEBUGGER_ENABLED` global kernel variable indicates whether kernel debugging is enabled.
- (Windows XP and later) The `KD_DEBUGGER_NOT_PRESENT` global kernel variable indicates whether a kernel debugger is currently attached.
- (Windows Server 2003 and later) The **`KdRefreshDebuggerNotPresent`** routine refreshes the value of `KD_DEBUGGER_NOT_PRESENT`.

For complete documentation, see the Windows Driver Kit.

Kernel-Mode Driver Framework Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

Debugging extensions for Kernel-Mode Driver Framework (KMDF) are contained in the Wdfkd.dll extension library.

You can use the extension commands that the Wdfkd.dll extension library contains to debug drivers that use KMDF.

For a description of the extension commands in Wdfkd.dll, see [Kernel-Mode Driver Framework Extensions \(Wdfkd.dll\)](#).

These extensions can be used on Microsoft Windows XP and later operating systems. Some extensions have additional restrictions; these restrictions are noted on the individual reference pages.

Note When you create a new KMDF or UMDF driver, you must select a driver name that has 32 characters or less. This length limit is defined in wdfglobals.h. If your driver name exceeds the maximum length, your driver will fail to load.

To use this extension library, you must load the library into your debugger. For information about how to load extension libraries into a debugger, see [Loading Debugger Extension DLLs](#).

[Send comments about this topic to Microsoft](#)

User-Mode Driver Framework Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

For an overview of how to debug User-Mode Driver Framework (UMDF) drivers, including information on how to start this kind of debugging session, see the [Debugging UMDF Drivers](#) section of the Windows Driver Kit (WDK) documentation.

UMDF Debugging Extensions

User-Mode Driver Framework (UMDF) debugging extensions are implemented in the extension module Wudfext.dll. You can use these extensions to debug drivers that use UMDF.

For a complete description of the extension commands in Wudfext.dll, see [User-Mode Driver Framework Extensions \(Wudfext.dll\)](#).

These extensions can be used on Microsoft Windows XP and later operating systems. Some extensions have additional restrictions on the Windows version or UMDF version that is required; these restrictions are noted on the individual reference pages.

Note When you create a new KMDF or UMDF driver, you must select a driver name that has 32 characters or less. This length limit is defined in wdfglobals.h. If your driver name exceeds the maximum length, your driver will fail to load.

To use this extension library, you must load the library into your debugger. For information about how to load extension libraries into a debugger, see [Loading Debugger Extension DLLs](#).

Debugging a User-Mode Failure with KD

5/26/2017 • 1 min to read • [Edit Online](#)

To properly debug user-mode failures, you need CDB or WinDbg. However, sometimes a user-mode exception will break into KD because no user-mode debugger is present. There are also times when it is helpful to monitor what specific user-mode processes are doing while debugging a kernel-mode problem.

By default, the kernel debugger attempts to load the first user-mode symbol that matches the address specified (for a **k**, **u**, or **ln** command).

Unfortunately, user-mode symbols are often not specified in the symbol path or the first symbol is not the correct one. If the symbols are not there, either copy them into the symbol path or use a [.sympath \(Set Symbol Path\)](#) command to point to the full symbol tree, and then use the [.reload \(Reload Module\)](#) command. If the wrong symbol is loaded, you can explicitly load a symbol by doing a [.reload <binary.ext>](#).

Most of the Windows DLLs are rebased so they load at different addresses, but there are exceptions. Video adapters are the most common exceptions. There are dozens of video adapters that all load at the same base address, so KD will almost always find ati.dll (the first video symbol, alphabetically). For video, there is also a .sys file loaded that can be identified by using a [!drivers](#) extension. With that information, you can issue a [.reload](#) to get the correct video DLLs. There are also times when the debugger gets confused and reloading specific symbols will help give the correct stack. Unassemble the functions to see if the symbols look correct.

Similar to the video DLLs, almost all executables load at the same address, so KD will report access. If you see a stack trace in access, do a [!process](#) and then a [.reload](#) of the executable name given. If the executable does not have symbols in the symbol path, copy them there and do the [.reload](#) again.

Sometimes KD or WinDbg has trouble loading the correct user-mode symbols even when the full symbol tree is in the symbol path. In this case, ntdll.dll and kernel32.dll are two of the most common symbols that would be required. In the case of debugging CSRSS from KD, winsrv.dll and csrssrv.dll are also common DLLs to load.

[Send comments about this topic to Microsoft](#)

Debugging a Device Installation Co-Installer

5/26/2017 • 3 min to read • [Edit Online](#)

Some hardware device installation packages include DLL files known as *co-installers*, which assist with installing the device.

You cannot debug a co-installer in the same fashion as other modules. This is because of the unique way in which a co-installer is loaded, and because many installation scenarios occur automatically without providing the developer an opportunity to break into the running process.

You can resolve this issue by programmatically installing the device. Attaching a debugger to the application which installs the device allows access to the co-installer itself. The simplest way to accomplish this is to install or reinstall the device using the [DevCon](#) tool that is included in the Windows Driver Kit (WDK). You can then debug the co-installer with WinDbg.

Use the following procedure to accomplish this task. This procedure assumes you have developed a working driver installation package for your device which uses a co-installer. It also assumes that you have the latest copy of the WDK. For information on developing drivers, driver installation packages, and driver installation co-installers, see the WDK documentation.

Debugging a Co-installer Using DevCon and WinDbg

1. Plug in the hardware device.
2. Cancel the **New Hardware Found** wizard.
3. Start WinDbg.
4. Select **Open Executable** from WinDbg's **File** menu.
5. In the **Open Executable** dialog box, do the following:
 - a. In the file selection text box, select the DevCon tool (Devcon.exe). For this, browse to the WDK installation folder, then open the subdirectory tools, then open the subdirectory devcon, then open the subdirectory that matches the processor architecture of your machine, and then select Devcon.exe. Click only once on Devcon.exe and do not yet press **Open**.
 - b. In the **Arguments** text box, enter the following text, where *INFFile* is the filename of your Device Installation Information (INF) file, and *HardwareID* is the hardware ID of your device:

```
update INFFile HardwareID
```
- c. In the **Start directory** text box, enter the path to your device installation package.
- d. Click **Open**.

6. The debugging process will begin, and WinDbg will break into the DevCon process before DevCon installs your driver.
7. Configure the debugger to break into the co-installer process when it is loaded. You can do this by either of the following methods:
 - In the Debugger Command window, use the **sxe (Set Exceptions)** command followed by **Id:** and then the filename of the co-installer, excluding the file extension. There should be no space after the colon. For example, if the name of the co-installer is mycoinst.dll, you would use the following

command:

```
sxe ld:mycoinst
```

- Select **Event Filters** from WinDbg's **Debug** menu. In the **Event Filters** dialog box, select **Load module**. Under **Execution**, select **Enabled**. Under **Continue**, select **Not Handled**. Click the **Argument** button, and then in the text box enter the filename of the co-installer, excluding the file extension (for example, enter "mycoinst" for mycoinst.dll). Click **OK** and then click **Close**.
8. Resume execution by pressing F5 or entering the **g (Go)** command in the Debugger Command window.
 9. When the co-installer is loaded, execution will break back into the debugger. At this point, you can set any additional breakpoints that you need.

Limitations of This Procedure

In certain cases, running a device installation package under DevCon may result in slightly different behavior than that of a PnP installation, because of different security tokens and the like. If you are trying to debug a specific problem in your co-installer, it is possible that this problem will not replicate if DevCon is involved. Therefore, before using this technique, you should use DevCon to install your driver without a debugger attached to verify that this problem exists in both the PnP and the DevCon scenarios.

If the problem vanishes whenever DevCon initiates the installation, then you will have to debug your co-installer without using DevCon. One way of doing this is to use the [TList](#) tool with the **/m** option to determine which process is loading the co-installer module, and then attaching the debugger to that process.

Debugging a Dual-Boot Machine

5/26/2017 • 1 min to read • [Edit Online](#)

How should you respond when the alternate operating system does not start on a dual-boot machine?

First, check that the boot options point to the correct path for the other operating system. See [Getting Set Up for Debugging](#) for details.

On an x86 computer, you should also verify that boosect.ini exists. This file contains the boot record for the other operating system. To unhide this file, use the **attrib -r -s -h boosect.ini** command.

Debugging CSRSS

5/31/2017 • 1 min to read • [Edit Online](#)

The Client Server Run-Time Subsystem (CSRSS) is the user-mode process that controls the underlying layer for the Windows environment. There are a number of problems that make it necessary to debug CSRSS itself.

Debugging CSRSS is also useful when the Windows subsystem terminates unexpectedly with a **Bug Check 0xC000021A** (STATUS_SYSTEM_PROCESS_TERMINATED). In this case, debugging CSRSS will catch the failure before it gets to an "unexpected" point.

Controlling NTSD from the Kernel Debugger

The easiest way to debug CSRSS is to use NTSD and [control it from the kernel debugger](#).

Enabling CSRSS Debugging

CSRSS debugging must be enabled before you can proceed. If the target computer is running a *checked build* of Windows, CSRSS debugging is always enabled. If the target computer is running a *free build* of Windows, you will have to enable CSRSS debugging through the Global Flags Utility (GFlags).

To do this, start the GFlags utility, select the **System Registry** radio button, and select **Enable debugging of Win32 subsystem**.

Alternatively, you can use the following GFlags command-line:

```
gflags /r +20000
```

Or, if you prefer, you can edit the registry key manually instead of using GFlags. Open the following registry key:

```
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control\Session Manager
```

Edit the **GlobalFlag** value entry (of type REG_DWORD) and set the bit 0x00020000.

After using GFlags or manually editing the registry, you must reboot for the changes to take effect.

Starting NTSD

Because you will be controlling the user-mode debugger from the kernel debugger, you will need to set up a kernel debugging connection. See [Getting Set Up for Debugging](#) for details.

After the registry has been properly configured, it is a simple matter of starting NTSD as follows:

```
ntsd --
```

See [Controlling the User-Mode Debugger from the Kernel Debugger](#) for an explanation of how to proceed.

You will have to set your symbol path to a location on your host computer or to some other location on your network. When CSRSS is being debugged, network authentication on the target computer will not work properly.

Note that you may see an "in page io error" message. This is another manifestation of a hardware failure.

In Windows XP and later versions of Windows, when the debugging session ends, the debugger will detach from CSRSS while the CSRSS process is still running. This avoids termination of the CSRSS process itself.

[Send comments about this topic to Microsoft](#)

Debugging WinLogon

5/31/2017 • 1 min to read • [Edit Online](#)

WinLogon is the user-mode process that handles the task of interactive users logging on and logging off, and handles all instances of CTRL+ALT+DELETE.

Controlling NTSD from the Kernel Debugger

The easiest way to debug WinLogon is to use NTSD and [control it from the kernel debugger](#).

Enabling WinLogon Debugging

Because you will be redirecting the user-mode debugger output to the kernel debugger, you will need to set up a kernel debugging connection. See [Getting Set Up for Debugging](#).

To attach a debugger to WinLogon, you must go through the registry so the process is debugged from the time it starts up. To set up WinLogon debugging, set **HKEY_LOCAL_MACHINE\Software\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\WinLogon.EXE\Debugger** to:

```
ntsd -d -x -g
```

The **-d** option passes control to the kernel debugger. The **-x** option causes the debugger to capture access violations as second-chance exceptions. The **-g** option causes the WinLogon process to run after the attachment. Do not add the **-g** if you want to start debugging before Winlogon.exe begins (for example, if you want to set an initial breakpoint).

In addition, you should set the GlobalFlag value under the **winlogon.exe** key to REG_DWORD "0x000400F0". This sets heap checking and FLG_ENABLE_KDEBUG_SYMBOL_LOAD. However, since this second flag only affects the kernel debugger, symbols must also be copied to the target computer before starting the debugger.

The registry change requires a reboot to take effect.

Performing the Debugging

After the next reboot, the debugger will break into WinLogon automatically.

See [Controlling the User-Mode Debugger from the Kernel Debugger](#) for an explanation of how to proceed.

You will have to set your symbol path to a location on your host computer or to some other location on your network. When WinLogon is being debugged, network authentication on the target computer will not work properly.

[Send comments about this topic to Microsoft](#)

Debugging BIOS Code

5/26/2017 • 1 min to read • [Edit Online](#)

BIOS code is not built from standard assembly code, so it requires different debugging techniques.

On an x86-based processor, the BIOS uses 16-bit code. To disassemble this code, use the **ux (Unassemble x86 BIOS)** command. To display information about the Intel Multiprocessor Specification (MPS), use the **!mps** extension.

If you are debugging ACPI BIOS code, the preceding commands do not work, because ACPI BIOS is written in ACPI Machine Language (AML). To disassemble this code, you should use **!aml u**. For more information about this kind of debugging, see [ACPI Debugging](#).

[Send comments about this topic to Microsoft](#)

Specifying Module and Function Owners

5/31/2017 • 4 min to read • [Edit Online](#)

The **!analyze** and **!owner** extensions use a file that is named Triage.ini to determine the owner of the symbols that the debugger encounters.

When you use these extensions, the identities of the function or module owner are displayed after the word "Followup".

The Triage.ini file is a text file that resides in the \triage subdirectory of your Debugging Tools for Windows installation. A sample Triage.ini file is included as part of the Debugging Tools for Windows package.

Warning If you install an updated version of Debugging Tools for Windows in the same directory as the current version, it overwrites all of the files in that directory, including Triage.ini. After you modify or replace the sample Triage.ini file, save a copy of it to a different directory. After you reinstall the debuggers, you can copy the saved Triage.ini over the default version.

Format of the Triage.ini File

Although the Triage.ini file is intended to help you determine the owner of a function that has broken into the debugger, the "owner" strings in this file can be anything that might help you with debugging. The strings can be names of people who wrote or maintain the code. Or, the strings can be short instructions about what you can do when an error occurs in a module or function.

Each line in this file has the following syntax.

```
Module[!Function]=Owner
```

You can add an asterisk (*) only at the end of a module or function name. If it appears elsewhere, it is interpreted as a literal character.

You cannot add spaces in the owner string. If spaces do exist in the owner string, they are ignored.

For more information about syntax options, see [Special Triage.ini Syntax](#).

The following examples shows a sample Triage.ini file.

```
module1=Person1
module2!functionA=Person2
module2!functionB=Person3
module2!funct*=Person4
module2!=Person5
module3!singleFunction=Person6
mod*!functionC=Person7
```

Triage.ini and !owner

When you pass a module or function name to the **!owner** extension, the debugger displays the word "Followup" followed by the name of the module or function's owner.

The following example uses the previous sample Triage.ini file.

```
0:000> !owner module2!functionB
Followup: Person3
```

According to the file, "Person3" owns **module2!functionB**, and "Person4" owns **module2!functionC**. Both of these strings match the argument that is passed to `**!owner*`, so the more complete match is used.

Triage.ini and !analyze

When you use the **!analyze** extension, the debugger looks at the top faulting frame in the stack and tries to determine the owner of the module and function in this frame. If the debugger can determine the owner, the owner information is displayed.

If the debugger cannot determine the owner, the debugger passes to the next stack frame, and so on, until the debugger determines the owner or the stack is completely examined.

If the debugger can determine the owner, the owner name is displayed after the word "Followup". If the debugger searches the whole stack without finding any information, no name is displayed.

The following example uses the sample Triage.ini file that is given earlier in this topic.

Suppose the first frame on the stack is **MyModule!someFunction**. The debugger does not find **MyModule** in the Triage.ini file. Next, it continues to the second frame on the stack.

Suppose the second frame is **module3!anotherFunction**. The debugger does see an entry for **module3**, but there is no match for **anotherFunction** in this module. Next, the debugger continues to the third frame.

Suppose the third frame is **module2!functionC**. The debugger first looks for an exact match, but such a match does not exist. The debugger then trims the function name and discovers **module2!funct*** in Triage.ini. This match ends the search, because the debugger determines that the owner is "Person4".

The debugger then displays output that is similar to the following example.

```
0:000> !analyze
*****
*                                     *
*             Exception Analysis      *
*                                     *
*****
Use !analyze -v to get detailed debugging information.

Probably caused by : module2 ( module2!functionC+15a )

Followup: Person4
-----
```

A more complete match takes precedence over a shorter match. However, a module name match is always preferred to a function name match. If **module2!funct*** had not been in this Triage.ini file, the debugger would have selected **module2!*** as the match. And if both **module2!funct*** and **module2!*** were removed, **mod*!functionC** would have been selected.

Special Triage.ini Syntax

If you omit the exclamation point and function name or add `!*` after a module name, all functions in that module are indicated. If a function within this module is also specified separately, the more precise specification takes precedence.

If you use "default" as a module name or a function name, it is equivalent to a wildcard character. For example, **nt!*** is the same as **nt!default**, and **default** is the same as ***!***.

If a match is made, but the word **ignore** appears to the right of the equal sign (=), the debugger continues to the next frame in the stack.

You can add **last_** or **maybe_** before an owner's name. This prefix gives the owner less priority when you run

!analyze. The debugger chooses a definite match that is lower on the stack over a **maybe_** match that is higher on the stack. The debugger also chooses a **maybe_** match that is lower on the stack over a **last_** match that is higher on the stack.

Sample Triage.ini

A sample Triage.ini template is included in the Debugging Tools for Windows package. You can add the owners of any modules and functions that you want to this file. If you want to have no global default, delete the **default=MachineOwner** line at the beginning of this file.

Overview of RPC Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

Microsoft Remote Procedure Call (RPC) makes it easy to cross process and machine boundaries and carry data around. This network programming standard is one reason that networking with Microsoft Windows is so powerful.

However, because RPC hides network calls from individual processes, it obscures the details of the interactions between the computers. This can make it hard to be sure why threads are doing what they are doing -- or fail to do what they are supposed to do. As a result, debugging and troubleshooting RPC errors can be difficult. In addition, the vast majority of problems that appear to be RPC errors are actually configuration issues, or network connectivity issues, or other component issues.

Debugging Tools for Windows contains a tool called DbgRpc, as well as RPC-related debugger extensions. These can be used to analyze a variety of RPC problems on Windows XP and later versions of Windows.

These Windows versions can be configured to save RPC run-time state information. Different amounts of state information can be saved; this allows you to obtain the information you need without placing a significant burden on your computer. See [Enabling RPC State Information](#) for details.

This information can then be accessed through either the debugger or the DbgRpc tool. In each case, a collection of queries is available. See [Displaying RPC State Information](#) for details.

In many cases, you can troubleshoot a problem by using the techniques outlined in [Common RPC Debugging Techniques](#).

If you want to explore the mechanics of how this information is stored, or if you want to devise your own techniques for state information analysis, see [RPC State Information Internals](#).

These tools and techniques do not work on Windows 2000.

Enabling RPC State Information

5/26/2017 • 2 min to read • [Edit Online](#)

Two different levels of RPC run-time state information can be gathered: **Server** information and **Full** information. This information gathering must be enabled before the debugger or DbgRpc can be used to analyze state information.

Only Windows XP and later versions of Windows support the gathering of RPC state information.

Gathering **Server** state information is very lightweight. It costs about 100 machine instructions per RPC call, resulting in no detectable load, even during performance tests. However, gathering this information does use memory (about 4KB per RPC server), so it is not recommended on a machine that is already experiencing memory pressure. **Server** information includes data about endpoints, threads, connection objects, and Server Call (SCALL) objects. This is sufficient to debug most RPC problems.

Gathering **Full** state information is more heavyweight. It includes all the information gathered at the **Server** level and, in addition, includes Client Call (CCALL) objects. **Full** state information is usually not needed.

To enable state information to be gathered on an individual machine, run the Group Policy Editor (Gpedit.msc). Under the Local Computer Policy, navigate to **Computer Configuration/Administrative Templates/System/Remote Procedure Call**. Under this node you will see the **RPC Troubleshooting State Information** item. When you edit its properties, you will see five possible states:

None

No state information will be maintained. Unless your machine is experiencing memory pressure, this is not recommended.

Server

Server state information will be gathered. This is the recommended setting on a single computer.

Full

Full state information will be gathered.

Auto1

On a computer with less than 64 MB of RAM, this is the same as **None**. On a computer with at least 64 MB of RAM, this is the same as **Server**.

Auto2

On a computer running Windows Server 2003 with less than 128 MB of RAM, or on any Windows XP computer, this is the same as **None**. On a Windows Server 2003 computer with at least 128 MB RAM, this is the same as **Server**.

This is the default.

If you want to simultaneously set these levels on a set of networked computers, use the Group Policy Editor to roll out a machine policy to the preferred set of machines. The policy engine will take care that the settings you want are propagated to the preferred set of machines. The **Auto1** and **Auto2** levels are especially useful in this case, because the operating system and amount of RAM on each computer may vary.

If the network includes computers running versions of Windows that are earlier than Windows XP, the settings will be ignored on those machines.

Displaying RPC State Information

5/26/2017 • 1 min to read • [Edit Online](#)

All RPC run-time state information is contained in cells. A cell is the smallest unit of information that can be viewed and updated individually. Both the DbgRpc tool and the RPC debugger extensions allow you to view the contents of any given cell or to run high-level queries.

Each key object in the RPC Run-Time will maintain one or more cells of information about its state. Each cell has a cell ID. When an object refers to another object, it does so by specifying that object's cell ID.

The key objects that the RPC Run-Time can maintain information about are endpoints, threads, connection objects, Server Call (SCALL) objects, and Client Call (CCALL) objects. Server Call objects are usually referred to simply as *call objects*.

The RPC state information queries produce the same information whether you are using the DbgRpc tool or the RPC debugger extensions. The following sections describe how queries are used in each vehicle:

[Using the RPC Debugger Extensions](#)

[Using the DbgRpc Tool](#)

The most basic query simply displays an individual cell:

[Get RPC Cell Information](#)

The following high-level queries are also available:

[Get RPC Endpoint Information](#)

[Get RPC Thread Information](#)

[Get RPC Call Information](#)

[Get RPC Client Call Information](#)

[Send comments about this topic to Microsoft](#)

Using the RPC Debugger Extensions

5/26/2017 • 1 min to read • [Edit Online](#)

A variety of RPC debugger extensions are exported from Rpcexts.dll.

The RPC extensions used to display RPC state information will only run in user mode. They can be used from CDB (or NTSD) or from user-mode WinDbg.

The user-mode debugger must have a target application, but the target is irrelevant to the RPC extensions. If the debugger is not already running, you can simply start it with an uninteresting target (for example, **windbg notepad** or **cdb winmine**). Then, use **CTRL+C** in CDB or **Debug | Break** in WinDbg to stop the target and access the Debugger Command window.

If you need to analyze RPC state information from a remote computer, you should start the user-mode debugger on the computer that needs to be analyzed, and then use [Remote Debugging](#).

Accessing RPC state information through the debugger is especially useful in stress environments, or when a debugger already happens to be running.

[Send comments about this topic to Microsoft](#)

Using the DbgRpc Tool

5/26/2017 • 1 min to read • [Edit Online](#)

The DbgRpc tool (DbgRPC.exe) is located in the root directory of the Debugging Tools for Windows installation and must be started in a Command Prompt window. Double-clicking the icon will not start this tool.

The Command Prompt window must be running under an account with administrative privileges on the local computer, or with domain administrative privileges.

DbgRpc makes no calls to any system services (such as LSASS). This makes it useful for debugging even if a system service has crashed, as long as the kernel is still running.

Using DbgRpc on a Remote Computer

DbgRpc can also be used to examine information from a remote machine. For this to work, the remote machine must be able to accept remote connections and authenticate remote users. If the remote machine's RPCSS (RPC Endpoint Mapper) service has crashed, DbgRpc will not be able to work. Administrative or domain administrative privileges on the remote machine are required.

The **-s** command-line option is used to specify the server name, and the **-p** parameter is used to specify the transport protocol. Both TCP and named pipe protocols are available. TCP is the recommended protocol; it should work in almost every situation.

Here is an example:

```
G:\>dbgRPC -s MyServer -p ncacn_ip_tcp -l -P 1e8 -L 0.1
Getting remote cell info ...
Endpoint
Status: Active
Protocol Sequence: LRPC
Endpoint name: OLE18
```

DbgRpc Command Line

For a description of the full command syntax, see [DbgRpc Command-Line Options](#).

[Send comments about this topic to Microsoft](#)

Get RPC Cell Information

5/26/2017 • 1 min to read • [Edit Online](#)

Detailed cell information is displayed by the **!rpcexts.getdbgcell** extension, or by DbgRpc when the **-I** switch is used.

The process ID of the process that contains the preferred cell must be specified, as well as the cell number.

In the following example, the process ID is 0x278, and the cell number is 0000.0002:

```
D:\wmsg>dbgrpc -l -P 278 -L 0.2
Getting cell info ...
Thread
Status: Dispatched
Thread ID: 0x1A4 (420)
Last update time (in seconds since boot):470.25 (0x1D6.19)
```

For details on the optional parameters, see [DbgRpc Command-Line Options](#).

For a similar example using the RPC debugger extensions, see [!rpcexts.getdbgcell](#).

[Send comments about this topic to Microsoft](#)

Get RPC Endpoint Information

5/26/2017 • 1 min to read • [Edit Online](#)

Endpoint information is displayed by the **!rpcexts.getendpointinfo** extension, or by DbgRpc when the **-e** switch is used.

If an endpoint number is specified, information about that endpoint is shown. If it is omitted, the endpoints for all processes on the system are displayed.

The following example displays all endpoints. This is often a useful way to obtain process IDs and cell numbers that can be used as arguments for additional commands:

```
D:\wmsg>dbgrpc -e
Searching for endpoint info ...

Get RPC Thread Information

5/26/2017 • 1 min to read • [Edit Online](#)

Thread information is displayed by the **!rpcexts.getthreadinfo** extension, or by DbgRpc when the **-t** switch is used.

The PID of a process must be specified. You may specify a thread within that process as well. If the thread is omitted, all threads within that process will be displayed.

In the following example, the process ID is 0x278 and the thread ID is omitted:

```
D:\wmsg>dbgrpc -t -P 278
Searching for thread info ...
## PID  CELL ID  ST TID      LASTTIME
-----
0278 0000.0002 01 000001a4 00072c09
0278 0000.0005 03 0000031c 00072bf5
```

For details on the optional parameters, see [DbgRpc Command-Line Options](#).

For a similar example using the RPC debugger extensions, see [!rpcexts.getthreadinfo](#).

[Send comments about this topic to Microsoft](#)

Get RPC Call Information

5/26/2017 • 2 min to read • [Edit Online](#)

Server-side call (SCALL) information is displayed by the **!rpcexts.getcallinfo** extension, or by DbgRpc when the **-c** switch is used.

Four optional parameters are permitted. Three of these -- *CallID*, *IfStart*, and *ProcNum* -- are identifying information used by RPC to keep track of its calls. The fourth parameter, *ProcessID*, is the PID of the server process that owns the call. You should supply whatever parameters you know to narrow down the search.

If no parameters are supplied, all known SCALLs in the system will be displayed. The following is an example of this long display:

```

D:\wmsg>dbgrpc -c
Searching for call info ...
## PID  CELL ID  ST PNO IFSTART  TIDNUMBER CALLFLAG CALLID  LASTTIME CONN/CLN
-----

Get RPC Client Call Information

5/26/2017 • 1 min to read • [Edit Online](#)

Client call (CCALL) call information is displayed by the **!rpcexts.getclientcallinfo** extension, or by DbgRpc when the **-a** switch is used.

Four optional parameters are permitted. Three of these -- *CallID*, *IfStart*, and *ProcNum* -- are identifying information used by RPC to keep track of its calls. The fourth parameter, *ProcessID*, is the PID of the process that owns the call. You should supply whatever parameters you know to narrow down the search.

If no parameters are supplied, all known CCALLs in the system will be displayed. The following is an example of this (potentially long) display:

```
D:\wmsg>dbgrpc -a
Searching for call info ...
## PID  CELL ID  PNO  IFSTART  TIDNUMBER CALLID  LASTTIME PS CLTNUMBER ENDPOINT
-----
0390  0000.0001  0000  19bb5061  0000.0000  00000001  00072bff  07  0000.0002  1120
```

For details on the optional parameters, see [DbgRpc Command-Line Options](#).

For a similar example using the RPC debugger extensions, see [!rpcexts.getclientcallinfo](#).

Note Information about Client Call objects is only gathered if the **Full** state information is being gathered. See [Enabling RPC State Information](#) for details.

Common RPC Debugging Techniques

5/26/2017 • 1 min to read • [Edit Online](#)

This section describes four common RPC-related problems. RPC state information can be used to troubleshoot these problems.

Either the DbgRpc tool or the RPC debugger extensions can be used in any of these four situations.

[Analyzing a Stuck Call Problem](#)

[Tracking Contention in the Server Process](#)

[Checking for Stuck Threads](#)

[Identifying the Caller From the Server Thread](#)

[Send comments about this topic to Microsoft](#)

Analyzing a Stuck Call Problem

5/26/2017 • 3 min to read • [Edit Online](#)

A common problem occurs when a process makes an RPC call, directly or indirectly, while holding a critical section or a resource. In this case, the RPC call goes to another process or machine and dispatches to the manager routine (server routine), which then hangs or takes too long. This causes the original caller to encounter a critical section time-out.

When examined through the debugger, RPC is on top of the stack of the thread owning the critical section, but it is not clear what it is waiting for.

Here is one example of such a stack. Many variations are possible.

```
0:002> ~1k

```

Here's how to troubleshoot this problem.

Troubleshooting a stuck call problem

1. Make sure the debugger is debugging the process that owns the stuck cell. (This is the process containing the client thread that is suspected of hanging in RPC.)
2. Get the stack pointer of this thread. The stack will look like the one shown in the preceding example. In this example, the stack pointer is 0x0068FBA0.
3. Get the call information for this thread. In order to do that, use the **!rpcexts.rpcreadstack** extension with the thread stack pointer as its parameter, as follows:

```
0:001> !rpcexts.rpcreadstack 68fba0
CallID: 1
IfStart: 19bb5061
ProcNum: 0
Protocol Sequence: "ncacn_ip_tcp" (Address: 00692ED8)
NetworkAddress: "" (Address: 00692F38)
Endpoint: "1120" (Address: 00693988)
```

The information displayed here will allow you to trace the call.

4. The network address is empty, which indicates the local machine. The endpoint is 1120. You need to

determine which process hosts this endpoint. This can be done by passing this endpoint number to the [!rpcexts.getendpointinfo](#) extension, as follows:

```
0:001> !rpcexts.getendpointinfo 1120
Searching for endpoint info ...
PID  CELL ID  ST PROTSEQ      ENDPOINT
-----
0278 0000.0001 01          TCP 1120
```

5. From the preceding information, you can see that process 0x278 contains this endpoint. You can determine if this process knows anything about this call by using the [!rpcexts.getcallinfo](#) extension. This extension needs four parameters: *CallID*, *IfStart*, and *ProcNum* (which were found in step 3), and the *ProcessID* of 0x278:

```
0:001> !rpcexts.getcallinfo 1 19bb5061 0 278
Searching for call info ...
PID  CELL ID  ST PNO IFSTART  TIDNUMBER CALLFLAG CALLID  LASTTIME CONN/CLN
-----
0278 0000.0004 02 000 19bb5061 0000.0002 00000001 00000001 00072c09 0000.0003
```

6. The information in step 5 is useful, but somewhat abbreviated. The cell ID is given in the second column as 0000.0004. If you pass the process ID and this cell number to the [!rpcexts.getdbgcell](#) extension, you will see a more readable display of this cell:

```
0:001> !rpcexts.getdbgcell 278 0.4
Getting cell info ...
Call
Status: Dispatched
Procedure Number: 0
Interface UUID start (first DWORD only): 19BB5061
Call ID: 0x1 (1)
Servicing thread identifier: 0x0.2
Call Flags: cached
Last update time (in seconds since boot): 470.25 (0x1D6.19)
Owning connection identifier: 0x0.3
```

This shows that the call is in state "dispatched", which means it has left the RPC Run-Time. The last update time is 470.25. You can learn the current time by using the [!rpcexts.rptime](#) extension:

```
0:001> !rpcexts.rptime
Current time is: 6003, 422
```

This shows that the last contact with this call was approximately 5533 seconds ago, which is about 92 minutes. Thus, this must be a stuck call.

7. As a last step before you attach a debugger to the server process, you can isolate the thread that should currently service the call by using the Servicing thread identifier. This is another cell number; it appeared in step 6 as "0x0.2". You can use it as follows:

```
0:001> !rpcexts.getdbgcell 278 0.2
Getting cell info ...
Thread
Status: Dispatched
Thread ID: 0x1A4 (420)
Last update time (in seconds since boot): 470.25 (0x1D6.19)
```

Now you know that you are looking for thread 0x1A4 in process 0x278.

It is possible that the thread was making another RPC call. If necessary, you can trace this call by repeating this procedure.

Note This procedure shows how to find the server thread if you know the client thread. For an example of the reverse technique, see [Identifying the Caller From the Server Thread](#).

[Send comments about this topic to Microsoft](#)

Tracking Contention in the Server Process

5/26/2017 • 1 min to read • [Edit Online](#)

In order to service incoming requests, RPC will maintain a set of worker threads. Ideally, the number of threads will be small. However, this ideal situation has only been seen in lab environments, where the server manager routines are carefully tuned. In a real situation, the number of threads will vary depending on server workload, but it can be anywhere from 1 to 50.

If the number of worker threads is above 50, you may have excessive contention in the server process. Common causes of this are indiscriminate use of the heap, memory pressure, or serializing most activities in a server through a single critical section.

To see the number of threads in a given server process, use the **!rpcexts.getthreadinfo** extension, or use DbgRpc with the **-t** switch. Supply the process ID (in the following example, 0xC4):

```
D:\wmsg>dbgrpc -t -P c4
Searching for thread info ...
## PID  CELL ID  ST TID      LASTTIME
-----
00c4 0000.0004 03 0000011c 000f164f
00c4 0000.0007 03 00000120 008a6290
00c4 0000.0015 03 0000018c 008a6236
00c4 0000.0026 03 00000264 0005c443
00c4 0000.002d 03 00000268 000265bb
00c4 0000.0030 03 0000026c 000f1d32
00c4 0000.0034 03 00000388 007251e9
```

In this case, there are only seven worker threads, which is reasonable.

If there are over 100 threads, a debugger should be attached to this process and the cause investigated.

Note Running queries such as **dbgrpc -t** remotely is expensive to the server and the network. If you use this query in a script, you should make sure this command is not run too often.

[Send comments about this topic to Microsoft](#)

Checking for Stuck Threads

5/26/2017 • 1 min to read • [Edit Online](#)

RPC needs its worker threads available in order to perform normally. A common problem is that some component in the same process will deadlock while holding one of the global critical sections (for example, loader lock or heap lock). This will cause many threads to hang -- very possibly including some RPC worker threads.

If this occurs, the RPC server will not respond to the outside world. RPC calls to it will return `RPC_S_SERVER_UNAVAILABLE` or `RPC_S_SERVER_TOO_BUSY`.

A similar problem can result if a faulty driver prevents IRPs from completing and reaching the RPC server.

If you suspect that one of these problems may be occurring, use `DbgRpc` with the `-t` switch (or use the [!rpcexts.getthreadinfo](#) extension). The process ID should be used as a parameter. In the following example, assume the process ID is `0xC4`:

```
D:\wmsg>dbgrpc -t -P c4
Searching for thread info ...
## PID  CELL ID  ST TID      LASTTIME
-----
00c4 0000.0004 03 0000011c 000f164f
00c4 0000.0007 03 00000120 008a6290
00c4 0000.0015 03 0000018c 008a6236
00c4 0000.0026 03 00000264 0005c443
00c4 0000.002d 03 00000268 000265bb
00c4 0000.0030 03 0000026c 000f1d32
00c4 0000.0034 03 00000388 007251e9
```

The `TID` column gives the thread ID for each thread. The `LASTTIME` column contains the time stamp of the last change in state for each thread.

Whenever the server receives a request, at least one thread will change state, and its time stamp will be updated. Therefore, if an RPC request is made to the server and the request fails but none of the time stamps change, this indicates that the request is not actually reaching the RPC Run-Time. You should investigate the cause of this.

[Send comments about this topic to Microsoft](#)

Identifying the Caller From the Server Thread

5/26/2017 • 2 min to read • [Edit Online](#)

It is possible to determine what made a given RPC call, even if the only information you have is the server thread that serviced the call.

This can be very useful -- for example, to find out who passed invalid parameters to an RPC call.

Depending on which protocol sequence is used by this particular call, you can get varying degrees of detail. Some protocols (such as NetBios) do not have this information at all.

Identifying the caller from the server thread

1. Start a user-mode debugger with the server thread as the target.
2. Get the process ID by using the **| (Process Status)** command:

```
0:001> |
0      id: 3d4 name: rtsvr.exe
```

3. Get the active calls in this process by using the **!rpcexts.getcallinfo** extension. (See the reference page for an explanation of the syntax.) You need to supply the process ID of 0x3D4:

```
0:001> !rpcexts.getcallinfo 0 0 FFFF 3d4
Searching for call info ...
PID  CELL ID  ST PNO IFSTART  THRDCELL  CALLFLAG CALLID  LASTTIME CONN/CLN
-----
03d4 0000.0004 02 000 19bb5061 0000.0002 00000001 00000001 00a1aced 0000.0003
```

Look for calls with status 02 or 01 (dispatched or active). In this example, the process only has one call. If there were more, you would have to use the **!rpcexts.getdbgcell** extension with the cell number in the THRDCELL column. This would allow you to examine the thread IDs so you could determine which call you were interested in.

4. After you know which call you are interested in, look at the cell number in the CONN/CLN column. This is the cell ID of the connection object. In this case, the cell number is 0000.0003. Pass this cell number and the process ID to **!rpcexts.getdbgcell**:

```
0:001> !rpcexts.getdbgcell 3d4 0.3
Getting cell info ...
Connection
Connection flags: Exclusive
Authentication Level: Default
Authentication Service: None
Last Transmit Fragment Size: 24 (0x6F56D)
Endpoint for the connection: 0x0.1
Last send time (in seconds since boot):10595.565 (0x2963.235)
Last receive time (in seconds since boot):10595.565 (0x2963.235)
Getting endpoint info ...
Process object for caller is 0xFF9DF5F0
```

This extension will display all the information available about the client of this connection. The amount of actual information will vary, depending on the transport being used.

In this example, local named pipes are being used as the transport and the process object address of the caller is displayed. If you attach a kernel debugger (or start a local kernel debugger), you can use the [!process](#) extension to interpret this process address.

If LRPC is used as the transport, the process ID and thread ID of the caller will be displayed.

If TCP is used as the transport, the IP address of the caller will be displayed.

If remote named pipes are used as the transport, no information will be available.

Note The previous example shows how to find the client thread if you know the server thread. For an example of the reverse technique, see [Analyzing a Stuck Call Problem](#).

RPC State Information Internals

5/26/2017 • 5 min to read • [Edit Online](#)

This section provides details of the internal structure of the state information gathered by the RPC Run-Time.

All RPC run-time state information is contained in cells. A cell is the smallest unit of information that can be viewed and updated individually.

Each key object in the RPC Run-Time will maintain one or more cells of information about its state. Each cell has a cell ID. When an object refers to another object, it does so by specifying that object's cell ID. The key objects that the RPC Run-Time can maintain information about are endpoints, threads, connection objects, Server Call (SCALL) objects, and Client Call (CCALL) objects.

When an RPC server is running, the RPC Run-Time listens on a set of endpoints using one or more worker threads. Whenever data is transmitted to the server, a thread picks up the data and determines what the incoming request is. If the request is to create a connection, a Connection object is created, and this object then services all calls on the connection. When an RPC call is made on the connection, the Connection object instantiates a Server Call (SCALL) object corresponding to the Client Call (CCALL) object. This Server Call object then handles this particular call.

When an RPC client is running, the RPC Run-Time creates a Client Call object each time a call is made. This Client Call object contains information about this particular call.

Endpoint Cells

From the RPC run-time's point of view, an endpoint is an entry point through which the particular server can be contacted. The endpoint is always associated with a given RPC transport. The endpoint state information is used to associate a client call with a particular process on the server.

The fields in an endpoint cell are:

ProtseqType

The protocol sequence for this endpoint.

Status

The status value: *allocated*, *active*, or *inactive*. Most endpoints are active. An endpoint has *allocated* status when the creation process has started, but is not complete yet. An endpoint is *inactive* if it is no longer in use (for example, when a protocol has been uninstalled).

EndpointName

The first 28 characters of the endpoint name.

Thread Cells

Server threads are worker threads (standard Win32 threads for use by RPC).

The fields in a thread cell are:

Status

The status value: *processing*, *dispatched*, *allocated*, or *idle*. A *processing* thread is one that is within the Run-Time and is processing information. A *dispatched* thread has already dispatched (called) to the server-provided manager routine (usually just called the *server routine*). An *allocated* thread has been cached. An *idle* thread is available to service requests.

LastUpdateTime

The time (in milliseconds after boot) when the information was last updated.

TID

The thread ID of this thread. This is useful when trying to correlate with the thread list in the debugger.

Connection Object Cells

The fields in a connection object cell are:

Flags

Flag values include *exclusive/non-exclusive*, *authentication level*, and *authentication service*.

LastTransmitFragmentSize

The size of the last fragment transmitted over the connection.

Endpoint

The cell ID of the endpoint that this connection was picked up from.

LastSendTime

The last time data was sent on a connection.

LastReceiveTime

The last time data was received on a connection.

Server Call Object Cells

The fields in a Server Call (SCALL) object cell are:

Status

The status value: *allocated*, *active*, or *dispatched*. An *allocated* call is inactive and cached. When a call is *active*, the RPC Run-Time is processing information related to this call. When a call is *dispatched*, the manager routine (server routine) has been called and has not returned yet.

ProcNum

The procedure number (operation number, in netmon capture files) of this call. The RPC Run-Time identifies individual routines from an interface by numbering them by position in the IDL file. The first routine in the interface will be number zero, the second number one, and so on.

InterfaceUUIDStart

The first DWORD of the interface UUID.

ServicingTID

The cell ID of the thread that is servicing this call. If the call is not *active* or *dispatched*, this contains stale information.

CallFlags

These flag values indicate whether this is the cached call in an exclusive connection, whether this is an asynchronous call, whether this is a pipe call, and whether this is an LRPC or OSF call.

LastUpdateTime

The time (in milliseconds after boot) when the call object state information was last updated.

PID

The Process ID of the caller. Valid only for LRPC calls.

TID

The Thread ID of the caller. Valid only for LRPC calls.

Client Call Object Cells

A Client Call (CCALL) object is broken into two cells, because the information about a client call is too large to fit in one cell. The first cell is called *Client Call Information*, and the second is called *Call Target Information*. Most tools will show the information together, so you do not need to distinguish between them.

Information about client calls is not maintained unless you are gathering Full state information. There is one exception to this rule: information about client calls made within a server call is maintained even when only Server state information is being gathered. This allows you to trace calls spanning multiple hops.

The fields in the Client Call Information cell are:

ProcNum

The procedure number (operation number, in netmon capture files) of the method being called. The RPC Run-Time identifies individual routines from an interface by numbering them by position in the IDL file. The first routine in the interface will be number zero, the second number one, and so on.

ServicingThread

The cell ID of the thread on which this call is made.

IfStart

The first DWORD of the interface UUID on which the call is made.

Endpoint

The first 12 characters of the endpoint on the server to which the call was made.

The fields in the Call Target Information cell are:

ProtocolSequence

The protocol sequence for this call.

LastUpdateTime

The time (in milliseconds after boot) when the information about the client call or the call target was updated.

TargetServer

The first 24 characters of the name of the server to which the call is made.

Introduction to the AMLI Debugger

5/26/2017 • 1 min to read • [Edit Online](#)

There are significant differences between debugging standard kernel-mode code and debugging an ACPI (Advanced Configuration and Power Interface) BIOS.

Whereas Windows and its drivers are composed of binary machine code compiled for a specific processor, the core of an ACPI BIOS is not in machine code. Rather, it is stored as ACPI Machine Language (AML) and is processed by the Microsoft AML interpreter as it is run.

The Microsoft AMLI Debugger is a special debugging tool that can debug AML code. The AMLI Debugger is not actually a free-standing program. Rather, it consists of two components. One component is the checked build of the Microsoft Windows ACPI driver (Acpi.sys). The other component is located in certain debugger extensions included in the Debugging Tools for Windows package.

On Windows XP and later versions of Windows, the AMLI Debugger is completely 64-bit aware. No matter what processor is being used by the target computer or the host computer, the AMLI Debugger will function correctly.

[Send comments about this topic to Microsoft](#)

Setting Up an AML Debugging Session

5/26/2017 • 1 min to read • [Edit Online](#)

The AMLI Debugger code is contained in Acpi.sys. In order to fully perform AML debugging, this driver must be installed on your target computer.

To activate breaking into debugger on free builds, use the **!amliset dbgbrkon** command, that is part of the AMLI Debugger extensions. For more information, see [!amliset](#).

[Send comments about this topic to Microsoft](#)

Basic AML Debugging

5/26/2017 • 2 min to read • [Edit Online](#)

The AMLI Debugger supports two types of specialized commands: *AMLI Debugger extensions* and *AMLI Debugger commands*.

When you are performing AML debugging, you should carefully distinguish between two different kinds of prompts that will appear in the Debugger Command window:

- When you see the **kd>** prompt, you are controlling the kernel debugger. All the standard kernel debugger commands and extensions are available. In addition, the AMLI Debugger extensions are also available. In Windows 2000, these extensions have a syntax of **!acpikd.amli command**. In Windows XP and later versions of Windows, these extensions have a syntax of **!amli command**. The AMLI Debugger commands are not available in this mode.
- When you see the **AMLI(? for help)->** prompt, you are controlling the AMLI Debugger. (When you are using WinDbg, this prompt will appear in the top pane of the Debugger Command window, and an **Input>** prompt will appear in the bottom pane.) From this prompt, you can enter any AMLI Debugger command. You can also enter any AMLI Debugger extension; these extensions should not be prefixed with **!amli**. The standard kernel debugging commands are not available in this mode.
- When you see no prompt at all, the target computer is running.

At the beginning of any debugging session, you should set your AMLI Debugger options with the **!amliset** extension. The **verboseon**, **traceon**, and **errbrkon** options are also very useful. When your target computer is running Windows XP or later, you should always activate the **spewon** option. See the extension reference page for details.

There are several ways for the AMLI Debugger to become active:

- If a breakpoint in AML code is encountered, ACPI will break into the AMLI Debugger.
- If a serious error or exception occurs within AML code (such as an **int 3**), ACPI will break into the AMLI Debugger.
- If the **errbrkon** option has been set, any AML error will cause ACPI to break into the AMLI Debugger.
- If you want to deliberately break into the AMLI Debugger, use the **!amlidebugger** extension and then the **(Go)** command. The next time any AML code is executed by the interpreter, the AMLI Debugger will take over.

When you are at the AMLI Debugger prompt, you can type **q** to return to the kernel debugger, or type **g** to resume normal execution.

The following extensions are especially useful for AML debugging:

- The **!amlidns** extension displays the ACPI namespace for a particular object, the namespace tree subordinate to that object, or even the entire namespace tree. This command is especially useful in determining what a particular namespace object is -- whether it is a method, a fieldunit, a device, or another type of object.
- The **!amlifind** extension takes the name of any namespace object and returns its full path.
- The **!amliu** extension unassembles AML code.

- The **!amlilc** extension displays brief information about all active ACPI contexts.
- The **!amlir** extension displays detailed information about the current context of the interpreter. This is useful when the AMLI Debugger prompt appears after an error is detected.
- Breakpoints can be set and controlled within AML code. Use **!amlibp** to set a breakpoint, **!amlibc** to clear a breakpoint, **!amlibd** to disable a breakpoint, **!amlibe** to re-enable a breakpoint, and **!amlibl** to list all breakpoints.
- The AMLI Debugger is able to run, step, and trace through AML code. Use the **run**, **p**, and **t** commands to perform these actions.

For a full list of extensions and commands, see [Using AMLI Debugger Extensions](#) and [Using AMLI Debugger Commands](#).

[Send comments about this topic to Microsoft](#)

Using AMLI Debugger Extensions

5/31/2017 • 1 min to read • [Edit Online](#)

In Windows XP and later versions of Windows, AMLI Debugger extension commands are contained in the extension module Kdexts.dll and use the following syntax:

```
kd> !amli command [parameters]
```

In Windows 2000, these extension commands are contained in Acpikd.dll and use the following syntax:

```
kd> !acpikd.amli command [parameters]
```

As with any extension module, after it has been loaded you can omit the **acpikd** prefix.

If you are at the AMLI Debugger prompt, you can execute any of these extension commands by simply entering the *command* name without the **!amli** prefix:

```
AMLI(?) for help)-> command [parameters]
```

When you are at this prompt, the **!amli debugger** command is not available (because it would be meaningless). Also, the help command (**?**) at this prompt shows all AMLI Debugger extensions and commands, while the **!amli ?** extension only displays help on actual extensions.

ACTION	EXTENSION COMMAND
Display Help	!amli ?
Set AML Breakpoint	!amli bp

Using AMLI Debugger Commands

5/26/2017 • 4 min to read • [Edit Online](#)

The following commands can be issued from the AMLI Debugger prompt.

GENERAL CATEGORY	SPECIFIC ACTION	AMLI DEBUGGER COMMANDS
Controlling the Debugger	Continue Execution Break to Kernel Debugger	g q
Controlling AML Execution	Run Method Step Over AML Code Trace Into AML Code	run p t
Controlling Trace Mode Settings	Configure Trace Mode	trace
Notifying a Namespace Object	Notify Namespace Object	notify
Displaying the Object Count Table	Display Object Count Table	dc
Accessing Memory	Display Data Display Data Bytes Display Data Words Display Data DWORDs Display Data String Edit Memory	d db dw dd da e
Accessing Ports	Read Byte from Port Read Word from Port Read DWORD from Port Write Byte to Port Write Word to Port Write DWORD to Port	i iw id o ow od
Displaying Help	Display Help	?

Controlling the Debugger

These commands exit the AMLI Debugger. The **g** command will resume normal execution of the target computer, and the **q** command will freeze the target computer and break into the kernel debugger.

g q

Controlling AML Execution

These commands allow you to run or step through AML methods. The **run** command begins execution at a specified point. The **p** and **t** commands allow you to step through one instruction at a time. If a function call is encountered, the **p** command treats the function as a single step, while the **t** command traces into the new function one instruction at a time.

run *MethodName* [*ArgumentList*] **run** *CodeAddress* [*ArgumentList*] **p t**

MethodName

Specifies the full path and name of a method. Execution will start at the beginning of this method's memory

location.

CodeAddress

Specifies the address where execution is to begin.

ArgumentList

Specifies a list of arguments to be passed to the method. Each argument must be an integer. Multiple arguments should be separated with spaces.

Controlling Trace Mode Settings

The **trace** command controls the AML interpreter's trace mode settings. If this command is used with no parameters, the current trace mode settings are displayed.

trace [trigon|trigoff] [level=Level] [add=TPStrings] [zap=TPNumbers]

trigon

Activates trace trigger mode.

trigoff

Deactivates trace trigger mode.

Level

Specifies the new setting for the trace level.

TPStrings

Specifies one or more trigger points to be added. Each trigger point is specified by name. Multiple trigger point strings should be separated by commas.

TPNumbers

Specifies one or more trigger points to be deleted. Each trigger point is specified by number. Multiple trigger point numbers should be separated by commas. To see a list of trigger point numbers, use the **trace** command with no parameters.

Notifying a Namespace Object

The **notify** command sends a notification to an ACPI namespace object. The notification will be placed in the specified object's queue.

notify ObjectName Value

notify ObjectAddress Value

ObjectName

Specifies the full namespace path of the object to be notified.

ObjectAddress

Specifies the address of the object to be notified.

Value

Specifies the notification value.

Displaying the Object Count Table

The **dc** command displays the memory object count table.

dc

Accessing Memory

The memory access commands allow you to read and write to memory. When reading memory, you can choose the size of the memory units with the **db**, **dw**, **dd** or **da** command. A simple **d** command displays memory in the most recently-chosen units. If this is the first display command used, byte units are used.

If no address or method is specified, display will begin where the previous display command ended.

These commands have the same effect as the standard kernel debugger memory commands; they are duplicated within the AMLI Debugger for easy access.

d[b|w|d|a] [[l=Length] [Method | [%%]Address]]

e [%%]Address Datalist

b

Specifies that the data should be displayed in byte units.

w

Specifies that the data should be displayed in word (16-bit) units.

d

Specifies that the data should be displayed in DWORD (32-bit) units.

a

Specifies that the data should be displayed as a string. The data is displayed as ASCII characters. The display terminates when a NULL character is read, or when *Length* characters have been displayed.

Length

Specifies the number of bytes to be displayed. *Length* must be a hexadecimal number (without an **0x** prefix). If *Length* is omitted, the default display size is 0x80 bytes.

Method

Specifies the full path and name of a method. The display will start at the beginning of this method's memory location.

Address

Specifies the memory address where reading or writing will begin. If the address is prefixed with two percent signs (%%), it is interpreted as a physical address. Otherwise, it is interpreted as a virtual address.

DataList

Specifies the data to be written to memory. Each item in the list can be either a hexadecimal byte or a string. When a string is used, it must be enclosed in quotation marks. Multiple items should be separated by spaces.

Accessing Ports

The port commands allow you to send output or receive input from a data port. The **i** and **o** commands transfer single bytes, the **iw** and **ow** commands transfer words (16 bits), and the **id** and **od** commands transfer DWORDS (32 bits).

These commands have the same effect as the standard kernel debugger port commands; they are duplicated within the AMLI Debugger for easy access.

i Port iw Port id Port o Port DataForPort ow Port DataForPort od Port DataForPort

Port

Specifies the address of the port to be accessed. The port size must match the command chosen.

DataForPort

Specifies the data to be written to the port. The size of this data must match the command chosen.

Displaying Help

This command displays help text for the AMLI Debugger commands.

? [Command]

Command

Specifies the command for which to display help. If this is omitted, a list of all AMLI Debugger commands and AMLI Debugger extensions is displayed.

[Send comments about this topic to Microsoft](#)

AML Debugging Examples

5/31/2017 • 3 min to read • [Edit Online](#)

Here are examples that illustrate how to get started with AML debugging.

Investigating a Frozen Computer

If the target computer has frozen and you suspect it may be an ACPI problem, begin by using the [!amli lc](#) extension to display all the active contexts:

```
kd> !amli lc
*Ctxxt=ffffffff8128d000, ThID=ffffffff81277880, Flgs=----R----, pb0p=ffffffff8124206c,
Obj=\_SB.PCI0.ISA0.FDC0._CRS
```

If no contexts are displayed, the error is probably not ACPI-related.

If there are contexts shown, look for the one marked with an asterisk. This is the *current context* (the one that is being executed by the interpreter at the present moment).

In this example, the target computer is running Windows XP or Windows Server 2003 on a 32-bit processor. Therefore all addresses are cast to 64 bits, producing a gratuitous FFFFFFFF in the high 32 bits. The abbreviation **pbOp** indicates the instruction pointer ("pointer to binary op codes"). The **Obj** field gives the full path and name of the method as it appears in the ACPI tables. For a description of the flags, see [!amli lc](#).

You can use the [!amli u](#) command to disassemble the _CRS method as follows:

```
kd> !amli u \_SB.PCI0.ISA0.FDC0._CRS

ffffffff80e4a535 : CreateDWordFieldCRES, 0x76, RAMT)
ffffffff80e4a540 : CreateDWordField(CRES, 0x82, PCIT)
ffffffff80e4a54b : Add(MLEN(), 0x10000, RAMT)
ffffffff80e4a559 : Subtract(0xffe0000, RAMT, PCIT)
ffffffff80e4a567 : Return(CRES)
```

Breaking Into the AMLI Debugger

The [!amli debugger](#) command causes the AML interpreter to break into the AMLI Debugger the next time any AML code is executed.

After the AMLI Debugger prompt appears, you can use any of the AMLI Debugger commands. You can also use [!amli](#) extension commands without prefixing them with "!amli":

```

kd> !amli debugger
kd> g

AMLI(? for help)-> find _crs
\_SB.LNKA._CRS
\_SB.LNKB._CRS
\_SB.LNKC._CRS
\_SB.LNKD._CRS
\_SB.PCI0._CRS
\_SB.PCI0.LPC.NCP._CRS
\_SB.PCI0.LPC.PIC._CRS
\_SB.PCI0.LPC.TIME._CRS
\_SB.PCI0.LPC.IDMA._CRS
\_SB.PCI0.LPC.RTC._CRS
\_SB.PCI0.LPC.SPKR._CRS
\_SB.PCI0.LPC.FHUB._CRS
\_SB.PCI0.SBD1._CRS
\_SB.PCI0.SBD2._CRS
\_SB.MBRD._CRS

AMLI(? for help)-> u \_SB.PCI0._CRS

ffffffff80e4a535 : CreateDWordFieldCRES, 0x76, RAMT)
ffffffff80e4a540 : CreateDWordField(CRES, 0x82, PCIT)
ffffffff80e4a54b : Add(MLEN(), 0x10000, RAMT)
ffffffff80e4a559 : Subtract(0xffe00000, RAMT, PCIT)
ffffffff80e4a567 : Return(CRES)

```

Using Breakpoints

In the following example, you will break into the AMLI Debugger before the method `_BST` is executed.

Even if you have located a `_BST` object, you should verify that it is indeed a method. You can use the [!amli dns](#) extension to do this.

```

kd> !amli dns /s \_sb.pci0.isa.bat1._bst

ACPI Name Space: \_SB.PCI0.ISA.BAT1._BST (c29c2044)
Method(_BST:Flags=0x0,CodeBuff=c29c20a5,Len=103)

```

Now you can use the [!amli bp](#) command to place the breakpoint:

```

kd> !amli bp \_sb.pci0.isa.bat1._bst

```

You may also want to place breakpoints within the method. You could use the [!amli u](#) command to disassemble `_BST` and then place a breakpoint on one of its steps:

```

kd> !amli u \_sb.pci0.isa.bat1._bst

fffffffffc29c20a5: Acquire(\_SB_.PCI0.ISA_.EC0_.MUT1, 0xffff)
fffffffffc29c20c0: Store("CMBatt - _BST.BAT1", Debug)
fffffffffc29c20d7: \_SB_.PCI0.ISA_.EC0_.CPOL()
fffffffffc29c20ee: Release(\_SB_.PCI0.ISA_.EC0_.MUT1)
fffffffffc29c2107: Return(PBST)

kd> !amli bp c29c20ee

```

Responding to a Triggered Breakpoint

In the following example, the method `_WAK` is running and then encounters a breakpoint:

```
Running \_WAK method
Hit Breakpoint 0.
```

Use the **!amli ln** extension to see the nearest method to the current program counter. The following example is taken from a Windows 2000 system, so the addresses are shown in 32-bit form:

```
kd> !amli ln
c29accf5: \_WAK
```

The **!amli lc** extension displays all the active contexts:

```
kd> !amli lc
Ctxt=c18b6000, ThID=00000000, Flgs=A-QC-W----, pbOp=c29bf8fe, Obj=\_SB.PCI0.ISA.EC0._Q09
*Ctxt=c18b4000, ThID=c15a6618, Flgs=----R----, pbOp=c29accf5, Obj=\_WAK
```

This shows that the active contexts are associated with the methods _Q09 and _WAK. The current context is _WAK.

Now you can use the **!amli r** command to display more details about the current context. From this you can see useful thread and stack information, as well as arguments passed to _WAK and the local data objects.

```
kd> !amli r
Context=c18b4000*, Queue=00000000, ResList=00000000
ThreadID=c15a6618, Flags=00000010
StackTop=c18b5eec, UsedStackSize=276 bytes, FreeStackSize=7636 bytes
LocalHeap=c18b40c0, CurrentHeap=c18b40c0, UsedHeapSize=88 bytes
Object=\_WAK, Scope=\_WAK, ObjectOwner=c18b4108, SyncLevel=0
AsyncCallBack=ff06b5d0,CallBackData=0,CallBackContext=c99efddc

MethodObject=\_WAK
c18b40e4: Arg0=Integer(:Value=0x00000001[1])
c18b5f3c: Local0=Unknown()
c18b5f54: Local1=Unknown()
c18b5f6c: Local2=Unknown()
c18b5f84: Local3=Unknown()
c18b5f9c: Local4=Unknown()
c18b5fb4: Local5=Unknown()
c18b5fcc: Local6=Unknown()
c18b5fe4: Local7=Unknown()
c18b4040: RetObj=Unknown()
```

Tracing, Stepping, and Running AML Code

If you want to trace through the code, you can turn on full tracing information by using the **!amli set** extension as follows:

```
kd> !amli set spewon verboseon traceon
```

Now you can step through the AML code, watching the code execute line by line. The **p** command steps over any function calls. The **t** command will step into function calls.

```
AMLI(? for help)-> p

c29bfcb7: Store(\_SB_.PCI0.ISA_.ACAD.CHAC(SEL0=0x10e1)
c29c17b1: {
c29c17b1: | Store(LGreater(And(Arg0=0x10e1,0xf0,)=0xe0,0x80)=0xffffffff,Local0)=0xffffffff

AMLI(? for help)-> p

c29c17bb: | If(LNot(LEqual(Local0=0xffffffff,ACP_=0xffffffff)=0xffffffff)=0x0)
c29c17ce: | {
c29c17ce: | | Return(Zero)
c29c17d0: | }
c29c17d0: },Local1)=0x0

AMLI(? for help)-> t

c29bfc4: Store(\_SB_.PCI0.ISA_.BAT1.CHBP(SEL0=0x10e1)
c29c293d: {
c29c293d: | Store("CMBatt - CHBP.BAT1",Debug)String(:Str="CMBatt - CHBP.BAT1")="CMBatt - CHBP.BAT1"
```

You may also run methods from within the AMLI Debugger if you choose. For example, you might evaluate the status of the LNKA device by running its control method _STA:

```
AMLI(? for help)-> run \_sb.lnka._sta
PCI OpRegion Access on region c29b2268 device c29b2120

\_SB.LNKA._STA completed successfully with object data:
Integer(:Value=0x0000000b[11])
```

Other ACPI Debugging Extensions

5/26/2017 • 1 min to read • [Edit Online](#)

The following extension commands are useful for debugging problems with an Advanced Configuration and Power Interface (ACPI) BIOS:

- **!acpicache** displays all of the ACPI tables cached by the hardware application layer (HAL)
- **!acpiinf** displays information on the configuration of the ACPI
- **!acpiirqarb** displays the contents of the ACPI IRQ arbiter structure
- **!facs** displays a Firmware ACPI Control Structure
- **!fadt** displays a Fixed ACPI Description Table
- **!mapic** displays an ACPI Multiple APIC Table
- **!nsobj** displays an ACPI namespace object
- **!nstree** displays a section of the ACPI namespace tree
- **!rsdt** displays the ACPI Root System Description Table

For a complete list of ACPI-related extensions, see [!acpikd.help](#).

For details on the **!aml**xxx extensions, see [The AMLI Debugger](#).

NDIS Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

This section includes:

[Overview of NDIS Debugging](#)

[Preparing for NDIS Debugging](#)

[Enabling NDIS Debug Tracing](#)

[Send comments about this topic to Microsoft](#)

Overview of NDIS Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

The two primary tools for debugging a network driver are debug tracing and the Network Driver Interface Specification (NDIS) extensions. For more information on debug tracing, see [Enabling NDIS Debug Tracing](#). For more information on the NDIS debugging extensions, see [NDIS Extensions](#), which provides a complete list of the extension commands found in the extension module Ndiskd.dll. The Windows 2000 version of this extension module appears in the w2kfre and w2kchk directories. The Windows XP and later version of this extension module appear in the winxp directory.

An additional tool for debugging a network driver is the collection of regular debugging extensions, which are useful for obtaining debugging information. For example, entering **!stacks 2 ndis!** displays all threads in the stack beginning with **ndis!**. This information can be useful for debugging hangs and stalls.

There is also an NDIS-specific bug check code, bug check 0x7C (BUGCODE_NDIS_DRIVER). For a complete list of its parameters, see [Bug Check 0x7C](#).

Another useful tool for testing an NDIS driver is NDIS Verifier. For more information, consult the NDIS Verifier topic in the Windows Driver Kit (WDK) documentation.

[Send comments about this topic to Microsoft](#)

Preparing for NDIS Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

To debug NDIS components, a checked version of Ndis.sys is required on the target computer. However, instead of installing an entire checked-build operating system, you can copy the checked version of Ndis.sys onto an otherwise free-build operating system. Before you copy the checked version of Ndis.sys to the target computer, you must disable Windows File Protection (WFP). To ensure that WFP is disabled, start the operating system in safe mode.

The NDIS symbols are publicly available on the Microsoft symbol store. For details on how to access this, see [Microsoft Public Symbols](#).

[Send comments about this topic to Microsoft](#)

Enabling NDIS Debug Tracing

5/26/2017 • 1 min to read • [Edit Online](#)

NDIS debug tracing is the primary method for debugging NDIS drivers. When you set up NDIS debug tracing, you are actually enabling one or more levels of `DbgPrint` statements with NDIS. The resulting information is sufficient for debugging most network driver problems.

You can enable debug tracing by setting appropriate registry values. For details, see [Enabling NDIS Debug Tracing By Setting Registry Values](#).

Setting registry values to enable debug tracing works even if the host computer does not have the checked version of the `Ndis.sys` symbols installed.

[Send comments about this topic to Microsoft](#)

Enabling NDIS Debug Tracing By Setting Registry Values

5/26/2017 • 1 min to read • [Edit Online](#)

You can enable different levels of debug tracing in various NDIS components by editing the registry. Typically, you should add the following entries and values to the

HKLM\SYSTEM\CurrentControlSet\Services\NDIS\Parameters registry key:

```
"DebugLevel"=dword:00000000
"DebugSystems"=dword:000030F3
"DebugBreakPoint"=dword:00000001
```

The following values are acceptable for **DebugBreakPoint**, **DebugLevel** and **DebugSystems**:

DebugBreakPoint

Controls whether an NDIS driver will automatically break into the debugger. If this value is set to 1, NDIS will break into the debugger when a driver enters Ndis.sys's **DriverEntry** function.

DebugLevel

Selects the level or amount of debug tracing in the NDIS components that you select with the **DebugSystems** value. The following values specify levels that you can select:

LEVEL	DESCRIPTION	VALUE
DBG_LEVEL_INFO	All available debug information. This is the highest level of trace.	0x00000000
DBG_LEVEL_LOG	Log information.	0x00000800
DBG_LEVEL_WARN	Warnings.	0x00001000
DBG_LEVEL_ERR	Errors.	0x00002000
DBG_LEVEL_FATAL	Fatal errors, which can cause the operating system to crash. This is the lowest level of trace.	0x00003000

DebugSystems

Enables debug tracing for specified NDIS components. This corresponds to using the **!ndiskd.dbgsystems** extension. The following values specify the NDIS components that you can select:

COMPONENT	DESCRIPTION	VALUE
DBG_COMP_INIT	Handles adapter initialization.	0x00000001

COMPONENT	DESCRIPTION	VALUE
DBG_COMP_CONFIG	Handles adapter configuration.	0x00000002
DBG_COMP_SEND	Handles sending data over the network.	0x00000004
DBG_COMP_RECV	Handles receiving data from the network.	0x00000008
DBG_COMP_PROTOCOL	Handles protocol operations.	0x00000010
DBG_COMP_BIND	Handles binding operations.	0x00000020
DBG_COMP_BUSINFO	Handles bus queries.	0x00000040
DBG_COMP_REG	Handles registry operations.	0x00000080
DBG_COMP_MEMORY	Handles memory management.	0x00000100
DBG_COMP_FILTER	Handles filter operations.	0x00000200
DBG_COMP_REQUEST	Handles requests.	0x00000400
DBG_COMP_WORK_ITEM	Handles work-item operations.	0x00000800
DBG_COMP_PNP	Handles Plug and Play operations.	0x00001000
DBG_COMP_PM	Handles power management operations.	0x00002000
DBG_COMP_OPENREF	Handles operations that open reference objects.	0x00004000
DBG_COMP_LOCKS	Handles locking operations.	0x00008000
DBG_COMP_RESET	Handles resetting operations.	0x00010000
DBG_COMP_WMI	Handles Windows Management Instrumentation operations.	0x00020000

COMPONENT	DESCRIPTION	VALUE
DBG_COMP_CO	Handles Connection-Oriented NDIS.	0x00040000
DBG_COMP_REF	Handles reference operations.	0x00080000
DBG_COMP_ALL	Handles all NDIS components.	0xFFFFFFFF

You can select more than one NDIS component. If more than one component is selected, combine the data values with an OR operator. For example, to select DBG_COMP_PNP, DBG_COMP_PM, DBG_COMP_INIT and DBG_COMP_CONFIG, you would combine the corresponding values (0x1000, 0x2000, 0x1, and 0x2) to obtain the value 0x3003, and then set it in the registry thus:

```
"DebugSystems"=dword:00003003
```

Whenever you change registry values for debug tracing, you must restart your computer for the new settings to take effect.

[Send comments about this topic to Microsoft](#)

Overview of Kernel Streaming Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

Kernel streaming debugging extensions can be found in the extension module Ks.dll.

You can use Ks.dll to help debug KS, AVStream, port class and stream class drivers.

For a complete list of the extension commands in Ks.dll, see [Kernel Streaming Extensions \(Ks.dll\)](#).

If you wish to use these extensions with Windows 2000, you must copy Ks.dll from the kdexts directory to the w2kfre directory.

[Send comments about this topic to Microsoft](#)

Analyzing a Video Stream Stall

5/26/2017 • 1 min to read • [Edit Online](#)

This section shows how to analyze a video stream stall. All sample output is generated from an AVStream minidriver after an independent hardware vendor (IHV) driver bug has been introduced.

[Determining the Cause](#)

[Debugging a Processing Stall](#)

[Using Logging to Track Important Events](#)

[Interpreting Bug Check 0xCB](#)

[Send comments about this topic to Microsoft](#)

Determining the Cause of a Video Stream Stall

5/26/2017 • 1 min to read • [Edit Online](#)

There are two basic causes for a video stream stall:

- **A hang.** Either a user-mode thread or a kernel-mode thread is not being released by the driver.
- **A stall.** This is the result of a problem with a component in the streaming path. Some possibilities include:
 - The capture driver is not completing packets. In this case, either a driver component or the hardware might be the source of the stall.
 - The capture driver has no packets to complete. In this case, the buffers might be stalled in a codec or other downstream component.

If you can reproduce the problem, attach a debugger at this point to determine which is the actual cause.

To determine if the problem is a hang

1. Attach a user-mode debugger to the application and look for blocked user-mode threads.
2. Determine whether the application is responsive. Can the graph be paused? Can the graph be stopped? Does streaming restart if the graph is stopped and restarted?
3. If the application is non-responsive, attempt to end the task by using Task Manager. If this fails, there is a kernel-mode hang.

To determine if the problem is a stall

1. Determine where the samples are in the graph. This can be done locally or in a kernel-mode debugging session.
2. Determine whether samples are flowing downstream. If you can reproduce the bug in [GraphEdit](#), place an intermediate filter in the graph to display samples.
3. Determine if the processing routine is being called. This can be done by attaching a kernel-mode debugger and setting a breakpoint in this routine.

[Send comments about this topic to Microsoft](#)

Debugging a Processing Stall

5/26/2017 • 2 min to read • [Edit Online](#)

Begin by finding the relevant pin. In a hypothetical case, the relevant video capture pin has address **8160DDE0**, so we use the **!ks.dump** extension command on this address to get more details:

```
kd> !ks.dump 8160DDE0 7
Pin object 8160DDE0 [CKsPin = 8160DD50]
  DeviceState    KSSTATE_RUN
  ClientState    KSSTATE_RUN
CKsPin object 8160DD50 [KSPIN = 8160DDE0]
  State          KSSTATE_RUN
  Processing Mutex 8160DFD0 is not held
  And Gate &      8160DF88
  And Gate Count  1
```

First, determine if the pin is in the appropriate state and whether the processing mutex is being held by another thread. In this case, the pin state is **KSSTATE_RUN**, as it should be, and the processing mutex is not being held, so we next use the **!ks.dumpqueue** extension to determine if there are frames available:

```
kd> !ks.dumpqueue 8160DDE0 7
Queue 8172D5D8:
  Frames Received : 763
  Frames Waiting  : 5
  ...<this part of display not shown>...
Queue 8172D5D8:
  Frame Header 81B77E60:
    Irp = 816EE008
    Refcount = 1
  Frame Header 81A568D0:
    Irp = 816DE008
    Refcount = 0
  Frame Header 81844ED8:
    Irp = FFA0F650
    Refcount = 0
  Frame Header 8174B0B0:
    Irp = FFABB460
    Refcount = 0
  Leading Edge:
    Stream Pointer 8183EA58 [Public 8183EA90]:
      Frame Header = 81B77E60
  ...<this part of display not shown>...
```

In the above partial display of the **!ks.dumpqueue** output, we see that there are five frames waiting, or available. Are these frames ahead of or behind the leading edge? In the **!ks.dumpqueue** display, the frames are always listed from oldest to newest. The frame header of the leading edge matches that of the first frame listed, the oldest frame. Thus all of the available frames are ahead of the leading edge.

If this were not the case, and instead all of the frames were behind the leading edge, and they had a reference count due to clone pointers, the problems most likely originate with either the hardware or the driver's programming of hardware. Make sure that the hardware is signaling buffer completions (check interrupts and DPCs) and determine that the driver is responding appropriately to those notifications (by deleting clones upon buffer completion, for example).

If, as in our example, all of the frames are ahead of the leading edge, the problem is almost certainly a software

issue. Further information can be obtained by looking at the pin's And gate.

Interpreting the And Gate

The pin's And gate controls processing. If the gate count is one, processing can occur. Obtain the current status of the And gate by using the **!ks.dump** extension:

```
kd> !ks.dump 8160DDE0 7
Pin object 8160DDE0 [CKsPin = 8160DD50]
  DeviceState      KSSTATE_RUN
  ClientState      KSSTATE_RUN
  CKsPin object 8160DD50 [KSPIN = 8160DDE0]
    State          KSSTATE_RUN
    Processing Mutex  8160DFD0 is not held
    And Gate &    8160DF88
    And Gate Count 1
```

Because the gate count is one, the And gate is open. In this case, investigate the following potential causes for the processing stall:

- The process dispatch incorrectly returned STATUS_PENDING.
- The data availability case is missing a [KsPinAttemptProcessing](#) call.

[Send comments about this topic to Microsoft](#)

Using Logging to Track Important Events

5/26/2017 • 3 min to read • [Edit Online](#)

In general, data is moved downstream only by triggering events, the minidriver's processing, and buffer completions. To isolate the cause of a hang or stall:

- Check for mismatched **KsGate*Xxx*** calls.
- Check for omitted **KsXxxAttemptProcessing** calls.
- Look for problems in code related to triggering events, including code that either references the pin flags for the problem stream or that calls **KsPinAttemptProcessing**.
- Look for problems in the code related to the processing dispatch, in particular where it queues to hardware and where clone pointers are created.
- Look for problems in the code related to the driver's deferred procedure call (DPC), especially where buffers are completed or any calls are made to **KsStreamPointerDelete**.
- Look for problems in the startup code for the stream.

The most effective way to collect this information is by logging everything in the affected region, including processing, buffer acquisition (such as cloning and programming hardware), buffer release (such as deleting clones), and any gate manipulations. Most of this information is highly timing dependent and requires memory-based logging or ETW.

To maintain a rolling memory-based log, use the following code:

```
typedef struct _LOGENTRY {
    ULONG Tag;
    ULONG Arg[3];
} LOGENTRY, *PLOGENTRY;
#define LOGSIZE 2048
LONG g_LogCount;
LOGENTRY g_Log [LOGSIZE];
#define LOG(tag,arg1,arg2,arg3) do { \
    LONG i = InterlockedIncrement (&g_LogCount) % LOGSIZE; \
    g_Log [i].Tag = tag; \
    g_Log [i].Arg [0] = (ULONG)(arg1); \
    g_Log [i].Arg [1] = (ULONG)(arg2); \
    g_Log [i].Arg [2] = (ULONG)(arg3); \
} while (0)
```

Then, use a simple "dc g_Log" to view the contents of the **g_Log** array in the debugger.

The following example uses the above memory-based scheme to determine the cause of a processing stall. Output is from an AVStream streaming scenario in graphedt. The following minidriver events were logged:

ABBREVIATION	DESCRIPTION
<i>Strt</i>	This event occurs when the minidriver first queues buffers for the device from within the minidriver's <i>Start</i> dispatch.

ABBREVIATION	DESCRIPTION
Prc<	This event occurs at the start of the minidriver's <i>Process</i> dispatch.
AddB	This event occurs when the minidriver queues buffers to the device from within its <i>Process</i> dispatch.
DPC<	This event occurs at the start of the minidriver's <i>CallOnDPC</i> . It indicates buffer completion.
Atmp	This event occurs when the minidriver calls from within the DPC to KsPinAttemptProcessing .
Dele	This event occurs when the minidriver calls from within the DPC to delete a clone stream pointer.

Log excerpts are as follows:

```

f9494b80 3c435044 816e2c90 00000000 00000000 DPC<,n.....

f9494c10 42646441 819c1f00 ffa3d9b8 00000000 AddB.....

```

This first log excerpt is representative of the normal streaming state. In the first line, the minidriver's *CallOnDPC* is called to complete a buffer (*DPC<*). The buffer is deleted (*Dele*), and **KsPinAttemptProcessing** is called to move the leading edge forward, if there are any unprocessed buffers in the queue (*Atmp*). In this case, there were, as can be seen by the call to the process dispatch (*Prc<*). More buffers are added to the queue (*AddB*), and the whole scenario repeats.

This next excerpt includes the last entries in the log right before the stall occurred.

```

f949b430 3c435044 816e2c90 00000000 00000000 DPC<,n.....
f949b440 656c6544 816e2c90 ffac4de8 00000000 Dele.,n..M.....

f949b460 3c435044 816e2c90 00000000 00000000 DPC<,n.....
f949b470 656c6544 816e2c90 816ffc80 00000000 Dele.,n...o.....
f949b480 706d7441 816e2c90 ffa4d418 00000000 Atmp.,n.....
f949b490 3c435044 816e2c90 00000000 00000000 DPC<,n.....
f949b4a0 656c6544 816e2c90 ffa80348 00000000 Dele.,n.H.....
f949b4b0 706d7441 816e2c90 ffa4d418 00000000 Atmp.,n.....
f949b4c0 3c435044 816e2c90 00000000 00000000 DPC<,n.....
f949b4d0 656c6544 816e2c90 8174e1c0 00000000 Dele.,n...t.....
f949b4e0 706d7441 816e2c90 ffa4d418 00000000 Atmp.,n.....

```

In this example, several buffers are being completed (indicated by the repeated instances of *DPC<*), but there are no unprocessed buffers in the queue, so the process dispatch is not being called (indicated by the absence of *Prc<*). In fact, all of the processed buffers in the queue have been completed, apparently before any new unprocessed

buffers could be added. Because the application is already running (so that *Start* will not be called) and no calls are being made to *CallOnDPC* (because there are no processed buffers ready to be completed), any new buffers are apparently accumulating ahead of the leading edge, waiting to be processed, with nothing initiating processing.

The problem is that the `KSPIN_FLAG_DO_NOT_INITIATE_PROCESSING` flag has been set. When this flag is set, processing occurs only through a call to *Start* or *CallOnDPC*. If this flag is not set, processing will be initiated whenever new buffers are added to the queue.

Interpreting Bug Check 0xCB

5/31/2017 • 1 min to read • [Edit Online](#)

The most common bug check code associated with debugging a video stream stall is Bug Check 0xCB (DRIVER_LEFT_LOCKED_PAGES_IN_PROCESS). For a detailed list of its parameters, see [Bug Check 0xCB](#).

The message displayed when the bug check occurs will point to Ks.sys as the cause.

```
Use !analyze -v to get detailed debugging information.
BugCheck CB, {f90c6ae0, f9949215, 81861788, 26}
Probably caused by : ks.sys ( ks!KsProbeStreamIrp+333 )
```

As suggested, use [!analyze -v](#) to get more detailed information.

```
kd> !analyze -v
DRIVER_LEFT_LOCKED_PAGES_IN_PROCESS (cb)
Caused by a driver not cleaning up completely after an I/O.
When possible, the guilty driver's name (Unicode string) is printed on
the bugcheck screen and saved in KiBugCheckDriver.
Arguments:
Arg3: 81861788, A pointer to the MDL containing the locked pages.
```

Now, use the [!search](#) extension to find the virtual addresses that are associated with the MDL pointer.

```
kd> !search 81861788
Searching PFNs in range 00000001 - 0000FF76 for [FFFFFFF81861788 - FFFFFFF81861788]

Pfn      Offset      Hit      Va      Pte
-----
000008A7 00000B0C 81861788 808A7B0C C020229C
00000A04 00000224 16000001 80A04224 C0202810
...
00001732 000009B4 81861788 817329B4 C0205CC8
```

For each virtual address (VA) found, look for an IRP signature. Do this by using the [dd](#) command with the VA minus one DWORD.

```
kd> dd 808A7B0C-4 14
808a7b08 f9949215 81861788 00000026 00000000
kd> $ Not an Irp
kd> dd 80A04224-4 14
80a04220 00000000 00000000 00000000 00000000
kd> $ Not an Irp
kd> dd 817329B4-4 14
817329b0 01900006 81861788 00000070 ffa59220
kd> $ Matches signature
```

After a VA with an IRP signature has been found, use the [!irp](#) extension to find out what driver is pending on this IRP.

```
kd> !irp 817329b0 7
Irp is active with 2 stacks 2 is current (= 0x81732a44)
Mdl = 81861788 System buffer = ffa59220 Thread 00000000: Irp stack trace.
>[ e, 0] 1 1 81a883c8 81ae6158 00000000-00000000 pending
\Driver\TESTCAP
Args: 00000070 00000000 002f4017 00000000
```

In this case, \Driver\TESTCAP is the likely cause of the bug check.

Analyzing a Capture Stall

5/26/2017 • 2 min to read • [Edit Online](#)

The following is an artificially created scenario that simulates a capture stall. This is a particularly valuable scenario since similar situations frequently occur in stress testing. The scenario is as follows:

The Windows recording component Sndrec32 is recording from the primary capture device, in this case a Creative SBLive wave device. For a period of time, it records normally; however, the graph stalls at 8.50 seconds because we have explicitly caused portcls not to complete capture IRPs for purposes of this test.

The application shows running, but the stream position is not advancing. Position is halted at 8.50 seconds.

Since the primary capture device on this machine is a PCI sound card, first use the **!ks.pciaudio** command to try and determine a starting point. Use a flag value of 1 to request a display of all running streams:

```
kd> !pciaudio 1

1 Audio FDOs found:
  Functional Device 8121c030 [\Driver\emu10k]
    Wave Cyclic Streams:
      Pin 812567c0 RUN [emu10k1m!CMiniportWaveCyclicStreamSBLive ff9ec7f8]
```

In this case, there is only one PCI audio device and it is serviced by the Intel emu10k driver (\Driver\emu10k). This driver currently has a single running stream (0x812567C0). Now you can use **!ks.graph** to view the kernel graph. Set *Level* and *Flags* both to 7 to obtain maximum detail on the stall:

```
kd> !graph 812567c0 7 7
Attempting a graph build on 812567c0... Please be patient...
Graph With Starting Point 812567c0:
"emu10k" Filter ff9ebb98, Child Factories 5
  Output Factory 0:
    Pin 812567c0 (File 811c6630, -> "splitter" 811df960) Irps(q/p) = 8, 0
    Queued: 81255418 811df008 81252008 81255280 81250b30 ffa1fe70 81252e70 ffa01d98
```

The above shows the details for factory 0. The emu10k output pin 0x812567C0 is connected to the splitter input pin 0x811DF960. There are eight IRPs queued to emu10k's output pin. The output from **!ks.graph** continues as follows:

```
"splitter" Filter ffb18890, Child Factories 2
  Output Factory 0:
    Pin 811df430 (File ffa55f90) Irps(q/p) = 10, 0
    Queued: ffadd008 ffa73b00 ffa1e998 811de310 ffa54370 ffaaf008 811dee70 81250e70 811de580 811de8c0
```

There are ten IRPs queued to splitter's output pin.

```
Input Factory 1:
  Pin 811df960 (File 81187820, <- "emu10k" 812567c0) Irps(q/p) = 0, 8
  Pending: 81255418 811df008 81252008 81255280 81250b30 ffa1fe70 81252e70 ffa01d98
```

Splitter's input pin has no queued IRPs; however, it is waiting for the eight from emu10k to enter the queue.

Analyzing a Hung Graph From 812567c0:

Suspect Filters (For a Hung Graph):

"emu10k" Filter ff9ebb98 or class "PortCls Wave Cyclic" is suspect.

Reasons For This Analysis:

- No critical pin has less than 8 queued Irps
- Downstream "splitter" pin 811df960 is starved

Irps to check:

81255418 811df008 81252008 81255280 81250b30 ffa1fe70 81252e70 ffa01d98

From this information, the analyzer suggests that either emu10k or WaveCyclic may be at fault. It also provides a list of the suspect IRPs; these are the IRPs that are queued to emu10k's input pin. If any of those IRPs were to complete, splitter would copy data and complete an IRP and the graph would progress. For some reason, emu10k is not completing those capture Irps.

Live Local Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

In Microsoft Windows XP and later operating systems, it is possible to do local kernel debugging by starting the kernel debugger (KD) or WinDbg with the **-kl** command line option:

```
kd [-y SymbolPath] -kl
```

or

```
windbg [-y SymbolPath] -kl
```

In Windows Vista and later, local kernel debugging requires the computer to be booted with the **/debug** option. Open a Command Prompt Window as Administrator, and enter **bcdedit /debug on**. Reboot the computer.

In Windows Vista and later, local kernel debugging requires the debugger to be run as Administrator.

Live local debugging is extremely useful for debugging issues that are difficult to reproduce when the debugger is attached; however, anything that requires knowledge of time sensitive information, including packet, IRP, and SRB data, is unlikely to work unless the problem is a hang or a stall.

When performing local debugging, consider the following variables:

- **Overall states.** For example, is the stream running? Is the stream paused?
- **Packet counts.** For example, are there IRPs queued to the stream?
- **Changes in packet counts.** Is the stream moving?
- **Changes in packet lists.**
- **Hung kernel threads.**

Consider the last of these.

Examining a Hung Thread in LKD

First, use the **!process 0 0** extension to identify the process containing the hung thread. Then, issue **!process** again for more information about that thread:

```
1kd> !process 816a550 7
      THREAD 81705da8  Cid 0b5c.0b60  Teb: 7ffde000 Win32Thread: e1b2d890 WAIT: (Suspended)
      IRP List:
          816c9ad8: (0006,0190) Flags: 00000030  Mdl: 00000000
          Start Address kernel32!BaseProcessStartThunk (0x77e5c650)
          Win32 Start Address 0x0101c9be
          Stack Init f50bf000 Current f50bea74 Base f50bf000 Limit f50b9000 Call 0
          Priority 10 BasePriority 8 PriorityDecrement 0
```

The threads are not displayed, but the stack addresses are. Using the **dds** (or **ddq**) command on the current address on the stack yields a starting point for further investigation, because it specifies which process is calling.

```
1kd> dds f50bea74
f50bea74  f50bebc4
f50bea78  00000000
f50bea7c  80805795 nt!KiSwapContext+0x25
f50beab4  8080ece0 nt!KeWaitForSingleObject
f50beabc  f942afda ks!CKsQueue::CancelAllIrp+0x14
f50bead8  f94406c4 ks!CKsQueue::SetDeviceState+0x170
f50beb00  f943f6f1 ks!CKsPipeSection::DistributeDeviceStateChange+0x1d
f50beb24  f943fb1e ks!CKsPipeSection::SetDeviceState+0xb2
```

Graph Analysis with Unloadable Modules

5/26/2017 • 3 min to read • [Edit Online](#)

This section describes a scenario that may affect you if you are working with unloadable modules such as KMixer.

After loading, the extension module initializes at the first command usage. At initialization, the extension module checks whether every module is loaded and has correct symbols. If any individual module is unloaded or has incorrect symbols loaded, the extension disables the library extension which handles identification, dumping, etc. for that module. In this case, you need to manually re-enable the disabled module.

The above situation may occur if you load the extension at boot time. Specifically, you may encounter this scenario if you load Ks.dll and then issue a **.reboot** command. Or, it could happen if you break into the debugger during boot and load Ks.dll at that point.

In the following example, we are capturing two streams (sndrec32) from a Telex USB microphone. Breaking on **splitter!FilterProcess** and running **!ks.graph** on splitter's filter yields:

```
kd> !graph ffa0c6d4 7
Attempting a graph build on ffa0c6d4... Please be patient...
Graph With Starting Point ffa0c6d4:
"usbaudio" Filter ffaaa768, Child Factories 2
    Output Factory 0:
        Pin ffb1caf0 (File 811deeb8, -> "splitter" ffa8b008) Irps(q/p) = 7, 1
"splitter" Filter ffa0c660, Child Factories 2
    Output Factory 0:
        Pin 81250008 (File ffb10028) Irps(q/p) = 3, 0
        Pin 811df9c0 (File ffaaf2f0) Irps(q/p) = 3, 0
    Input Factory 1:
        Pin ffa8b008 (File ffb26d68, <- "usbaudio" ffb1caf0) Irps(q/p) = 1, 7
```

In this example, KMixer has been loaded and connected to splitter, but Kmixer does not appear in the graph. There are IRPs queued to splitter's output pin, yet the **!ks.graph** command is unable to backtrace and discover KMixer. Issue a **!ks.libexts details** command to investigate further:

```
kd> !libexts details
## LibExt Details:
-----
LibExt "portcls!" :
    Status : ACTIVE
    This is the port class library extension to the KS DLL.  It supports
    dumping wave cyclic, wave pci, irp streams, and several other upper
    level structures.
    Commands Exported: pciaudio
    Help : pchelp
    Hooks : dump dumpqueue dumpcircuit conv(file) conv(device) graph
LibExt "STREAM!" :
    Status : ACTIVE
    This is the stream class library extension to the KS DLL.  It supports
    dumping device extensions, filters, streams, and SRBs.
    Hooks : dump enumdevobj graph
LibExt "kmixer!" :
    Status : INACTIVE
    This is the KMIXER extension to the KS DLL.  It supports
    virtually nothing at this point!
    Hooks : dump graph
```

According to the above output, the KMixer section of the extension is currently disabled (Status : INACTIVE). Since the extension module was first used in a context in which KMixer was not loaded, Ks.dll has disabled the KMixer section of the extension to prevent time-consuming references to an unloaded module.

To enable KMixer explicitly, you can use **!ks.libexts** with the **enable** parameter, as follows:

```
kd> !libexts enable kmixer
LibExt "kmixer" has been enabled.

kd> !graph ffa0c6d4 7
Attempting a graph build on ffa0c6d4... Please be patient...
Graph With Starting Point ffa0c6d4:
"usbaudio" Filter ffaaa768, Child Factories 2
    Output Factory 0:
        Pin ffb1caf0 (File 811deeb8, -> "splitter" ffa8b008) Irps(q/p) = 7, 1
    "splitter" Filter ffa0c660, Child Factories 2
        Output Factory 0:
            Pin 81250008 (File ffb10028, -> "kmixer" 8123c000) Irps(q/p) = 3, 0
            Pin 811df9c0 (File ffaaf2f0, -> "kmixer" 81236000) Irps(q/p) = 3, 0
        Input Factory 1:
            Pin ffa8b008 (File ffb26d68, <- "usbaudio" ffb1caf0) Irps(q/p) = 1, 7
    "kmixer" Filter ffa65b70, Child Factories 4
        Input Factory 2:
            Pin 81236000 (File ffaaf7d0, <- "splitter" 811df9c0) Irps(q/p) = 0, 0
        Output Factory 3:
            Pin 81252d00 (File 811df1d8) Irps(q/p) = 10, 0
    "kmixer" Filter ffb03808, Child Factories 4
        Input Factory 2:
            Pin 8123c000 (File ffb10130, <- "splitter" 81250008) Irps(q/p) = 0, 0
        Output Factory 3:
            Pin ffa1e9c0 (File 81253468) Irps(q/p) = 10, 0
```

KMixer now appears as expected in the capture graph.

[Send comments about this topic to Microsoft](#)

Using !ks.graph

5/26/2017 • 3 min to read • [Edit Online](#)

The **!ks.graph** command is one of most powerful extension commands in the kernel streaming extension module. This command displays a picture of an entire graph in kernel mode from any given starting point.

Before running **!ks.graph**, you may want to enable all library extensions that are capable of being active. To do this, issue a **!ks.libexts enableall** command. The output of **!ks.graph** will be a textual description of the kernel mode graph in topologically sorted order. Here is an example:

```
kd> !graph ffa0c6d4 7
Attempting a graph build on ffa0c6d4... Please be patient...
Graph With Starting Point ffa0c6d4:
"usbaudio" Filter ffaaa768, Child Factories 2
    Output Factory 0:
        Pin ffb1caf0 (File 811deeb8, -> "splitter" ffa8b008) Irps(q/p) = 7, 1
```

This example displays a capture graph in which two Sndrec32.exe's are capturing from a Telex USB Microphone. Each individual record begins with a name (usbaudio, in the above section) and shows the filter address (0xFFFAAA768) and quantity of child pin factories (2) on the filter.

Below each entry, each factory is enumerated and lists the address of each pin instance (0xFFB1CAF0), the file object (0x811DEEB8) corresponding to each instance, the direction of the connection, the destination of that connection, and the address of the destination pin (0xFFA8B008). The number of queued (7) and pending IRPs (1) for each pin is also displayed.

Connections which have forward direction symbols (->) indicate that the pin is an output pin and is connected to an input pin. Connections which have reverse direction symbols (<-), on the other hand, are input pins and show the origination of the connection. The output continues as follows:

```
"splitter" Filter ffa0c660, Child Factories 2
    Output Factory 0:
        Pin 81250008 (File ffb10028, -> "kmixer" 8123c000) Irps(q/p) = 3, 0
        Pin 811df9c0 (File ffaaf2f0, -> "kmixer" 81236000) Irps(q/p) = 3, 0
    Input Factory 1:
        Pin ffa8b008 (File ffb26d68, <- "usbaudio" ffb1caf0) Irps(q/p) = 1, 7
"kmixer" Filter ffa65b70, Child Factories 4
    Input Factory 2:
        Pin 81236000 (File ffaaf7d0, <- "splitter" 811df9c0) Irps(q/p) = 0, 0
    Output Factory 3:
        Pin 81252d00 (File 811df1d8) Irps(q/p) = 10, 0
"kmixer" Filter ffb03808, Child Factories 4
    Input Factory 2:
        Pin 8123c000 (File ffb10130, <- "splitter" 81250008) Irps(q/p) = 0, 0
    Output Factory 3:
        Pin ffa1e9c0 (File 81253468) Irps(q/p) = 10, 0
```

In order to follow the graph, use the following procedure:

To follow this graph:

1. Find the pin of interest. Consider 0xFFB1CAF0, usbaudio's output pin (factory 0).
2. Find the connected pin. In this example, this is splitter pin 0xFFA8B008.

3. Look at the connection direction and visually move that way looking for the filter name. (Remember, the list is topologically sorted.) In this example, the right-pointing arrow indicates that we need to look below this entry in the list to find the corresponding pin. The splitter filter 0xFFA0C660 is immediately below.
4. Find the destination pin address in the filter pin instance list. In this case, this address is 0xFFA8B008.

The `To follow this graph:` command can also be used to analyze stalled graphs from any given starting point. To do this, specify 4 in the `Flags` parameter:

```

kd> !graph 812567c0 7 4

Attempting a graph build on 812567c0... Please be patient...

Graph With Starting Point 812567c0:

"emu10k" Filter ff9ebb98, Child Factories 5
  Output Factory 0:
    Pin 812567c0 (File 811c6630, -> "splitter" 811df960) Irps(q/p) = 8, 0
"splitter" Filter ffb18890, Child Factories 2
  Output Factory 0:
    Pin 811df430 (File ffa55f90) Irps(q/p) = 10, 0
  Input Factory 1:
    Pin 811df960 (File 81187820, <- "emu10k" 812567c0) Irps(q/p) = 0, 8

Analyzing a Hung Graph From 812567c0:

Suspect Filters (For a Hung Graph):
  "emu10k" Filter ff9ebb98 or class "PortCls Wave Cyclic" is suspect.
  Reasons For This Analysis:
    - No critical pin has less than 8 queued Irps
    - Downstream "splitter" pin 811df960 is starved
  Irps to check:
    81255418 811df008 81252008 81255280 81250b30 ffa1fe70 81252e70 ffa01d98

NOTE: The above is based on heuristic analysis. It is not designed to be a
replacement for an actual developer looking at this particular hang! The
filters listed as suspects may or may not be the actual cause of the
stall!

```

For such output, look at the "suspects" list. These suspect filters are those that are in the critical path of progress being made in the graph. Begin debugging from that point based on the reasons that the analyzer has produced for the stall.

Note This functionality should only be used on stalled graphs! The analyzer has no way of knowing how long the graph has been in this state. Breaking into the debugger and analyzing a running graph as a stalled graph still displays a suspect filter.

Overview of SCSI Miniport Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

Small computer system interface (SCSI) debugging extensions can be found in two extension modules: Scsikd.dll and Minipkd.dll. For an overview of the most important extension commands in these modules, see [Extensions for Debugging SCSI Miniport Drivers](#). For a complete list, see [SCSI Miniport Extensions](#).

The SCSIkD.dll extension commands can be used in any version of Windows. The Minipkd.dll extension commands can only be used in Windows XP and later versions of Windows. Commands in Minipkd.dll are only applicable to miniport drivers that work with the SCSI Port driver.

To test a SCSI miniport driver, use the SCSI Verification feature of Driver Verifier. For information about Driver Verifier, see [Driver Verifier](#) in the Windows Driver Kit (WDK) documentation.

Extensions for Debugging SCSI Miniport Drivers

5/31/2017 • 4 min to read • [Edit Online](#)

When you debug SCSI miniport drivers, you may find the following debugger extensions useful. General debugger extensions are listed first, followed by those specific to SCSI miniport debugging.

!devobj

The **!devobj** extension displays detailed information about a DEVICE_OBJECT. If the **Current Irp** field is nonnull, this could be caused by the SCSI driver waiting for map registers.

Here is an example:

```
0: kd> !devobj 8633da70
Device object (8633da70) is for:
  adpu160m1 \Driver\adpu160m DriverObject 8633eeb8
  Current Irp 860ef008 RefCount 0 Type 00000004 Flags 00000050
  Dacl e129871c DevExt 8633db28 DevObjExt 8633dfd0
  ExtensionFlags (0000000000)
  AttachedTo (Lower) 863b2978 \Driver\PCI
  Device queue is not busy.
```

!errlog

The **!errlog** extension displays the contents of any pending entries in the I/O system's error log.

!object

The **!object** extension displays information about a system object. This extension displays all SCSI devices.

For example:

```
0: kd> !object \device\scsi
Object: e12a2520  Type: (863d12c8) Directory
  ObjectHeader: e12a2508
  HandleCount: 0  PointerCount: 9
  Directory Object: e1001100  Name: Scsi

  Hash Address  Type          Name
  ----- -----
  04  86352040  Device       adpu160m1Port3Path0Target6Lun0
  11  86353040  Device       adpu160m1Port3Path0Target1Lun0
  13  86334a70  Device       1p6nds351
  22  862e6040  Device       adpu160m1Port3Path0Target0Lun0
  24  8633da70  Device       adpu160m1
  25  86376040  Device       adpu160m2
  34  862e5040  Device       adpu160m1Port3Path0Target2Lun0
```

!pcr

The **!pcr** extension displays detailed information about the Processor Control Region (PCR) on a processor. The information includes the items in the DPC queue, which can be useful when you are debugging a stalled driver or a time-out.

!minipkd.help

The **!minipkd.help** extension displays a list of all of the Minipkd.dll extension commands.

If an error message similar to the following appears, it indicates that the symbol path is incorrect and does not point to the correct version of the Scsiport.sys symbols.

```
minipkd error (0) <path> ... \minipkd\minipkd.c @ line 435
```

The **.sympath (Set Symbol Path)** command can be used to display the current path and to change the path. The **.reload (Reload Module)** command will reload symbols from the current path.

!minipkd.adapter Adapter

The **!minipkd.adapter** extension displays detailed information about a specified adapter. The **Adapter** can be found by looking at the **DevExt** field in the **!minipkd.adapters** display.

!minipkd.adapters

The **!minipkd.adapters** extension displays all the adapters that work with the SCSI Port driver that have been identified by Windows, and the individual devices associated with each adapter.

Here is an example:

```
0: kd> !minipkd.adapters
Adapter \Driver\lp6nds35      DO 86334a70      DevExt 86334b28
Adapter \Driver\adpu160m      DO 8633da70      DevExt 8633db28
LUN 862e60f8 @ (0,0,0) c ev  pnp(00/ff) pow(0,0) DevObj 862e6040
LUN 863530f8 @ (0,1,0) c ev  p d pnp(00/ff) pow(0,0) DevObj 86353040
LUN 862e50f8 @ (0,2,0) c ev  pnp(00/ff) pow(0,0) DevObj 862e5040
LUN 863520f8 @ (0,6,0)   ev  pnp(00/ff) pow(0,0) DevObj 86352040
Adapter \Driver\adpu160m      DO 86376040      DevExt 863760f8
```

An error message similar to the following indicates that either the symbol path is incorrect and does not point to the correct version of the Scsiport.sys symbols, or that Windows has not identified any adapters that work with the SCSI Port driver:

```
minipkd error (0) <path> ... \minipkd\minipkd.c @ line 435
```

If the **!minipkd.help** extension command returns help information successfully, the SCSI Port symbols are correct.

!minipkd.exports Adapter

The **!minipkd.exports** extension displays the addresses of the miniport exports for the specified adapter.

!minipkd.lun {LUN | Device}

The **!minipkd.lun** extension displays detailed information about a specified Logical Unit Extension (LUN). The LUN can be specified either by its address (which can be found by looking at the **LUN** field in the **!minipkd.adapters** display) or by its physical device object (which can be found in the **DevObj** field of the **!minipkd.adapters** display).

!minipkd.portconfig PortConfig

The **!minipkd.portconfig** extension displays detailed information about a specified PORT_CONFIGURATION_DATA. The **PortConfig** can be found in the **Port Config Info** field of the **!minipkd.adapter** display.

!minipkd.req {Adapter | Device}

The **!minipkd.req** extension displays information about all of the currently active requests on the specified adapter or LUN device.

!minipkd.srb SRB

The **!minipkd.srb** extension displays detailed information about a specified SCSI request block (SRB). The SRB is specified by address. The addresses of all currently active requests can be found in the **SRB** fields of the output from the **!minipkd.req** command.

!scsikd.classext [Device [Level]]

The **!scsikd.classext** extension displays detailed information about a specified class Plug and Play (PnP) device or a list of all such devices. The *Device* is the device object or device extension of the class PnP device. If *Device* is omitted, a list of all class PnP extensions is displayed.

Here is an example:

```
0: kd> !scsikd.classext

' !scsikd.classext 8633e3f0 ' (           ) "IBM"     " / "DDYS-T09170M" " / "S93E" / "           XBY45906"
' !scsikd.classext 86347b48 ' (paging device) "IBM"     " / "DDYS-T09170M" " / "S80D" / "           VDA60491"
' !scsikd.classext 86347360 ' (           ) "UNISYS" " / "003451ST34573WC" " / "5786" /
"HN022075000181300L6"
' !scsikd.classext 861d1898 ' (           ) "" / "MATSHITA CD-ROM CR-177" / "7T03" / ""

usage: !classext <class fdo> <level [0-2]>
```

!scsikd.scsiest Device

The **!scsikd.scsiest** extension displays detailed information about a specified SCSI port extension. The *Device* can be the device object or device extension of either the adapter or the LUN.

Here are some examples:

```
0: kd> !scsikd.scsiest 86353040
Common Extension:
< ..omitted.. >
Logical Unit Extension:
Address (3, 0, 1, 0) Claimed Enumerated Visible
LuFlags (0x00000000):
Retry 0x00 Key 0x008889ff
Lock 0x00000000 Pause 0x00000000 CurrentLock: 0x00000000
HwLuExt 0x862e6f00 Adapter 0x8633db28 Timeout 0x0000000a
NextLun 0x00000000 ReadyLun 0x00000000
Pending 0x00000000 Busy 0x00000000 Untagged 0x00000000
< ..omitted.. >
Request list @0x86353200:
Tick count is 2526
SrbData 8615d700 Srb 8611f4fc Irp 8611f2b8 Key 60197 <1s

LowerPdo 0x84f9fb68 HwDevExt 0x84634004 Active Requests 0x00000000
MaxBus 0x03 MaxTarget 0x40 MaxLun 0x08
Port Flags (0x00001000): PD_DISCONNECT_RUNNING
NonCacheExt 0x850d4000 IoBase 0xd80f0000 Int 0x23 < ..omitted.. >
```

!scsikd.srbdata Address

The **!scsikd.srbdata** extension displays detailed information about a specified SRB_DATA tracking block.

[Send comments about this topic to Microsoft](#)

Bug Checks for SCSI Miniport Debugging

5/26/2017 • 1 min to read • [Edit Online](#)

There are primarily two bug checks that arise in the course of debugging a SCSI miniport driver: bug check 0x77 (KERNEL_STACK_INPAGE_ERROR) and bug check 0x7A (KERNEL_DATA_INPAGE_ERROR). For full details of their parameters, see [Bug Check 0x77](#) and [Bug Check 0x7A](#).

Each of these bug checks indicates that a paging error has occurred. There are three main causes for these bug checks:

- Full bus reset due to a timeout on a particular device or no activity on an adapter
- Selection time-out
- Controller errors

To determine the precise cause of the failure, begin by using the **!scsikd.classext** extension, which displays information about recently failed requests, including the SRB status, SCSI status, and sense data of the request.

```
kd> !scsikd.classext 816e96b0
Storage class device 816e96b0 with extension at 816e9768

Classpnp Internal Information at 817b4008

Failed requests:

      Srb      Scsi
      Opcode  Status  Status  Sense  Code  Sector  Time   Stamp
      -----  -----  -----  -----  -----  -----  -----  -----
      2a      0a      02      03 0c 00  0000abcd 23:01:07.453  Retried
      28      0a      02      03 04 00  0000abcd 23:01:07.984  Retried

dt classpnp!_CLASS_PRIVATE_FDO_DATA 817b4008 -
...
```

In the previous example, opcode 0x2A indicates a write operation, and 0x28 indicates a read operation. The SCSI status in the example is 02, which indicates a check condition. The sense codes provide more error information.

As always, miniport driver developers are responsible for associating error codes from their hardware to the SRB status codes. Typically, timeouts are associated with SRB 0x0A, the code for a selection timeout. SRB 0x0e is typically associated with a full bus reset, but it can also be associated with controller errors.

[Send comments about this topic to Microsoft](#)

Analyzing Stalled Drivers and Time-Outs

5/26/2017 • 1 min to read • [Edit Online](#)

When debugging a SCSI miniport driver, the three most common causes for hangs and time-outs are:

- The SCSI miniport DPC is not running
- The SCSI miniport fails to ask for the next request
- A request is not being completed by the SCSI miniport, usually because it is waiting for map registers.

If you suspect that the SCSI miniport DPC is not running, use **!pqr** to display the DPC queue for the current processor. If the SCSI port DPC routine is in the DPC queue, place a breakpoint on this routine to determine whether this routine is ever called. Otherwise, use **!scsikd.scsixt** on each device. Consider the following sample output from the **!scsikd.scsixt** extension:

```
0: kd> !scsikd.scsixt 86353040
Common Extension:
  < ..omitted.. >
Logical Unit Extension:
  Address (3, 0, 1, 0) Claimed  Enumerated  Visible
  LuFlags (0x00000000):
    Retry 0x00          Key 0x008889ff
    Lock 0x00000000  Pause 0x00000000  CurrentLock: 0x00000000
    HwLuExt 0x862e6f00  Adapter 0x8633db28  Timeout 0x0000000a
    NextLun 0x00000000  ReadyLun 0x00000000
    Pending 0x00000000  Busy 0x00000000  Untagged 0x00000000

  . . .

Request list @0x86353200:
  Tick count is 2526
  SrbData 8615d700  Srb 8611f4fc  Irp 8611f2b8  Key 60197  <1s
  SrbData 85e72868  Srb 86100c3c  Irp 861009f8  Key e29dc7  <1s
```

If the timeout slot is -1 and the untagged slot is nonzero, or the time-out slot is nonzero and there are requests shown, the miniport has failed to ask for the next request.

Alternatively, if the retry slot and the busy slot are nonzero, a request may not be completed by the SCSI miniport because it is waiting for map registers. Similarly, if the untagged and pending slots are nonzero, the SCSI miniport might be waiting for map registers. In either case, the address of the SCSI request block (SRB) is the address in the busy slot and the address of the request that is not being completed. For more information about the SRB, use the **!minipkd.srb** extension with this address as input.

The **!devobj** extension determines whether the SCSI miniport is waiting for map registers. Use the device object address of the device that is issuing the request as input to **!devobj**. If the current IRQ is nonzero, it is highly probable that the SCSI miniport is waiting for map registers.

[Send comments about this topic to Microsoft](#)

Important Breakpoints for Analyzing Reproducible Problems

5/26/2017 • 1 min to read • [Edit Online](#)

When debugging a SCSI miniport driver, there are three routines in which it is useful to set a breakpoint:

- **scsiprt!scsiprtnotification**
- **scsiprt!spstartiosynchronized**
- **miniport!HwStartIo**

The routine **scsiprt!scsiprtnotification** is called right after a request is sent to the miniport. Thus, if you set a breakpoint in **scsiprt!scsiprtnotification** and then run a stack backtrace using **kb 3**, you can determine whether the miniport is receiving and completing requests. If the first parameter is zero, the request has been completed. If the first parameter is nonzero, the third parameter is the address of the SCSI request block (SRB) that is not being completed, and you can use the **!minipkd.srb** extension to further analyze the situation.

Placing a breakpoint in either **scsiprt!spstartiosynchronized** or **miniport!HwStartIo** will cause a break just prior to sending a request to the miniport.

[Send comments about this topic to Microsoft](#)

Extensions for Debugging Plug and Play Drivers

5/31/2017 • 3 min to read • [Edit Online](#)

When you debug Plug and Play drivers, you may find the following debugger extensions useful.

!arbiter

Displays the current system resource arbiters. An arbiter is a piece of code that is exposed by the bus driver that arbitrates requests for resources, and attempts to solve the resource conflicts among the devices connected on that bus.

!cmreslist

Displays the CM_RESOURCE_LIST for the specified device object.

You must know the address of the CM Resource List.

Here is an example:

```
kd> !cmreslist 0xe12576e8

CmResourceList at 0xe12576e8 Version 0.0 Interface 0x1 Bus #0
Entry 0 - Port (0x1) Device Exclusive (0x1)
  Flags (0x01) - PORT_MEMORY PORT_IO
  Range starts at 0x3f8 for 0x8 bytes
Entry 1 - Interrupt (0x2) Shared (0x3)
  Flags (0x01) - LATCHED
  Level 0x4, Vector 0x4, Affinity 0xffffffff
```

This shows that the device with this CM resource list is using I/O Range 3F8-3FF and IRQ 4.

!dcs

This extension is obsolete -- its functionality has been subsumed by **!pci**. See the **!pci 100** example later in this section.

!devext

Displays bus-specific device extension information for a variety of devices.

!devnode

Displays information about a node in the device tree.

Device node 0 (zero) is the root of the device tree.

Here is an example:

```
0: kd> !devnode 0xfffffa8003634af0
DevNode 0xfffffa8003634af0 for PDO 0xfffffa8003658590
  Parent 0xfffffa8003604010  Sibling 0xfffffa80036508e0  Child 0000000000
  InstancePath is "ROOT\SYSTEM\0000"
  ServiceName is "swenum"
  State = DeviceNodeStarted (0x308)
  Previous State = DeviceNodeEnumerateCompletion (0x30d)
  StateHistory[09] = DeviceNodeEnumerateCompletion (0x30d)
  StateHistory[08] = DeviceNodeEnumeratePending (0x30c)
  StateHistory[07] = DeviceNodeStarted (0x308)
  StateHistory[06] = DeviceNodeStartPostWork (0x307)
  StateHistory[05] = DeviceNodeStartCompletion (0x306)
  StateHistory[04] = DeviceNodeStartPending (0x305)
  ...
  Flags (0x6c000131)  DNF_MADEUP, DNF_ENUMERATED,
                      DNF_IDS_QUERIED, DNF_NO_RESOURCE_REQUIRED,
                      DNF_NO_LOWER_DEVICE_FILTERS, DNF_NO_LOWER_CLASS_FILTERS,
                      DNF_NO_UPPER_DEVICE_FILTERS, DNF_NO_UPPER_CLASS_FILTERS
  UserFlags (0x00000008)  DNUF_NOT_DISABLEABLE
  DisableableDepends = 1 (including self)
```

!devobj

Displays detailed information about a DEVICE_OBJECT.

Here is an example:

```
kd> !devobj 0xff0d4af0

Device object (ff0d4af0) is for:
 00252d \Driver\PnpManager DriverObject ff0d9030
 Current Irp 00000000 RefCount 0 Type 00000004 Flags 00001040AttachedDev ff0b59e0

DevExt ff0d4ba8 DevNode ff0d4a08
Device queue is not busy.
```

!drivers

The **!drivers** command is no longer supported. Please use the **!m tn** command instead.

!drvobj

Displays detailed information about a DRIVER_OBJECT.

Lists all the device objects created by the specified driver.

Here is an example:

```
kd> !drvobj serial

Driver object (ff0ba630) is for:
  \Driver\Serial
Driver Extension List: (id , addr)

Device Object list:
 ffba3040  ff0b4040  ff0b59e0  ff0b5040
```

!ecb, !ecd, !ecw

(x86 target computers only) Writes a sequence of values into the PCI configuration space.

ib, iw, id

Reads data from an I/O port.

These three commands are useful for determining whether a certain I/O range is claimed by a device other than

the driver being debugged. A byte value of 0xFF at a port indicates that the port is not in use.

!ioreslist

Displays the specified IO_RESOURCE_REQUIREMENTS_LIST.

!irp

Displays information about an IRP.

!irpfind

Displays information about all IRPs currently allocated in the target system, or information about those IRPs whose fields match the specified search criteria.

!pci

(x86 target computers only) Displays the current status of the PCI buses and any devices attached to them. It can also display the PCI configuration space.

The following example displays the devices on the primary bus:

```
kd> !pci
PCI Bus 0
00:0 8086:1237.02 Cmd[0106:.mb..s] Sts[2280:.....] Device Host bridge
0d:0 8086:7000.01 Cmd[0007:imb...] Sts[0280:.....] Device ISA bridge
0d:1 8086:7010.00 Cmd[0005:i.b...] Sts[0280:.....] Device IDE controller
0e:0 1011:0021.01 Cmd[0107:imb..s] Sts[0280:.....] PciBridge 0->1-1 PCI-PCI
    bridge
10:0 5333:8811.43 Cmd[0023:im.v..] Sts[0200:.....] Device VGA compatible controller
```

The following example displays the devices for the secondary bus, with verbose output:

```
kd> !pci 1 1

PCI Bus 1
08:0 10b7:5900.00 Cmd[0107:imb..s] Sts[0200:.....] Device Ethernet
    cf8:80014000 IntPin:1 IntLine:f Rom:fa000000 cis:0 cap:0
    IO[0]:fce1

09:0 9004:8178.00 Cmd[0117:imb..s] Sts[0280:.....] Device SCSI controller
    cf8:80014800 IntPin:1 IntLine:f Rom:fa000000 cis:0 cap:0
    IO[0]:f801      MEM[1]:f9fff000

0b:0 9004:5800.10 Cmd[0116:.mb..s] Sts[0200:.....] Device SubID:9004:8940
1394 host controller
    cf8:80015800 IntPin:1 IntLine:e Rom:fa000000 cis:0 cap:0
    MEM[0]:f9ffec00
```

The following example displays the PCI configuration space for the SCSI controller (bus 1, device 9, function 0):

```
kd> !pci 100 1 9 0
00: 9004 ;VendorID=9004

```

!pcitree

Displays information about PCI device objects, including child PCI buses and CardBus buses, as well as the devices attached to them.

!pnpevent

Displays the PnP device event queue.

!rellist

Displays a PnP relation list and any related CM_RESOURCE_LIST and IO_RESOURCE_LIST structures.

Determining the Status of a Device

5/31/2017 • 3 min to read • [Edit Online](#)

To display the entire device tree, starting with the root, use **!devnode 0 1**:

```
kd> !devnode 0 1
```

Identify the devnode for which you are searching, either by examining the driver or the bus that exposed it.

The devnode status flags describe the status of the device. For details, see [Device Node Status Flags](#).

In the example for the **!devnode** command in the [Extensions for Debugging Plug and Play Drivers](#) section, the swenum device was created by the PnP Manager, so the DNF_MADEUP (0x00000001) flag is set.

The following example shows a device that was created by the PCI bus. This device does not have the DNF_MADEUP flag set.

```
0: kd> !devnode 0xfffffa8004483490
DevNode 0xfffffa8004483490 for PDO 0xfffffa800448d060
  Parent 0xfffffa80036766d0  Sibling 0xfffffa8004482010  Child 0xfffffa80058ad720
  InstancePath is "PCI\VEN_8086&DEV_293C&SUBSYS_2819103C&REV_02\3&21436425&0&D7"
  ServiceName is "usbehci"
  State = DeviceNodeStarted (0x308)
  Previous State = DeviceNodeEnumerateCompletion (0x30d)
  StateHistory[09] = DeviceNodeEnumerateCompletion (0x30d)
  StateHistory[08] = DeviceNodeEnumeratePending (0x30c)
  StateHistory[07] = DeviceNodeStarted (0x308)
  StateHistory[06] = DeviceNodeStartPostWork (0x307)
  ...
  Flags (0x6c0000f0)  DNF_ENUMERATED, DNF_IDS_QUERIED,
                      DNF_HAS_BOOT_CONFIG, DNF_BOOT_CONFIG_RESERVED,
                      DNF_NO_LOWER_DEVICE_FILTERS, DNF_NO_LOWER_CLASS_FILTERS,
                      DNF_NO_UPPER_DEVICE_FILTERS, DNF_NO_UPPER_CLASS_FILTERS
  CapabilityFlags (0x00002000)  WakeFromD3
```

Examples

1. A devnode for a device with insufficient resources:

```

kd> !devnode 0xff0d06e8 6

DevNode 0xff0d06e8 for PDO 0xff0d07d0 at level 0x3
  Parent 0xff0d1408  Sibling 0000000000  Child 0000000000
  InterfaceType 0xffffffff  Bus Number 0xffffffff
  InstancePath is "ISAPNP\SUP2171\00000067"
  ServiceName is "Modem"
  TargetDeviceNotify List - f 0xff0d074c  b 0xff0d074c
  Flags (.....)  DNF_PROCESSED, DNF_ENUMERATED,
                  DNF_INSUFFICIENT_RESOURCES, DNF_ADDED,
                  DNF_HAS_BOOT_CONFIG
                  Unknown flags 0x40000000

  IoResList at 0xe133e7a8 : Interface 0x1  Bus 0  Slot 0
    Alternative 0 (Version 1.1)
      Preferred Descriptor 0 - NonArbitrated/ConfigData (0x80) Shared (0x3)
        Flags (0000) -
        Data:           : 0x0 0x61004d 0x680063
      Preferred Descriptor 1 - Port (0x1) Undetermined Sharing (0)
        Flags (0x11) - PORT_IO 16_BIT_DECODE
        0x000008 byte range with alignment 0x000001
        2f8 - 0x2ff
      Preferred Descriptor 2 - Interrupt (0x2) Shared (0x3)
        Flags (0x01) - LATCHED
        0x3 - 0x3

```

Note that the devnode has no CM Resource List, because it is not started and is not using resources, although it has requested resources.

1. Note that there are no resources stored in this devnode for a legacy driver.

```

kd> !devnode 0xff0d1648 6

DevNode 0xff0d1648 for PDO 0xff0d22d0 at level 0x2
  Parent 0xff0d2e28  Sibling 0xff0d1588  Child 0000000000
  InterfaceType 0xffffffff  Bus Number 0xffffffff
  InstancePath is "PCI\VEN_102B&DEV_0519\0&60"
  ServiceName is "mga_mil"
  TargetDeviceNotify List - f 0xff0d16ac  b 0xff0d16ac
  Flags (0x6000500b)  DNF_PROCESSED, DNF_STARTED,
                      DNF_ENUMERATED, DNF_ADDED,
                      DNF_LEGACY_DRIVER, DNF_HAS_BOOT_CONFIG
                      Unknown flags 0x40000000

```

You can retrieve the device object list for the driver for the following types of devices:

```

kd> !drvobj mga_mil

Driver object (ff0bbc10) is for:
  \Driver\mga_mil
Driver Extension List: (id , addr)

Device Object list:
  ff0bb900

```

You can then dump the data for this device object:

```
kd> !devobj ff0bb900

Device object (ff0bb900) is for:
Video0 \Driver\mga_mil DriverObject ff0bbc10
Current Irp 00000000 RefCount 1 Type 00000023 Flags 0000204c
DevExt ff0bb9b8 DevNode ff0bb808
Device queue is not busy.
```

Finally, you can dump the devnode referred by the device object. This devnode is not linked in the device tree. It represents a "pseudo-devnode" used to claim resources for the legacy device. Note the DNF_RESOURCE_REPORTED flag that indicates the device is a reported detected device.

```
kd> !devnode ff0bb808 6

DevNode 0xff0bb808 for PDO 0xff0bb900 at level 0xffffffff
  Parent 0xff0daf48  Sibling 0000000000  Child 0000000000
  InterfaceType 0xffffffff Bus Number 0xffffffff
  TargetDeviceNotify List - f 0xff0bb86c b 0xff0bb86c
  Flags (0x00000400)  DNF_RESOURCE_REPORTED
  CmResourceList at 0xe12474e8 Version 0.0 Interface 0x5 Bus #0
    Entry 0 - Port (0x1) Shared (0x3)
      Flags (0x01) - PORT_MEMORY PORT_IO
      Range starts at 0x3c0 for 0x10 bytes
    Entry 1 - Port (0x1) Shared (0x3)
      Flags (0x01) - PORT_MEMORY PORT_IO
      Range starts at 0x3d4 for 0x8 bytes
    Entry 2 - Port (0x1) Shared (0x3)
      Flags (0x01) - PORT_MEMORY PORT_IO
      Range starts at 0x3de for 0x2 bytes
    Entry 3 - Memory (0x3) Device Exclusive (0x1)
      Flags (0000) - READ_WRITE
      Range starts at 0x0000000040000000 for 0x4000 bytes
    Entry 4 - Memory (0x3) Device Exclusive (0x1)
      Flags (0000) - READ_WRITE
      Range starts at 0x0000000040800000 for 0x800000 bytes
```

Device Node Status Flags

5/26/2017 • 2 min to read • [Edit Online](#)

The Device Node Status flags describe the status of a device.

The most important flags are:

DNF_MADEUP (0x00000001)

The device was created and is owned by the PnP Manager. It was not created by a bus driver.

DNF_DUPLICATE (0x00000002)

The device node is a duplicate of another enumerated device node.

DNF_HAL_NODE (0x00000004)

The device node is the root node created by the hardware abstraction layer (HAL).

DNF_REENUMERATE (0x00000008)

The device needs to be re-enumerated.

DNF_ENUMERATED (0x00000010)

The PDO for the device was exposed by its parent.

DNF_IDS_QUERIED (0x00000020)

The operating system should send IRP_MN_QUERY_ID requests to the device driver.

DNF_HAS_BOOT_CONFIG (0x00000040)

The device has resources assigned by the BIOS. The device is considered pseudo-started and needs to participate in rebalancing.

DNF_BOOT_CONFIG_RESERVED (0x00000080)

The boot resources of the device are reserved.

DNF_NO_RESOURCE_REQUIRED (0x00000100)

The device does not require resources.

DNF_RESOURCE_REQUIREMENTS_NEED_FILTERED (0x00000200)

The device's resource requirements list is a filtered list.

DNF_RESOURCE_REQUIREMENTS_CHANGED (0x00000400)

The device's resource requirements list has changed.

DNF_NON_STOPPED_REBALANCE (0x00000800)

The device can be restarted with new resources without being stopped.

DNF_LEGACY_DRIVER (0x00001000)

The device's controlling driver is a non-PnP driver.

DNF_HAS_PROBLEM (0x00002000)

The device has a problem and will be removed.

DNF_HAS_PRIVATE_PROBLEM (0x00004000)

The device reported PNP_DEVICE_FAILED without also reporting PNP_DEVICE_RESOURCE_REQUIREMENTS_CHANGED.

DNF_HARDWARE_VERIFICATION (0x00008000)

The device node has hardware verification.

DNF_DEVICE_GONE (0x00010000)

The device's PDO is no longer returned in an IRP_QUERY_RELATIONS request.

DNF_LEGACY_RESOURCE_DEVICENODE (0x00020000)

The device node was created for legacy resource allocation.

DNF_NEEDS_REBALANCE (0x00040000)

The device node has triggered rebalancing.

DNF_LOCKED_FOR_EJECT (0x00080000)

The device is being ejected or is related to a device that is being ejected.

DNF_DRIVER_BLOCKED (0x00100000)

One or more of the drivers for the device node have been blocked from loading.

DNF_CHILD_WITH_INVALID_ID (0x00200000)

One or more children of the device node have invalid IDs.

DNF_ASYNC_START_NOT_SUPPORTED (0x00400000)

The device does not support asynchronous starts.

DNF_ASYNC_ENUMERATION_NOT_SUPPORTED (0x00800000)

The device does not support asynchronous enumeration.

DNF_LOCKED_FOR_REBALANCE (0x01000000)

The device is locked for rebalancing.

DNF_UNINSTALLED (0x02000000)

An IRP_MN_QUERY_REMOVE_DEVICE request is in progress for the device.

DNF_NO_LOWER_DEVICE_FILTERS (0x04000000)

There is no Registry entry of the lower-device-filters type for the device.

DNF_NO_LOWER_CLASS_FILTERS (0x08000000)

There is no Registry entry of the lower-class-filters type for the device.

DNF_NO_SERVICE (0x10000000)

There is no Registry entry of the service the for the device.

DNF_NO_UPPER_DEVICE_FILTERS (0x20000000)

There is no Registry entry of the upper-device-filters type for the device.

DNF_NO_UPPER_CLASS_FILTERS (0x40000000)

There is no Registry entry of the upper-class-filters type for the device.

DNF_WAITING_FOR_FDO (0x80000000)

Enumeration of the device is waiting until the driver attaches its FDO.

[Send comments about this topic to Microsoft](#)

Device Manager Problem Codes

5/26/2017 • 1 min to read • [Edit Online](#)

The Device Manager marks a device with a yellow exclamation mark (!) when the device has a problem. The problem codes are in the form CM_PROB_XXX and are defined in the header file cfg.h. The most important are explained here, together with their mapping to the [Device Node Status Flags](#).

Code 1 (CM_PROB_NOT_CONFIGURED)

Indicates that the device is not installed and was not installed previously. (Corresponds to DNF_NOT_CONFIGURED.)

Code 10 (CM_PROB_FAILED_START)

Indicates that the device did not start for some reason, but the I/O Manager attempted to start it with a set of resources. (Corresponds to DNF_START_FAILED.)

Code 12 (CM_PROB_NORMAL_CONFLICT)

Indicates that there were not sufficient resources to start this device. (Corresponds to DNF_INSUFFICIENT_RESOURCES.)

Code 14 (CM_PROB_NEED_RESTART)

Indicates that user mode reconfigured the device and a reboot is required for the changes to take effect. (Corresponds to DNF_NEED_RESTART.)

Code 18 (CM_PROB_REINSTALL)

Indicates that the device needs to be installed and was installed previously. (Corresponds to DNF_REINSTALL.)

Code 21 (CM_PROB_WILL_BE_REMOVED)

Indicates that the user mode uninstalled this device. (Corresponds to DNF_WILL_BE_REMOVED.)

Code 22 (CM_PROB_DISABLED)

Indicates that the device is disabled. (Corresponds to DNF_DISABLED.)

Code 28 (CM_PROB_FAILED_INSTALL)

Indicates that the installation failed and there is no driver selected for this device, although the kernel did not report a problem (and there is no DNF_XXX match for this the problem). This problem can be the result of an on-board system device (ISA timer, ISA RTC, RAM Memory, and so forth) that does not yet have an INF file.

Code 31 (CM_FAILED_ADD)

Indicates that the device was not added. Reasons for the failure may include: a driver's **AddDevice** routine returned an error, there is no service listed for the device in the registry, there is more than one service listed, or the controlling driver could not be loaded. (Corresponds to DNF_ADD_FAILED.)

Checking for Resource Conflicts

5/26/2017 • 11 min to read • [Edit Online](#)

This section discusses techniques that can be used to detect resource conflicts.

The first technique involves dumping the arbiter data. The following example examines the arbiter data for the I/O ranges:

```

kd> !arbiter 1

DEVNODE ff0daf48
Port Arbiter "RootPort" at 8045b920
Allocated ranges:
  10 - 1f S      Owner ff0d6b30
  22 - 3f S      Owner ff0d6b30
  44 - 47 S      Owner ff0d6b30
  4c - 6f S      Owner ff0d6b30
  72 - 7f S      Owner ff0d6b30
  90 - 91 S      Owner ff0d6b30
  93 - 9f S      Owner ff0d6b30
  a2 - bf S      Owner ff0d6b30
  d0 - ef S      Owner ff0d6b30
  100 - 2f7 S    Owner ff0d6b30
  300 - cf7 S    Owner ff0d6b30
  d00 - ffff S   Owner ff0d6b30

Possible allocation:
< none >

DEVNODE ff0d2e28 (PCI_HAL\PNP0A03\0)
Port Arbiter "PCI I/O Port (b=00)" at e122c2c8
Allocated ranges:
  0 - f          Owner 00000000
  20 - 21         Owner 00000000
  40 - 43         Owner 00000000
  48 - 4b         Owner 00000000
  60 - 60         Owner ff0d4030
  64 - 64         Owner ff0d4030
  70 - 71         Owner 00000000
  80 - 8f         Owner 00000000
  92 - 92         Owner 00000000
  a0 - a1         Owner 00000000
  c0 - cf         Owner 00000000
  f0 - ff         Owner 00000000
  170 - 177        Owner ff0cf030
  1ce - 1cf S     Owner ff040040
  2f8 - 2ff        Owner 00000000
  376 - 376        Owner ff0cf030
  378 - 37f        Owner ff0d4e70
  3b0 - 3bb S     Owner ff040040
  3c0 - 3cf S     Owner ff0bb900
  3c0 - 3df S     Owner ff040040
  3d4 - 3db S     Owner ff0bb900
  3de - 3df S     Owner ff0bb900
  3ec - 3ef        Owner ff0d0b50 (This device conflicts with another device, see below)
  3f2 - 3f5        Owner ff0d4770
  3f7 - 3f7 S     Owner ff0d4770
  3f8 - 3ff        Owner ff0d4af0
  778 - 77b        Owner ff0d4e70
  cf8 - cff        Owner 00000000
  1000 - 10ff       Owner ff0d1030
  1400 - 140f       Owner ff0d1d30
  1410 - 141f       Owner ff0d1890
  10000 - ffffffff Owner 00000000

Possible allocation:
< none >

```

Note that there are two arbiters: one located in the root of the device tree, and one in PCI_HAL. Also note that the PCI arbiter claims and preallocates ranges for the devices it arbitrates (0xD000-0xFFFF, which is later suballocated by the PCI arbiter for its devices). The Owner field indicates the device object that owns the range. A value of zero for Owner indicates that the range is not on the bus. In the case of a PCI bridge, for example, all the ranges it does not pass will be assigned to **NULL**.

In the following example, the PCI bridge passes I/O 0xD000-0xFFFF so its arbiter will contain the following two

ranges:

```
0-CFFF Owner 00000000
E0000-FFFFFFFFFFFF Owner 00000000
```

The FFFFFFFFFFFFFF is because all arbitrated resources are treated as 64-bit ranges.

Examples:

```
kd> !devobj ff0bb900

Device object (ff0bb900) is for:
Video0 \Driver\mga_mil DriverObject ff0bbc10
Current Irp 00000000 RefCount 1 Type 00000023 Flags 0000204c
DevExt ff0bb9b8 DevNode ff0bb808
Device queue is not busy.

kd> !devnode ff0bb808

DevNode 0xff0bb808 for PDO 0xff0bb900 at level 0xffffffff
Parent 0xff0daf48 Sibling 0000000000 Child 0000000000
InterfaceType 0xffffffff Bus Number 0xffffffff
TargetDeviceNotify List - f 0xff0bb86c b 0xff0bb86c
Flags (0x00000400) DNF_RESOURCE_REPORTED
kd> !devnode ff0bb808 6

DevNode 0xff0bb808 for PDO 0xff0bb900 at level 0xffffffff
Parent 0xff0daf48 Sibling 0000000000 Child 0000000000
InterfaceType 0xffffffff Bus Number 0xffffffff
TargetDeviceNotify List - f 0xff0bb86c b 0xff0bb86c
Flags (0x00000400) DNF_RESOURCE_REPORTED
CmResourceList at 0xe12474e8 Version 0.0 Interface 0x5 Bus #0
Entry 0 - Port (0x1) Shared (0x3)
Flags (0x01) - PORT_MEMORY PORT_IO
Range starts at 0x3c0 for 0x10 bytes
Entry 1 - Port (0x1) Shared (0x3)
Flags (0x01) - PORT_MEMORY PORT_IO
Range starts at 0x3d4 for 0x8 bytes
Entry 2 - Port (0x1) Shared (0x3)
Flags (0x01) - PORT_MEMORY PORT_IO
Range starts at 0x3de for 0x2 bytes
Entry 3 - Memory (0x3) Device Exclusive (0x1)
Flags (0000) - READ_WRITE
Range starts at 0x0000000040000000 for 0x4000 bytes
Entry 4 - Memory (0x3) Device Exclusive (0x1)
Flags (0000) - READ_WRITE
Range starts at 0x0000000040800000 for 0x800000 bytes
```

As shown in the example, this operation retrieved the legacy video card that owns the range 3c0-3cf. The same device object is listed near the other ranges it owns (3de-3df and 3d4-3dc). Using the same tracking technique, the range of 3f8-3ff is determined to be that used by the serial port.

A similar technique is required to translate the interrupts:

```
kd> !arbiter 4

DEVNODE ff0daf48
Interrupt Arbiter "RootIRQ" at 8045bae0
Allocated ranges:
 31 - 31          Owner ff0d4030
 34 - 34 S        Owner ff0d4af0
 36 - 36          Owner ff0d4770
 3b - 3b S        Owner ff0d1030
 3b - 3b S        Owner ff0d1d30
 3c - 3c          Owner ff0d3c70
3f - 3f          Owner ff0cf030
Possible allocation:
< none >
```

Note that there is a single arbiter for interrupts: the root arbiter.

For example, translate the interrupt 3F to an IRQ. First dump the device object, then the devnode:

```

kd> !devobj ff0cf030

Device object (ff0cf030) is for:
  IdeFd0d0398Channel1 \Driver\IntelIde DriverObject ff0d0530
  Current Irp 00000000 RefCount 0 Type 00000004 Flags 00001040AttachedDev ff0cd030

  DevExt ff0cf0e8 DevNode ff0cfe88
  Device queue is not busy.

kd> !devnode ff0cfe88 6

  DevNode 0xff0cfe88 for PDO 0xff0cf030 at level 0x3
  Parent 0xff0d1348 Sibling 0000000000 Child 0xff0c84a8
  InterfaceType 0xffffffff Bus Number 0xffffffff
  InstancePath is "PCIIDE\IDEChannel\1&1"
  ServiceName is "atapi"
  TargetDeviceNotify List - f 0xff0cfeec b 0xff0cfeec

```

First, make the assumption that this is an I/O conflict and dump the arbiters (see the preceding example). The result shows that the range 0x3EC-0x3EF is owned by 0xFF0D0B50, which overlaps the serial device's resources request. Next, dump the device object for the owner of this range, and then dump the devnode for the owner:

```

kd> !devobj ff0d0b50

Device object (ff0d0b50) is for:
  Resource00413e \Driver\isapnp DriverObject ff0d0e10
  Current Irp 00000000 RefCount 0 Type 00000004 Flags 00001040
  DevExt ff0d0c08 DevNode ff0d0a68
  Device queue is not busy.
kd> !devnode ff0d0a68 6

```

This is a "pseudo-devnode" that corresponds to the range allocated by the ISAPNP driver for its read data port.

To determine the resources that the PnP Manager assigned to a particular device when it attempted to start the device:

1. Place a breakpoint on the routine that is called when the IRP_MN_START_DEVICE request is received by the driver. You can also place a breakpoint on the driver's dispatch routine (if you know its name). In both cases, the driver and its symbols should be loaded. This may require you to set an initial breakpoint.

For example, for PCMCIA you can set a breakpoint on **pcmcia!pcmciastartpccard**. The advantage of using this particular routine is that its second parameter is a CM Resource List that you can dump using **!cmreslist** (eliminating step 3). See the following PCMCIA example.

2. When you have determined which device is of interest, dump the device object (if you have not done so already), and then dump the devnode with the CM Resource List. Check which resources were assigned to the device. You may also check whether the resources are a subset of the I/O Resource List. Then type **g** or single step through the procedure, and determine whether the device was started and which resources were assigned. If a device was offered a set of resources to start but failed to do so, the driver might not be behaving properly (for example, if it incorrectly declared that it can use a set of resources it cannot actually use).

Example:

Debugging a Service Application

5/26/2017 • 1 min to read • [Edit Online](#)

A *service*, also known as a *Windows service*, is a user-mode process designed to be started by Windows without human interaction. It is started automatically at system boot, or by an application that uses the service functions included in the Win32 API. A service can also be started by a human user through the Services control panel utility. Every service must conform to the interface rules of the service control manager (SCM).

Each service is composed of three elements: a *service application*, a *service control program*, and the service control manager itself. Although a service application is sometimes (incorrectly) referred to as a "service," it is actually one of the three components that make up a service. The service application can contain almost any kind of user-mode code. The service control program controls when the service application starts and stops. The service control manager is part of Windows.

The following sections describe how to debug a service application:

[Choosing the Best Method](#)

[Preparing to Debug the Service Application](#)

[Debugging the Service Application Automatically](#)

[Debugging the Service Application Manually](#)

For an overview of services, service applications, and the service control manager, see *Microsoft Windows Internals: Microsoft Windows Server 2003, Windows XP, and Windows 2000* by David A. Solomon and Mark E. Russinovich (4th edition, Microsoft Press, 2005).

Choosing the Best Method

5/26/2017 • 2 min to read • [Edit Online](#)

There are several different ways to debug a service application. In order to choose the correct method, you must first make two choices: the time at which the debugger is attached to the service application and what debugging configuration to use.

There are three stages at which the debugger can be attached to the service application:

- The very beginning of the service startup. The debugger is automatically launched when the service begins. Choose this option if you want to debug the service's initialization code.
- The first time that the service encounters an exception. The debugger is automatically launched when an exception or crash occurs or if the service application calls the **DebugBreak** function. Choose this option if you want the debugger to appear when a problem is encountered but not before.
- After the service is running normally. You can manually attach a debugger to a service that is already running at any time. Choose this option if you do not want to make advance preparations for debugging.

There are three debugging configurations you can choose:

- Local debugging. A single debugger, running on the same computer as the service.
- Remote debugging. A debugging server running on the same computer as the service, being controlled from a debugging client running on a second computer.
- Kernel-controlled user-mode debugging. A user-mode debugger running on the same computer as the service, being controlled from a kernel debugger on a second computer.

If your service is running on Windows 2000, Windows XP, or Windows Server 2003, you can combine any of these three attach options with any of these three debugging configuration options.

If your service is running on Windows Vista or a later version of Windows, there is one restriction on how these choices can be combined. If you want to debug from the beginning of the service startup, or from the time that an exception is encountered, you must use either remote debugging or kernel-controlled user-mode debugging.

In other words, on Windows Vista and later, you cannot use local debugging unless you plan to attach the debugger manually after the service is already running. This restriction results from the fact that in these versions of Windows, services run in session 0, and any debugger that is automatically launched and attached to the service is also in session 0, and does not have a user interface on the computer that the service is running on.

Preparing to Debug the Service Application

5/26/2017 • 11 min to read • [Edit Online](#)

This topic lists all the preparatory steps that may be required prior to debugging a service application. Which steps are required in your scenario depends on which attach option you have chosen and which debugging configuration you have chosen. For a list of these choices, see [Choosing the Best Method](#).

Each of the preparatory steps described in this topic specifies the conditions under which it is required. These steps can be done in any order.

Enabling the Debugging of the Initialization Code

If you plan to debug the service application from the beginning of its execution, including its initialization code, this preparatory step is required.

Locate or create the following registry key, where *ProgramName* is the name of the service application's executable file:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows NT\CurrentVersion\Image File Execution Options\ProgramName
```

ProgramName should include the file name extension, but not the path. For example, *ProgramName* might be MyService.exe or Thisservice.dll.

Under this registry key, create a string data value entitled **Debugger**. The value of this string should be set to the full path and file name of a debugger to be attached to the service application.

- If you plan to debug locally, use a string such as the following:

```
c:\Debuggers\windbg.exe
```

Do not choose this option if you are running Windows Vista or a later version of Windows.

- If you plan to use remote debugging, specify NTSD with the **-noio** option. This causes NTSD to run without any console of its own, accessible only through the remote connection. For example:

```
c:\Debuggers\ntsd.exe -server ServerTransport -noio -y SymbolPath
```

If your debugging session begins before Windows is fully loaded, you may not be able to access symbols from a remote share; in such a case, you must use local symbols. *ServerTransport* must specify a transport protocol that is implemented by the Windows kernel without interfacing with a user-mode service, such as TCP or NPIPE. For the syntax of *ServerTransport*, see [Activating a Debugging Server](#).

- If you plan to control the user-mode debugger from a kernel-mode debugger, specify NTSD with the **-d** option. For example:

```
c:\Debuggers\ntsd.exe -d -y SymbolPath
```

If you plan to use this method and your user-mode symbols will be accessed from a symbol server, you should combine this method with remote debugging. In this case, specify NTSD with the **-ddefer** option. Choose a transport protocol that is implemented by the Windows kernel without interfacing with a user-mode service, such as TCP or NPIPE. For example:

```
c:\Debuggers\ntsd.exe -server ServerTransport -ddefer -y SymbolPath
```

For details, see [Controlling the User-Mode Debugger from the Kernel Debugger](#).

After this registry edit is complete, the debugger is launched whenever a service with this name is started or restarted.

Enabling the Service Application to Break Into the Debugger

If you want the service application to break into the debugger when it crashes or encounters an exception, this preparatory step is required. This step is also required if you want the service application to break into the debugger by calling the **DebugBreak** function.

Note If you have enabled debugging of the initialization code (the step described in the subsection "Enabling the Debugging of the Initialization Code"), you should skip this step. When initialization code debugging is enabled, the debugger attaches to the service application when it starts, which causes all crashes, exceptions, and calls to **DebugBreak** to be routed to the debugger without additional preparations being needed.

This preparatory step involves registering the chosen debugger as the postmortem debugger. This is done by using the **-iae** or **-iaec** options on the debugger command line. We recommend the following commands, but if you want to vary them, see the syntax details in [Enabling Postmortem Debugging](#).

- If you plan to debug locally, use a command such as the following:

```
windbg -iae
```

Do not choose this option if you are running Windows Vista or a later version of Windows.

- If you plan to use remote debugging, specify NTSD with the **-noio** option. This causes NTSD to run without any console of its own, accessible only through the remote connection. To install a postmortem debugger that includes the **-server** parameter, you must manually edit the registry; for details, see [Enabling Postmortem Debugging](#). For example, the **Debugger** value of the **AeDebug** key could be the following:

```
ntsd -server npipe:pipe=myproc% -noio -p %ld -e %ld -g -y SymbolPath
```

In the pipe specification, the **%x** token is replaced with the process ID of the process that launches the debugger. This guarantees that if more than one process launches a postmortem debugger, each has a unique pipe name. If your debugging session begins before Windows is fully loaded, you may not be able to access symbols from a remote share; in such a case, you must use local symbols. *ServerTransport* must specify a transport protocol that is implemented by the Windows kernel without interfacing with a user-mode service, such as TCP or NPIPE. For the syntax of *ServerTransport*, see [Activating a Debugging Server](#).

- If you plan to control the user-mode debugger from a kernel-mode debugger, specify NTSD with the **-d** option. For example:

```
ntsd -iaec -d -y SymbolPath
```

If you choose this method and intend to access user-mode symbols from a symbol server, you should combine this method with remote debugging. In this case, specify NTSD with the **-ddefer** option. Choose a transport protocol that is implemented by the Windows kernel without interfacing with a user-mode service, such as TCP or NPIPE. To install a postmortem debugger that includes the **-server** parameter, you must manually edit the registry; for details, see [Enabling Postmortem Debugging](#). For example, the **Debugger** value of the **AeDebug** key could be the following:

```
ntsd -server npipe:pipe=myproc%x -ddefer -p %ld -e %ld -g -y SymbolPath
```

For details, see [Controlling the User-Mode Debugger from the Kernel Debugger](#).

When you issue one of these commands, the postmortem debugger is registered. This debugger will be launched whenever any user-mode program, including a service application, encounters an exception or runs a **DebugBreak** function.

Adjusting the Service Application Timeout

If you plan to launch the debugger automatically (either when the service starts or when it encounters an exception), this preparatory step is required.

Locate the following registry key:

```
HKEY_LOCAL_MACHINE\SYSTEM\CurrentControlSet\Control
```

Under this key, locate or create a DWORD data value called **ServicesPipeTimeout**. Set this entry to the amount of time in milliseconds that you want the service to wait before timing out. For example, a value of 60,000 is one minute, while a value of 86,400,000 is 24 hours. When this registry value is not set, the default timeout is about thirty seconds.

The significance of this value is that a clock starts to run when each service is launched, and when the timeout value is reached, any debugger attached to the service is terminated. Therefore, the value you choose should be longer than the total amount of time that elapses between the launching of the service and the completion of your debugging session.

This setting applies to every service that is started or restarted after the registry edit is complete. If some service crashes or hangs and this setting is still in effect, the problem is not detected by Windows. Therefore, you should use this setting only while you are debugging, and return the registry key to its original value after your debugging is complete.

Isolating the Service

Sometimes, multiple services are combined in a single Service Host (Svchost) process. If you want to debug such a service, you must first isolate it into a separate Svchost process.

There are three methods by which you can isolate a service. Microsoft recommends the Moving the Service to its Own Group method, as follows. The alternative methods (Changing the Service Type and Duplicating the SvcHost Binary) can be used on a temporary basis for debugging, but because they alter the way the service runs, they are not as reliable as the first method.

Preferred Method: Moving the Service to its Own Group

1. Issue the following Service Configuration tool (Sc.exe) command, where *ServiceName* is the name of the service:

```
sc qc ServiceName
```

This displays the current configuration values for the service. The value of interest is **BINARY_PATH_NAME**, which specifies the command line used to launch the service control program. In this scenario, because your service is not yet isolated, this command line includes a directory path, Svchost.exe, and some SvcHost parameters, including the -k switch, followed by a group name. For example, it may look something like this:

```
%SystemRoot%\System32\svchost.exe -k LocalServiceNoNetwork
```

Remember this path and the group name; they are used in steps 5 and 6.

2. Locate the following registry key:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WindowsNT\CurrentVersion\SvcHost
```

Create a new REG_MULTI_SZ value with a unique name (for example, **TempGrp**).

3. Set this new value equal to the name of the service that you want to isolate. Do not include any directory path or file name extension. For example, you might set the new value **TempGrp** equal to **MyService**.
4. Under the same registry key, create a new key with the same name you used in step 2. For example:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WindowsNT\CurrentVersion\SvcHost\TempGrp
```

Now the SvcHost key contains a value with the new name and also has a subordinate key with this same name.

5. Look for another key subordinate to the SvcHost key that has the same name as the group you found in step 1. If such a key exists, examine all the values in it, and create duplicates of them in the new key you created in step 4.

For example, the old key might be named this:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WindowsNT\CurrentVersion\SvcHost\LocalServiceNoNetwork
```

and it might contain values such as **CoInitializeSecurityParam**, **AuthenticationCapabilities**, and other values. You would go to the newly created key:

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\WindowsNT\CurrentVersion\SvcHost\TempGrp
```

and create values in it that are identical in name, type, and data to those in the old key.

If the old key does not exist, you do not need to create a new key.

6. Use the following Service Configuration tool command to revise the path found in step 1:

```
sc config ServiceName binPath= "RevisedPath"
```

In this command, *ServiceName* is the name of the service, and *RevisedPath* is the new value you are supplying for **BINARY_PATH_NAME**. For *RevisedPath*, use the exact same path as the one displayed in step 1, including all the options shown on that line, making only one change: replace the parameter following the **-k** switch with the name of the new registry value you created in step 2. Enclose *RevisedPath* in quotation marks. The space after the equal sign is required.

For example, your command might look like this:

```
sc config MyService binPath= "%SystemRoot%\System32\svchost.exe -k TempGrp"
```

You may want to use the **sc qc** command again to review the change you have made.

These settings will take effect the next time the service is started. To clear the effects of the old service, we recommend that you restart Windows rather than just restarting the service.

After you have completed your debugging, if you want to return this service to the shared service host, use the **sc config** command again to return the binary path to its original value, and delete the new registry keys and values you created..

Alternative Method: Changing the Service Type

1. Issue the following Service Configuration tool (Sc.exe) command, where *ServiceName* is the name of the service:

```
sc config ServiceName type= own
```

The space after the equal sign is required.

2. Restart the service, by using the following commands:

```
net stop ServiceName  
net start ServiceName
```

This alternative is not the recommended method because it can alter the behavior of the service. If you do use this method, use the following command to revert to the normal behavior after you have completed your debugging:

```
sc config ServiceName type= share
```

Alternative Method: Duplicating the SvcHost Binary

1. The Svchost.exe executable file is located in the system32 directory of Windows. Make a copy of this file, name it svhost2.exe, and place it in the system32 directory as well.
2. Issue the following Service Configuration tool (Sc.exe) command, where *ServiceName* is the name of the service:

```
sc qc ServiceName
```

This command displays the current configuration values for the service. The value of interest is **BINARY_PATH_NAME**, which specifies the command line used to launch the service control program. In this scenario, because your service is not yet isolated, this command line will include a directory path, Svchost.exe, and probably some SvcHost parameters. For example, it may look something like this:

```
%SystemRoot%\System32\svchost.exe -k LocalServiceNoNetwork
```

3. To revise this path, issue the following command:

```
sc config ServiceName binPath= "RevisedPath"
```

In this command, *ServiceName* is the name of the service, and *RevisedPath* is the new value you are supplying for **BINARY_PATH_NAME**. For *RevisedPath*, use the exact same path as the one displayed in step 2, including all the options shown on that line, making only one change: replace Svchost.exe with Svchost2.exe. Enclose *RevisedPath* in quotation marks. The space after the equal sign is required.

For example, your command might look like this:

```
sc config MyService binPath= "%SystemRoot%\System32\svchost2.exe -k LocalServiceNoNetwork"
```

You can use the **sc qc** command again to review the change you have made.

4. Restart the service by using the following commands:

```
net stop ServiceName  
net start ServiceName
```

This alternative is not the recommended method because it can alter the behavior of the service. If you do use this method, use the **sc config** command to change the path back to its original value after you have completed your debugging.

Debugging the Service Application Automatically

5/26/2017 • 2 min to read • [Edit Online](#)

A debugger can be launched automatically when the service application starts up. Alternatively, it can be launched automatically when the service application encounters an exception or executes a **DebugBreak** command. If you have chosen one of these methods, this topic explains how to proceed. If you are not sure which method to choose, see [Choosing the Best Method](#).

Then use the following procedure:

1. Do one of the following preparatory steps:
 - If you plan to debug the service application from the very beginning, including its initialization code, follow the procedure described in [Enabling the Debugging of the Initialization Code](#). Alternatively, if you want the service application to break into the debugger when it crashes or encounters an exception, follow the procedure described in [Enabling the Service Application to Break Into the Debugger](#).
 - To assure that the service application will allow the debugger to run properly, perform the procedure described in [Adjusting the Service Application Timeout](#).
 - If the service is combined with other services in a single SvcHost process, perform the procedure described in [Isolating the Service](#).
2. If the service is already running, you must restart it for these changes to take effect. We recommend that you restart Windows itself, in order to remove any effects of the running service. If you do not want to restart Windows, use the following commands, where *ServiceName* is the name of the service:

```
net stop ServiceName
net start ServiceName
```

3. If you have chosen to debug the service application's initialization code, when the service starts, the debugger is launched and attaches to the service application.

If you have chosen to let the debugger be triggered by an exception, the service application executes normally until it encounters an exception or executes a **DebugBreak** function. At this point, the debugger is launched and attaches to the service application.

4. The next step depends on the debugger command line you specified during step 1:
 - If you specified a debugger without any remoting options, this debugger is launched and its window becomes visible.
 - If you specified NTSD with the -server and -noio options, NTSD is launched without a console window. You can then connect to the debugging session from another computer by starting any user-mode debugger with the -remote parameter. For instructions, see [Activating a Debugging Client](#).
 - If you specified NTSD with the -d option, NTSD is launched without a console window. You can then connect to the debugging session by using kernel debugger running on another computer. For instructions, see [Controlling the User-Mode Debugger from the Kernel Debugger](#).
